AMERICAN
ELECTRICIAN

A Journal of Practical Electrical and Steam Engineering

VOLUME XVI

JANUARY—DECEMBER, 1904

McGraw Publishing Company
114-118 Liberty St,
New York

LIBRAR
THE PA
COLL

GENERAL INDEX

Distribution of Page Numbers.—The pages of the 1904 volume are distributed as follows:—
1 to 64 in January; 65 to 110 in February; 111 to 168 in March; 169 to 210 in April; 211 to 260 in May; 261 to 324 in June; 325 to 388 in July; 389 to 444 in August; 445 to 492 in September; 493 to 564 in October; 565 to 612 in November; 613 to 668 in December.

**References to Notes in "Abstracts from Foreign Contemporaries" are distinguished by an asterisk preceding the page number.*
Descriptions of telephone exchanges are indexed only under the head "Telephone."
Descriptions of central station plants are indexed only under the head "Central Station" and the names of the cities.

A

Adams-Bagnall Electric Company: Arc lamp for blue-printing and photo-engraving.. 658
Advertising methods, By La Rue Vredenburgh 336
Alarms, low water, Water columns and, By R. T. Strohm 359
Alternating current and E.M.F. (Lessons) ... 56
——— ——— circuits, (Lessons) 160
——— ——— power factor, (Edit.) 189
American Blower Co.: Motor-driven disc fan,. 480
American Electric & Controller Company, The: Motor speed controller.................. 654
American Injector Company: U. S. automatic injector, ... 209
American Type Founders' Co's power plant at Communipaw, N. J., ... 565
Ammeter, Portable; Westinghouse Electric & Mfg. Co., ... 430
——— design, Phosphor bronze spring in Mr. Brocksmith's, (Q. & A.) 201
Ammeters, Hot-wire portable; Whitney Electrical Instrument Co., ... 601
Andrae, Julius, & Sons Co.: "O. K." distribution box ....—... 314
Anyun Lamp & Electric Co.: High-tension oil fuse 107
Applied Device Co.: Alligator wrench, 249; Fiberlite shade and holder, 370; Mirror lamp holder, ... 364
Arc, The luminous, By W. A. Holmes 332
Arc lamp, "Climax" enclosed; Keystone Electric & Mfg. Co., ... 479
——— ———, Double-voltage, (Edit.) 348
——— ———, Foster, with hot-wire control .*584
——— ———, Improved Heany 166
——— ———, Magnetite; General Electric Co. 368
——— ——— circuits, Source of current fór, (Edit) 231
——— ——— department, Organization and equipment of an, By Samuel G. Rhoades, 333
——— ———, Photo-engraving and blue-printing; Adams-Bagnall Electric Co... 658
Arc lamps, Small-candle-power, for street lighting, By J. H. Hallberg, 280; (Edit.) 292
Armature coils, De Kaiser arrangement for securing (patent) 462
——— ———, Useful device for baking, By J. B. O'Hanlon, ... 197
Armature windings, (Edit.) 349
Armatures, Testing defective, by A. Ellison 58
Aron two-rate wattmeter, ... *84
Atlas Hanger Mfg. Co.: Hanger for cables and pipes, ... 429
Automobile, Design for light gasoline, By J. C. Brocksmith, 350; By W. F. Hendry. 403
———, Mr. Brocksmith's design for gasoline, By H. K. Spencer (letter)........... 462

B

Babbitt metal for motor bearings, ... 420
Balancer, Steinmetz three-wire motor, (patent) 228
Balancing a three-wire direct-current system, (Edit.) 588
Barnes Brothers: Mil-ampere rule and constantnometer 107
Bastian and Salisbury's new mercury-vapor lamp *223
Batteries, Utilization of old dry, By Geo. T. Hanchett 239
———, Storage, and boosters, Operation of, By W. T. Fernandez, 52; (Letters) ... 101
Battery, primary, Gladstone-Lalande; Battery Supplies Co. 371
———, Storage, as central station auxiliary, (Edit.) 536
——— ——— discharge in conjunction with a booster, ...*459
———, ——— exhibit at St. Louis Exposition, By Cloyd Marshall, ... 221
Battery Supplies Co.: Gladstone-Lalande primary battery 371
Belcher & Loomis Hardware Co.: Boss weatherproof entrance bushing,............. 371
Bell connections, Problem in. See Problem.
——— wiring, Problem in. See Problem.
Bianchi's frequency and slip meter *226
Blake & Knowles Steam Pump Works: High-speed motor-driven pump, ... 369
Blower, Hand; B. F. Sturtevant Co., ... 315
Blue-printing, Outfits for; General Electric Co., ... 250
———, ———; Pittsburg Blue-print Company. 655
Boiler, Water-tube; E. Keeler Co., ... 247
——— ——— ———; Rust Boiler Co., ... 428
——— ——— ———, and superheater; Milne Boiler Co., ... 249
———, ——— ———, Combined superheater and, Rosenthal, ...*460
Boiler room management, By Walter W. Edwards, ... 467
——— ——— practice, By W. T. Edwards ... 94
Boiler scale, By George W. Lord 206
——— setting, Smokeless, By A. Bement ... 339
——— surfaces, Cleaning steam, By R. T. Strohm 174
Boilers, Hints on handling, ... 469
———, steam, Areas of safety-valves for, ... 125
———, ———, Feeding, By R. T. Strohm, .. 451
———, ———, Furnace fittings for, By R. T. Strohm, ... 269
———, water tube, Sprung tubes in, By J. C. Fuller, 547; (Letters) 598
———, ——— ——— vs. flue, ...*184
Books, New:
  Compendium of Drawing. (In two parts.) American School of Correspondence: Apr. Adv. 55
  Dynamo Electric Machinery. (Seventh edition.) By Silvanus P. Thompson....... 315
  Electric Motors. By H. M. Hobart, ... 480
  Fowler's Electrical Engineer's Year Book. By William H. Fowler 110
  Fowler's Mechanical Engineer's Pocket Book. By William H. Fowler 109
  Friction and Lubrication. By William M. Davis 110
  Handbook on Engineering. By H. C. Tulley. 658
  The Indicator Handbook. Part I. (Second edition.) By Chas. N. Pickworth 210
  Logarithms for Beginners. By Chas. N. Pickworth 659
  Mechanical Engineers' Reference Book. By H. H. Suplee, M. E................168, 659
  The "Mechanical World" Pocket Diary and Year Book. Emmott & Co., Ltd. 109
  Methods of Chemical Analysis and Foundry Chemistry. (Second edition.) By Frank L. Crobaugh, M. S. 603
  Modern Wiring Diagrams and Descriptions. By Henry C. Horstman and Victor H. Tousley 168
  Notes on Electrical Railway Economics. By W. C. Gotshall, ...Jan. Adv. 61
  Photograhic Lenses. (A Simple Treatise.) By Conrod Beck and Herbert Andrews. (Second edition) 603
  The "Practical Engineer" Pocket Book... 250
  Practical Lessons in Electricity ...Jan. Adv. 61
  Ready Reference Tables. By Carl Hering, . 372
  Secondary Batteries. London: H. Alabaster Gatehouse & Co., ... 168
  Spangenberg's Steam and Electrical Engineering. By E. Spangenberg, Albert Uhl and E. W. Pratt 557
  Submarine Cable Testing and Working. Beginner's Manual. By G. M. Baines..... 480
  Testing of Dynamos and Motors. By Charles F. Smith 250
  A Text Book of Electrical Machinery. By Harris J. Ryan, Henry H. Norris and George L. Hoxie 168
  Twentieth Century Hand Book for Steam Engineers and Electricians. By C. F. Swingle 250
  The Universal Electrical Directory. (1904 edition.) London: H. Alabaster, Gatehouse & Co. ....Apr. Adv. 55
  Wireless Telegraphy. By William Maver, 372
Boosters, Lancashire reversible, ...*342
———, Operation of storage batteries and, By W. T. Fernandez, 52; (Letters) 101
———, Thury reversible, ...*344
Bradford Electric Light & Power Company's central station 1
Brake, Electromagnetic track; British Thomson-Houston Company *224
Bridgeport Safety Emery Wheel Co.: Motor-driven buffing lathes and dry grinders, 314
Bristol Co., The: Thermometer-thermostat, .. 431
British Thomson-Houston Company's electromagnetic track brake *224
Brooklyn Heights Railroad Company's conduit system, Brooklyn, N. Y. 205
Brown and Bowman single-cylinder two-stroke cycle gas engine *459
Burt Mfg. Co.: Automatic oil filter, ... 370
Bushing, Boss weather-proof entrance; Belcher & Loomis Hardware Co. 371

C

Cable connector, Novelty; New Haven Novelty Machine Co., ... 123
——— grip, New...........................*584
——— lines, aerial, Cost of, By T. J. Dommerque 402
Callendar's electrical methods for taking indicator diagrams *223
Capacity and inductance, Combined (Lessons).. 240
Capital Gas Engine Company; Air-cooled gasoline motors 208
Carpenter Tap & Die Company, J. M.: Tap and reamer wrench...................... 656
Ceiling switch. See Switch, ceiling..........
Central station and municipal plant, Combined, at Wausau, Wis., 463; (Edit.).. 464
——— ——— of the Bradford Electric Light & Power Company, operated by gas power 1
——— ——— Engineers: John William Lieb, Jr., 586; (Edit.) 588
——— ——— ———. Robert E. Richardson. 634
——— ——— of the Kansas City Electric Light Co., By E. A. Barth. 261; (Edit.). 292
——— ——— records (Edit.)............. 636
——— ——— of the Rockland Light & Power Co., ... 169
——— ———, Steam-driven turbine, at Neuchatel, Switz.......................... 493
——— ——— supplies, Economy in, By Edgar B. Greene,......................... 335
Central stations, Some practical points for,... 420
Chain drive, Silent; The Morse Chain Company 653
Chimneys, By Chas. L. Hubbard............ 123
Circuit-breaker, Carbon-break; General Electric Co., ... 108
——— ———, Oil car; Hartman Circuit-Breaker Company 209
Circuits, Alternating-current, (Lessons)...... 306
———, ——— ———, Power factor of, (Edit.) 189
———, gas lighting and electric bell, Simple method of testing, By E. S. Lincoln... 199
Clutch, Magnetic, E. M. Hewlett, (patent)... 148
Coal storage under water.................... 55
Colorado Telephone Company's exchange at Boulder, Colo. 445
Commercial Electric Co.: Three-bearing generators for gas-engine plants, 370; Variable-speed motor, ... 166
Commutator trouble, A, By V. P. Maloney, 364; C. F. Barden, Herbert B. Brand, Jos. Yager, Jas. J. Fox, R. G. Kausch, 422; Wilson A. McCown, 423; Geo. W. Malcolm, Henry Mulford, 422; A. B. Weeks, ... 423

213667

Compounding of a dynamo, Adjusting the, By Lewis Jones 200
Condenser, The (Lessons) 197; By R. Arthur Joslyn (Letters) 242
Condensers for measuring alternating current potentials, *226
Condensing, Advantages of, 469
Conduit box, "O. K."; Julius Andrae & Sons Co., 314
—— system of Brooklyn Heights Railway Company, Brooklyn N. Y. 205
—— ——, Underground, at Manchester, Mass., 426
—— work, Hints on, By T. F. McMackin, 593, 644
——, ——, Notes on, By Arthur B. Weeks 97
Connectors, Plug and socket, for electrical testing rooms, By T. C. Emerson 299
Constantnometer; Barnes Brothers, 107
Control, apparatus. Electric-pneumatic, (Edit.). 588
Controller, Automatic motor starting, *37
—— —— —— ——; Holmes-Page, *531
——, Crane motor; Westinghouse Electric & Mfg. Co. 165
——, Motor speed, Wood and Geisenhoner, (patent) 586
——, —— ——; The American Electric & Controller Company 654
Conventions:
  American Institute of Electrical Engineers, 527
  American Street Railway Association, 582
  American Street Railway Mechanical & Electrical Association, 582
  Illinois State Electrical Association, 580
  Institution of Electrical Engineers of Great Britain, 527
  International Association of Municipal Electricians, 544
  Interstate Independent Telephone Association 41
  National Electric Light Association, 332; (Edit.) 348
  National Electrical Contractors' Association 511
  Northwestern Electrical Association, 81, Feb. Adv. 56
  Street Railway Accountants' Association of America, 582
Converters, rotary, Flashing-over of, By B. E. Jerome (Letters) 422; F. P. De Wilde, Jas. J. Fox, Wilson A. McCown, (Letters), 474
—— ——, Practical management of, By F. P. De Wilde, 541
Conveyor, Ridgway two-belt; Ridgway Belt Conveyor Co., 425
Cory & Sons, Chas.: Signaling apparatus for central stations 207
Crane Co., The: Improved pop safety valves, 370
Crescent Electrical Mfg. Co.: Receptacle for electric light work, 372
Crocker-Wheeler Co.: Motor-driven buffing lathes and dry grinders, 314
Crouse-Hinds Co.: Guy anchor 247
Cut-out, Arc lamp; Philadelphia Electrical & Mfg. Company 656
Cut-outs, Panel; Trumbull Electric Mfg. Co., 248
Cycle, Alternating-current (Edit) 411
C. & C. Electric Company: New line of direct-current dynamos and motors 207

D

Damper regulator. See Regulator, Automatic damper.
De La Vergne Machine Company: Oil engine for wireless telegraph work 657
Designs for Apparatus:
  Change-speed gear for motor-driven vehicles, By J. E. Pfeffer, 412
  Dynamos and motors, Design and Construction of small, By Cecil P. Poole, 538, 590 638; (Edit.) 537
  Gasoline motor, Two-cycle, By J. C. Brocksmith, 44, 90
  Mirror galvanometer, Home-made sensitive, By John D. Adams, 152
  Motor, 2-h.p., or 25-light incandescent dynamo, Construction of, By F. C. Mason, 190
  Motor car, Design for a light gasoline, By J. C. Brocksmith, 350; W. F. Hendry, 403
  Synchronizer, Construction of a three-phase, By Paul C. Percy, 232
  Synchronizer, Construction of a two-phase, By Paul C. Percy 294
  Testing battery, Construction of high-voltage, By Geo. T. Hanchett, 466
Detroit Electric Company: Volt-ammeter 658
Diagram, Zeuner valve, By C. C. Major 219
Diagrams, Alternating-current, (Lessons) 596
Dielectric losses, Notes on, *183
Distribution systems from the standpoint of theory and practice, By Philip Torchio, 572
D'Olier Engineering Co.: Universal shade and socket, 429
Dossert & Co.: New wire coupling, 552
Dunlop's self-contained self-regulating gas producer, *37
Dwyer Machine Co.: "Standard" station photometer, 551
Dynamo, Adjusting the compounding of a, By Lewis Jones 200
——, "Ideal" direct-current, Ideal Electric & Mfg. Co. 165
——, incandescent 25-light, Design for 2-h.p. motor or, By F. C. Mason, 190
——, Three-bearing, for gas-engine plants; Commercial Electric Co 370
——, Three-wire, By Geo. W. Malcolm, 470; 543
—— winding. See Winding, dynamo.
Dynamos, Humming of, *342
——, Paralleling three-wire. See Problem.
——, "Type R. E." motors and; Richmond Electric Co., 429
—— and motors, Construction of small, (Edit.) 537
—— and motors, Design and construction of small, By Cecil P. Poole, 538, 590, 638
—— and motors, direct-current, New line of; C. & C. Electric Company 207
D. & W. Fuse Company; "Deltabeston" magnet wire 244

E

Economizers, Standard and pony; B. F. Sturtevant Co., 427
Education of engineers. See Engineers.
Electric Appliance Co.: Electrically operated whistles, 313
Electric Gas Lighting Co., The: Solid-face watch-case telephone receiver, 109
Electrical equipment on steamships, By E. N. Percy, 172
Electrical Testing Laboratories, The 650
Electricians in the Philippines, Some materials used by, 403
Electricity, Application of, to mining operations, (Edit.) 589
Electrogalvanizing, Process for, Szirmay 80
Electromagnet, The De Mare, 86
——, Gregory quick-acting (patent) 227
Electromagnets, Interlocking, William Baxter, Jr., (patent) 533
Elevator Motors, Power consumption of, 409
Elevators, Hydraulic and Electric, By Edward van Winkle, 534
Elevators, Hydraulic and Electric, (Edit.) 465; By Edward van Winkle 534
Emerson Electric Mfg. Co.: Bipolar direct-current motors 656
Engine, gas, American-Crossley; Power & Mining Machinery Co., 103
——, ——, compared with turbine and steam engine *39
——, ——, Lister two-cycle *532
——, ——, Melhuish's *342
——, ——, The Oechelhauser, By A. Borsig 6
——, ——, Single-cylinder two-stroke cycle, B. Brown and F. E. Bowman *459
——, ——, Suction producer, *460
——, ——, Twin-cylinder vertical, The Meriam-Abbott Co., 109
——, ——, Verdet and Metais, *405
Engine, Oil. See also Oil engine.
——, ——, Vogt, *147
——, ——, New Crossley, *583
——, ——, for wireless telegraph work; De La Vergne Machine Co 657
——, Preparation for erection of an, By W. T. Edwards, 234
Engine room management, By Walter W. Edwards, 296
Engine, Steam, compared with turbine and gas engine *39
——, ——, New Hamilton-Corliss, Hooven-Owens-Rentschler Co., 367
——, ——, Reeves cross-compound; Reeves Engine Company 210
Engineer, The consulting, (Edit.) 637
Engineering development, Erratic, (Edit.) 410
—— English (Edit) 637
——, Unnecessary complications in, (Edit.) 43
Engineers, electrical, Technical education of, (Edit.) 293; (Edit.) 411
Engines, American gas and oil, 13; (Edit.) 42
Engines, Gas. See also Gas engine.
——, gas; Fairbanks, Morse & Co. 61
——, ——, Improvements in, *584
——, ——, for electric light and power, Westinghouse, 600
Engines and generators at the St. Louis Exposition, 7
——, Oil, By George E. Walsh, 3
——, ——, Development of, 13; (Edit.) 42
——, ——, Melhuish's improvements in, *631
——, ——, Reduction of clearance in, *633
——, steam, "Rolling mill type" of; Murray Iron Works Co., 61
Estimate blank, Convenient, By E. S. Lincoln, (Letters) 101
Exhaust pressure of a gas engine, (Edit.) 293
Exhibitors, Electrical, at the St. Louis Exposition. See St. Louis Exposition.
Extinguisher, Electric arc, Thomson, (patent) 408

F

Fairbanks, Morse & Co.: Gas engines 61
Fan, Motor-driven disc; American Blower Co., 480
Fan-motors for 1904, 126; (Edit.) 151
Feed-water heaters, By R. T. Strohm, 570
——, Purifying boiler, By R. T. Strohm 618
—— regulator, Automatic, *632
Ferranti alternating-current wattmeter *83
—— reheater for steam turbines, *287
Filter, oil, Automatic; Burt Mfg. Co. 370
Fire-alarm circuits, By Sidney Diamant, 418
Fires, electrical, Sources of, (Edit.) 465
—— from electrical causes, By B. Thomas (Letters) 474
Flasher, Sign. See Sign flasher.
Fly-wheel design 74
Formulas:
  Gas engine horse-power (Q. & A.) 59
  Temperature and pressure variation in gas engine cylinder (Q. & A.) 59
  Flow of gas through a pipe (Q. & A.) 201
  Horse-power developed by a three-phase motor (Q. & A.) 599
Ft. Wayne Electric Works: Series alternating arc lighting system, 552
Fuel regulator for oil engines *38
Furnace fittings for steam boilers, By R. T. Strohm, 269
——, Metal-melting; Lunkenheimer Company 108
Fuse, New form of; Horton-Massnick Co., 315
Fuse, Oil. See Oil fuse.
Fuse-block, Addie magazine, (patent) 587
—— —— and switch, Combined; Hart & Hegeman Mfg. Co., 601
Fuses, High-tension, *407

G

Gas engine, Exhaust pressure of a, (Edit.) 293
—— —— igniter generator, 34
—— —— situation in Europe, By G. L. Carden, 4
—— —— starter, "Perfect," *531
—— —— waste heat, (Edit.) 537
Gas engines. See also Engines, gas.
Gas engines, Small, vs. electric motors, *183
Gas for power, 296
Gas generators and motors, Development in, 40
Gas, Heating quality of acetylene and coal, 10
Gas producer, Dunlop's self-contained self-regulating, *36
—— —— for bituminous coal *35
—— —— plant using brown coal briquette fuel 229
—— producers, Regenerator for, Wilson, *35
—— stoves, Dangers of, 535
Gauge, Thermo; Morse Thermo Gage Co., 62
Gauges, Water, By R. T. Strohm, 399
——, ——, and low water alarms, By R. T. Strohm, 359
Gear, Design of change speed, for motor-driven vehicles, By J. E. Pfeffer, 412
General Electric Co.: Blue printing outfits, 250; Carbon-break circuit-breaker, 108; fuse plug cabinet panels, 249; Magnetite arc lamp, 368; Transformer for thawing water pipes, 657; Voltage regulators, 63
General Incandescent Arc Lamp Co.: Automatic lamp shade, 371; flush plug and receptacle, 601; Punched clip lever switches, 478
General Parisian Tramways Co., Plant of, By Francis Paul 65
Generating unit, direct-connected; The Meriam-Abbott Co., 109
—— ——; Fairbanks-Morse gas engine and dynamo 61
Generator, direct-current, Parsons' and Stoney's, *406
——, 1500-kw. alternating-current, for St. Louis Exposition 244
Generators, Electric, at St. Louis Exposition, 7
——, Igniting 34
Governors for engines driving electric generators; W. Lahmeyer & Co., *185
——, Steam engine, By J. J. McQuire 214
Grinders, dry, Motor-driven buffing lathes and; Bridgeport Safety Emery Wheel Co. and Crocker-Wheeler Co. 314
Grounding the neutral on high-potential alternators, By Geo. N. Eastman 333
Gutta gentzch, *184
Guy anchor; Crouse-Hinds Co., 247

H

Hall's motor-driven pump, 312
Hamilton-Corliss steam engine, New; Hooven-Owens-Rentschler Co. 367
Hamilton-Holzwarth steam turbine; Hooven-Owens-Rentschler Co., 549
Hanger for cables and pipes; Atlas Hanger Mfg. Co., 429
Hart & Hegeman Mfg. Co.: Combined switch and cut-out, 601; 500-volt circuit switch, 370
Hartman Circuit-Breaker Co.: High-potential oil switches, 64; Oil car circuit-breaker, 209
Heater, Feed-water. See Feed-water heater.
Heating, Electric, as a field for central stations, By James J. Ayer, 334, 337; (Edit.) 349
Heat transference through boiler plates, Experiments in, *145
Helena Light & Traction Co.'s sub-station, Helena, Mont. 282
Herzog and Feldman tests of twin flexible cord. *255
Hewitt, Cooper, Electric Co.: Cooper Hewitt mercury-vapor lamp, 602
Hill Electric Co.: Small standard switchboards, 63
Hoist, Electric crane; Sprague Electric Co. 167
Holden & Brooke's new balanced stop-valve, *185; Steam trap for high-pressures, *38

Holmes-Page automatic controller..........*531
Holtz telephone card directory 166
Hooven-Owens-Rentschler Co.: Hamilton-Holzwarth steam turbine, 549; New Hamilton-Corliss engine, ... 367
Horton-Massnick Co.: New form of fuse, ... 315

I

Ideal Electric & Mfg. Co.: Direct-current dynamos, 165; electric motors........... 64
Impedance (Lessons) 99
Improved Electric Light & Supply Co.: Nernst lamp 64
Incandescent lamp, Improved "Hylo;" The Phelps Co., ... 247
——— ———, "Monarch;" Monarch Electric Mfg. Co. 248
——— lamps, 220-volt, Adoption of, at St. Louis in 1899, By Walter I. Barnes, 535
Indicator, Simple polarity,................. 593
——— diagrams, Electrical methods for taking,*223
——— ———, Steam, By Chas. L. Hubbard, 55
Injector, U. S. automatic; American Injector Company 209
Instruments, Curve-drawing or graphic recording, By H. W. Young 283
——— for determining constants and energy losses of alternating-current apparatus, 245
———, Measuring, of precision; Westinghouse Electric & Mfg. Co................. 478
———, Standard, for central stations, By H. P. Davis........................... 338
Insulator, High-tension, tests, R. Thomas & Sons Co., ... 207
———, ——— ——— wall; Locke Insulator Mfg. Co., ... 245
———, Third rail *531
——— pin, James H. Bullard, (patent)...... 186
Insulators, porcelain, Losses in,.............*185
———, Locke, high-tension, (patents) 40.... 633
Interborough Rapid Transit Co.'s power plant, New York City, 501; Test of steam turbine in power station,................. 40
Interior wiring. See Wiring.................
International Electrical Congress, 86, 512, (Edit.) 536
International Specialty Co.: Emery wheel dresser, ... 552
Irrigation, Electrical, By George E. Walsh... 394
Isolated plant of the American Type Founders' Co., at Communipaw, N. J.,........... 565
——— ——— of the New England Confectionery Company, Boston, Mass...... 202
——— ——— of the Whitehall Building, New York City........................ 389

K

Kansas City Electric Light Co.'s plant at Kansas City, Mo., By E. A. Barth......... 261
Keeler, E., Co.: Water-tube boiler.......... 247
Kellogg harmonic telephone system, By A. Dallam O'Brien....................... 539
Keystone Electric & Mfg. Co.: "Climax" enclosed arc lamp,........................ 479

L

Lag, Angle of, (Lessons).................. 99
Lahmeyer, W., & Co.; Governor for engines driving electric generators,............*185
Lahmeyer regulator for alternating-current motors, ...*286
Lamme single-phase railway motor, 117; (Edit.) 150
Lamp: See Arc lamp, Incandescent lamp, Nernst lamp, Mercury-vapor lamp.....
Lamp bank, A convenient, By Geo. T. Hanchett 358
——— cord, Testing inflammability of, J. Herzog and C. Feldman,.................*225
——— holders, Mirror; Applied Device Co., 364
——— shade. See shade.................
Lancashire reversible boosters, ...*342
Lang, J., Electric Co.: Voltmeter and ground detector switch 551
Lanhoffer's direct-current voltage transformer.*227
Lathe, New screw-cutting bench; Seneca Falls Mfg. Co. 372
———, "Star" speed; Seneca Falls Mfg. Co., 167
Lathes and dry grinders, Motor-driven buffing; Bridgeport Safety Emery Wheel Co. and Crocker-Wheeler Co.............. 314
Leich four-party selective ringing system, By A. Dallam O'Brien.................. 237
LESSONS IN PRACTICAL ELECTRICITY:
  Alternating-current circuits 306
  Alternating-current circuits—Power factor, 160

CENTRAL STATION OPERATED BY GAS POWER.

PLANT OF THE BRADFORD ELECTRIC LIGHT AND POWER COMPANY.

THE applicability of gas engines to central station service is a subject of growing importance to the management of small as well as large electric light and power systems, in districts so situated that the price of coal prohibits a reasonable profit upon the station output, when sold at a rate sufficiently low to encourage the general use of electricity. It has been stated that the cost of gas power may be reduced from one-third to two-thirds that of steam power, depending upon the character of the equipment. In the abstract, this would appear difficult of substantiation by reason of the high efficiency reached by well designed modern steam plants, but the fact remains that gas power plants are regularly performing a duty of one effective horse-power per hour above the thermal equivalent of one pound of good steam coal.

A particularly instructive example is offered by the power station of the Bradford Electric Light and Power Company, of Bradford, Pa. The station is of comparatively small capacity, and in some mechanical features does not embody the most advanced engineering features. It is, however, representative of the class of central stations usually found in towns of corresponding size, and the results secured, since the introduction of gas power, give sufficient evidence of its general efficiency.

The company equipped its system and began operations in 1889, supplying single-phase 110-volt, alternating current, for incandescent lighting, constant current for direct current open arcs, and direct current at 550 volts for street railway use. The station building was a wooden structure containing about 575 horse-power capacity in engines, which were of the simple high-speed type, running non-condensing. Belt transmission was used throughout. The generators comprised T. H., arc machines, 133 cycle, alternating-current generators and a direct-current railway generator. Steam was furnished by horizontal return tubular boilers fired by natural gas obtained from a local distributing company at a nominal figure. Flat rates prevailed in all classes of service.

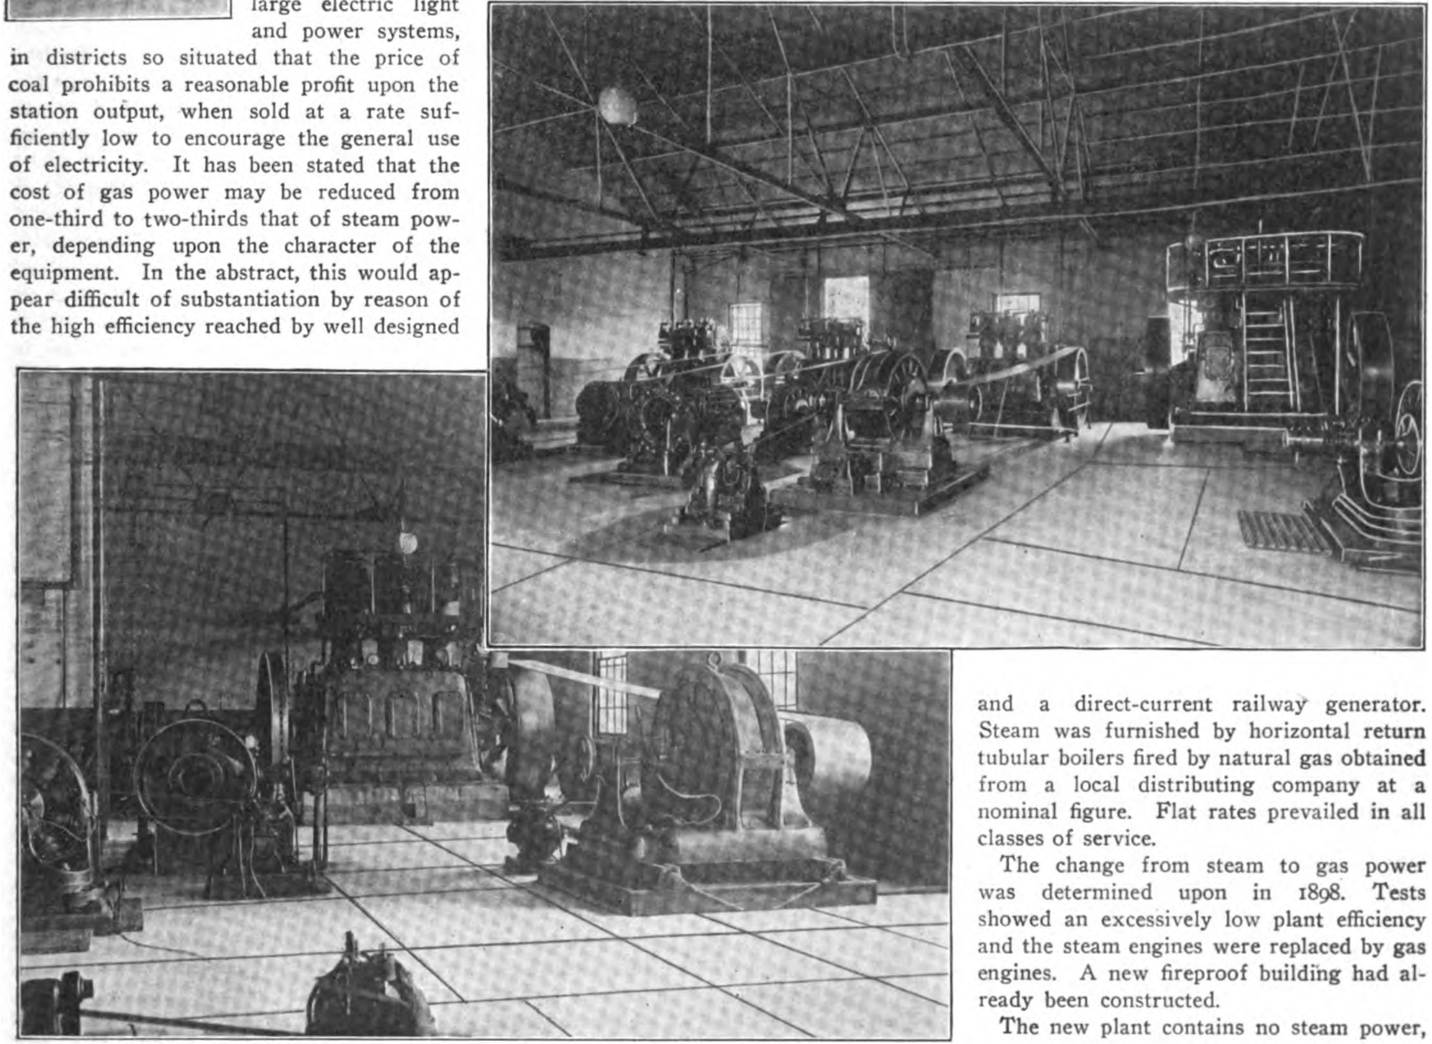

FIG. 1.—GENERATING EQUIPMENT OF THE BRADFORD ELECTRIC LIGHT AND POWER COMPANY.

The change from steam to gas power was determined upon in 1898. Tests showed an excessively low plant efficiency and the steam engines were replaced by gas engines. A new fireproof building had already been constructed.

The new plant contains no steam power, as may be observed from the interior views. Belt transmission was retained, as the expense necessary in changing from a high to a low frequency system, was unwarranted. An entirely new generator and transformer equipment had, of course, to be provided. The railway load was dropped and the alternating-current generator capacity increased to care for the gradual increase in demand upon the plant.

Flat rates were abandoned as fast as possible, and meter rates substituted. In 1902 the proportion of meter revenue to the total revenue was approximately 16 per cent, and this proportion is rapidly increasing with the lapsing of flat rate contracts. A considerable day load is furnished by single-phase motors in local factories. The meter rates range from fifteen cents to six cents per kilowatt-hour. Domestic lighting averages about 12 cents or 11.8 cents net. The system thus compares favorably in cost of current to the consumer with systems operated upon a much larger scale, and furnishes ample evidence of the general economy of gas power. At the present time there are over 4500 connected incandescent lamps of 16 candle-power and 164, 9.6 ampere open arc lamps, but the incandescent load will shortly be increased to an equivalent of over 6000 lamps.

The new station building is a substantial brick structure with concrete floors and steel roof trusses. By reason of the fireproof construction, no insurance is carried. The front of the building is occupied by offices with the engine-room immediately in the rear. A small space is reserved for a machine shop and storage of duplicate parts. Five generating units are at present in service, four regularly and one held in reserve. The engines are all of the Westinghouse three-cylinder vertical type, in two sizes, 13 by 14 ins. and 15 ins. by 22 ins., respectively.

Two engines each drive two 50-light arc generators, a third one 70 kw., alternating-current generator, and the two large engines 170-kw. and 180 kw., alternating-current generators, respectively, the 120-kw. unit being usually held as the reserve. A small 8-h.p. Otto engine operates continuously a triplex pump for providing circulating water and at intervals a 5 in. by 6 in. air compressor. The entire equipment occupies approximately 6.5 sq. ft. per brake horse-power.

The main engines receive gas from a main extending the length of the room along the lower chord of the roof trusses. A pressure-reducing valve in the station main lowers the pressure from 50 to 60 pounds to 8 ounces. Individual regulators in each engine supply pipe reduce the pressure to that of the atmosphere before the gas enters the mixing valve. The calorific value of the gas is about 1175 B. T. U. per cubic foot, and a mixture of 12 to 1 gives the best results.

Ignition current is furnished at 100 volts directly from the generator exciters. Two 100-volt 16-c.p. lamps in series with the igniters limit the current to about one ampere, which gives at this voltage sure and positive ignition. As the platinum igniter tips are sometimes found to be unequally worn after service for a considerable time with current in one direction, a reversing switch is inserted in the igniter feeder. At the end of the day's run, the switch is reversed and the current enters the igniters at the other tip. With this arrangement, the igniter tips last for eight or nine months. The point of ignition is set about 20 degrees in angular advance of the crank, on account of the richness of the gas.

Cooling water is also drawn from an overhead main supplied from a driven well upon the premises. The cylinder heads and exhaust valves are cooled by separate streams in order to maintain more uniform temperature in the working parts. These streams discharge into the exhaust header of the engine, thus keeping it at a safe temperature. The exhaust pipe for each engine extends through the building and to the roof, a water pocket draining off the cooling water which flows into the sewer.

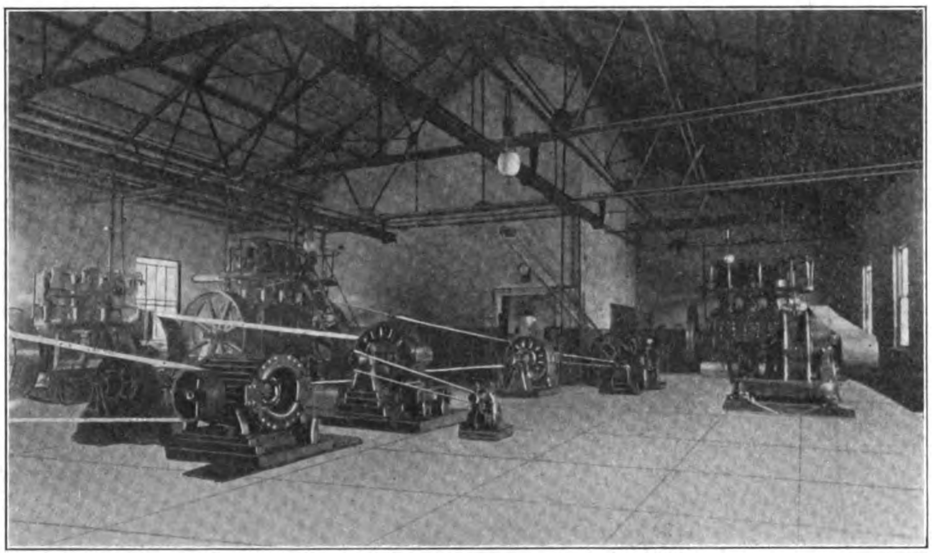

FIG. 2.—GENERAL VIEW OF ENGINE ROOM.

The consumption of cooling water can be estimated from a three weeks' run on city water, at a time when the pumping plant was out of commission. During this period the plant used an average of 63,500 gallons per day at a cost of 6 cents per thousand gallons, or 1.6 gallons per horse-power-hour capacity. No use has heretofore been made of this water, but it is contemplated that the use of natural gas for heating the station building will be discontinued and radiators installed instead, utilizing the waste heat from the jackets. The cooled water may then be returned to the jackets with such proportion of fresh water as will insure the proper cylinder temperatures.

A simple means for maintaining a constant though small head of cooling water on all parts of the engine consists of an inverted U in the discharge pipes from each part, the bend of the U being a few inches higher than the cored passages in the engines. Thus the engine may not be carelessly started up without cooling water.

Each engine is started by compressed air at 150-pound pressure stored in a long steel tank resting upon the lower chord of the roof trusses and supplying a distributing main similar to the gas and water mains. Starting is easily accomplished and load placed upon the generator within two minutes, but the operation may be performed in half the time if necessary. The air compressor is usually operated about one hour per day, as indicated by a telltale pressure gauge. The gauge normally registers 150 pounds, but should the pressure rise to 160 or fall to 140, the index makes contact with small brass pins which complete a circuit through a signal lamp placed in a prominent position in the engine room. Rise in pressure is indicated by a white light, and fall in pressure by a red light. Assuming an average operation of one hour per day, the air supplied at 150-pound pressure is 20 cubic feet, or .025 cubic feet per horse-power capacity, including leakage in piping, valves, etc. This represents the air consumption required to carry the entire plant through its daily cycle of operations and is evidently an insignificant item of expense.

The engines are regularly inspected for repairs twice each year, at which time pistons are lifted out and rings examined, bearings and boxes tightened up and exhaust valves reseated or replaced if necessary. These valves usually run about one year without reseating. A set of valves examined in November ran for 14 months and were then still in good condition.

Previous to the replacement of the steam plant, a 24-hour economy test upon the station showed a gas consumption referred to the engines of 57.09 cubic feet per indicated horse-power, at an average load of 250 horse-power. The engines were indicated every five minutes and the results represent average daily load conditions. Assuming an average engine efficiency of 85 per cent, generators 90 per cent, and transmission 95 per cent, the consumption of gas at the boilers per electrical horse-power was about 75 cubic feet, or 82,500 B. T. U.

The performance of the present equipment may be observed from several sources. A test upon the gas engines, shortly after they were installed, showed a gas consumption of 125 cubic feet for 760 watt-hours, equivalent to 12.27 cubic feet per electrical horse-power at full load, which is but 17½ per cent of that of the former steam plant. The accompanying curve sheet shows the economy determined at the builders' works under load tests with a Prony brake. At full load, the gas consumption was 10.9 cubic feet, or 9500 effective

B. T. U. per brake horse-power. It is apparent that the curve of total gas used is nearly a straight line, departing therefrom only on heavy overloads and resembling somewhat the total water rate curve of the steam turbine.

In the present service the engines are all considerably underloaded. The heaviest demands of the arc system furnishing but about 62 per cent of the engine rating. The results are consequently less favorable than if approximately full loads were obtainable. More recent figures were obtained from observations extending over six months from March to August, 1903.

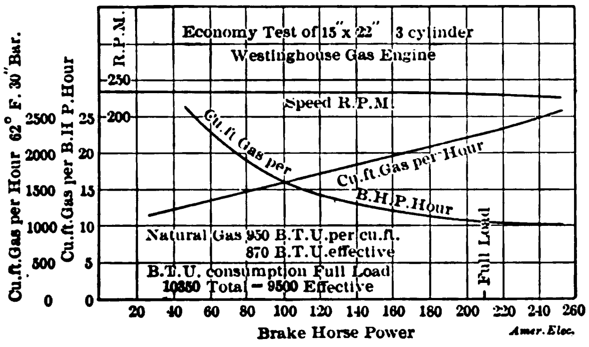

FIG. 3.—ENGINE TEST CURVES.

The total output in kilowatt-hours was 3,257,302, gas consumed 7,759,000 cubic feet, including heating of building, or 23.8 cubic feet per kilowatt-hour, 17.6 cubic feet per electrical horse-power-hour. As the gas could not be measured by a separate meter, it was estimated at about 750,000 cubic feet. Thus the net gas consumption on this estimate amounts to 21.5 cubic feet per kilowatt-hour or 16 cubic feet per electrical horse-power per hour. At an average plant efficiency of 75 per cent this is equivalent to an economy of 12 cubic feet per brake horse-power-hour, or a duty of 14,100 B. T. U.

The accompanying load curves represent typical Saturday and Sunday loads during the present season; the curve represented by the full line showing the incandescent load on Saturday, November 28, while the load curve of the following Sunday is shown dotted. The curves for the arc service on the same dates are shown in Fig. 6. Fig. 7 is a curve showing the meter rates charged for incandescent current. A discount of 10 per cent is allowed for prompt payment.

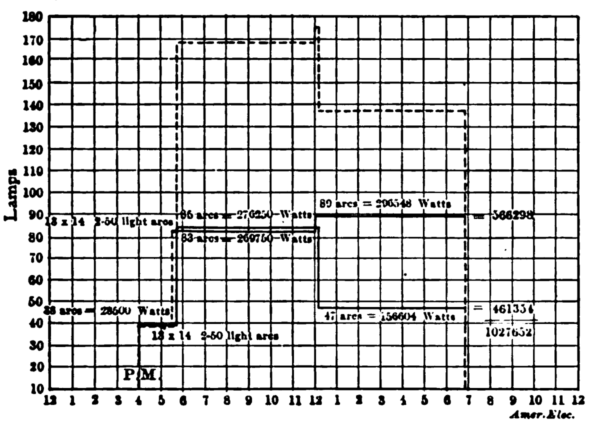

FIG. 6.—TYPICAL STATION LOAD, ARC SYSTEM.

The comparative cost of station operation by steam and by gas power is shown by the following figures which, although not stating actual output, represent comparative results. The figures are based upon averages of two years' operation of the steam plant and four years of the gas plant. The saving in total operating cost due to the latter was 33.9 per cent of the cost of operating the steam plant. During the six years covered by the records, there was an increase of 18.5 per cent in revenue, which however, does not represent the true rate of increase in output due to transition in rates. The actual increase is estimated to be fully 30 per cent. Further, gas is purchased at a flat rate with a minimum of 30,000,000 cubic feet. In the face of the increase in output, the gas consumption of the station has decreased to 16.5 per cent of the original amount in the steam station. The minimum rate was reached three years ago, and at the present time is considerably below resulting in a cost per cubic foot 60 per cent greater than by the original flat rate. The total operating cost per horse-power capacity per year is $36.60 for the steam station and $14.80 for the gas station. The latter figure, if credited with actual cost of fuel, would be approximately $14. This includes gas, labor, oil waste and packing, and repairs.

ECONOMY TEST.

Compression 120 lbs.				
Speed	227	229	232	233
Gas per B. H. P.	2720	2410	1681	1131
B. H. P.	254	220	112	27.5
Gas 62 deg.	10.7	10.9	15.0	....

The following summary includes fixed charges, *i.e.*, interest, 6 per cent on land and buildings; depreciation of buildings, 3 per cent; depreciation of machinery, 10 per cent:

	Steam plant.	Gas plant.
Per horse-power year capacity.		
Operating cost	$36.60	$14.80
Fixed charges	22.90	16.18
	$59.50	$30.98
Saving		$28.52
Saving, per cent		47.9

Assuming an average yearly station load factor of 17.5 per cent, this total cost per horse-power-hour is $.0373 and $.0099, respectively. The heretofore incomplete records of the system permits no more accurate analysis but the general deduction from the operating expenses is that the true cost of power has been reduced by one-half in the plant. The Bradford system is under the efficient management of Mr. J. H. Rose, whose appreciation of the merits of the gas engine has resulted in the successful operation of the station.

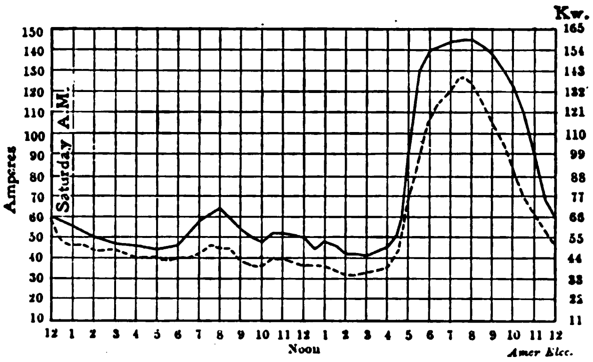

FIG. 5.—TYPICAL STATION LOAD, INCANDESCENT SYSTEM.

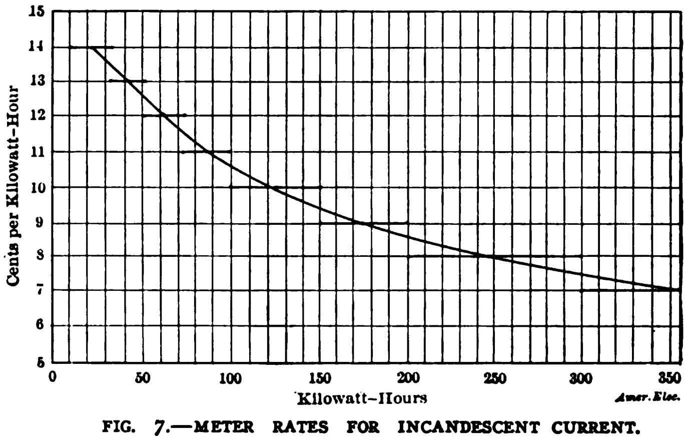

FIG. 7.—METER RATES FOR INCANDESCENT CURRENT.

◆◆◆

THE CRUDE OIL ENGINE.

BY GEORGE E. WALSH.

The efficiency of the crude oil engine for driving portable or small generator plants has slowly claimed recognition within the past year, and the general adoption of this form of power producer in certain lines of work is somewhat remarkable. The development of a high-power engine that could use crude or unrefined petroleum has been somewhat slow. The use of refined, high-grade oil did not promise such economy as the gas engine, and it was considered somewhat doubtful whether an internal combustion engine could be developed which would burn the crude oil. The difference between the cost of the crude and refined oil is so great that it practically determines the success of this form of engine.

The cost of oil varies all the way from

3 cents a gallon to 10 and even 15 cents; but crude oil in the oil regions can be obtained for 2½ cents a gallon or less. With fuel at this rate the cost of generating power is probably the lowest on record. In Texas and on the California coast crude oil engines are coupled to generators which show a fuel cost considerably less than a fraction of a cent per electrical horse-power-hour. Some experiments have placed the cost of operation as low as 0.15 cent per horse-power-hour, but this is exceptional if not impossible.

In mining for petroleum the cost of the crude oil is always one of the least important items. The cost of refining enhances the price of the oil and makes it a less formidable competitor with coal. This refined oil delivered to Northern manufacturing centers always costs more than double its cost at the producing centers. The refined oil always leaves a certain percentage of inferior, low-grade oil behind which can only be utilized by producing some of the series of by-products which in late years have attained a considerable commercial value. Some wells produce such a low grade oil that in the past it hardly paid to attempt to refine it. The Russian petroleum deposits are even poorer, as a rule, than those found in this country.

The question of utilizing all grades of oil for fuel, even the poorest crude petroleum, has offered plenty of difficulties for the inventor to overcome. There is first the question of low ignition temperature to solve. In the highly heated cylinder a premature explosion might cause disaster and throw the engine out of service. To prevent this, water vapor is added to the oil spray or mixture of air and atomized oil. The presence of water vapor gives the mixture a high specific heat and permits of a much higher degree of compression without danger of premature explosion. Some of the jacket water is vaporized and passes into the cylinder head with the oil spray and air. The steady flow of the water keeps the temperature of the gases in the chamber down to 150° to 170° Fahr. The water, which is instantly vaporized in the chamber mixes readily with the oil spray.

Another difficult feature of using crude oil has been the tendency to form carbon deposits in the engine cylinder, which in a very short time would put the machine out of service. These carbon deposits appear more abundantly when the poorer grades of crude oil are used, and in some cases they are so great that only specially-fitted engines can be used with advantage. In order to use these grades of oil, resort has been had to automatic scavengers for cleaning out the cylinder after each compression and explosion.

The economy and reliability of the oil engine depends to a large extent upon the mixer and the water jacket. The mixer must be thorough and automatic in action. Every drop of fuel entering the cylinder without being perfectly vaporized and mixed with air is wasted. The perfect mixture and vaporization are obtained by a number of different methods, but most designers seek to perform this work directly in the cylinder itself, doing away with mixing valves and carburettors. Mixing and vaporizing directly in the cylinder has the advantage that there is no danger of mixing valves or carburettors getting clogged, and imperfect mixing of the oil and air resulting therefrom. The fuel efficiency of the engine is thus directly dependent upon this part of the design.

THE GAS ENGINE SITUATION IN EUROPE.

BY G. L. CARDEN.

It seems to be fairly well recognized that Germany to-day is leading in the development of high-powered gas engines, and when we say Germany, we refer to results achieved by students of German technical schools. At the Paris Exposition in 1900, the Société Anonyme John Cockerill, of Seraing, Belgium, exhibited a 650-h.p. gas engine, and probably no one item in the machinery department of that Exposition excited more interest. The head of the Cockerill house at present is Director General A. Greiner, and many of his assistants are Germans. This establishment has now under construction a 3000-h.p. gas engine, and this machine will at the time of its installation in the spring of 1904 probably be the largest size of gas engine in service in the world. It is an interesting fact that the rights for the manufacture of the Cockerill product were acquired recently by the Wellman - Seaver - Morgan Company, of Cleveland, Ohio.

The principal dimensions of the Cockerill 3000-h.p. engine are: Length over all, 67 feet 1⅛ inches; extreme width, 21 feet 4 inches; diameter of cylinders, 51 inches; length of stroke, 55 inches; diameter of flywheel, 26 feet 3 inches; revolutions per minute when developing three thousand horse-power, 85. This engine is of the horizontal two-cylinder tandem type. Its prototypes at the Cockerill works use blast furnace gas purified by passing through water reservoirs; but the engine is also adaptable to service in connection with almost any form of poor gas that is practically free of tar. In the winter of 1902-3 the Cockerill works were using in actual service at their plant three 700-h.p. gas engines, and the statement was made to the writer that within eighteen months the Cockerill works would probably not have in service any other type of power generators than gas engines.

To understand better the significance of the announcement of a 3000-h.p. gas engine, one must bear in mind that the 650-h.p. Cockerill engine at the Paris Exposition in 1900 was regarded as little short of a wonder. At the Pan-American Exposition at Buffalo in 1901, a 650-h.p. engine was also exhibited; in the latter case the manufacturer was an American. It will be seen from this that in Europe the gas engine has developed from 650 to 3000 horse-power in three years time. In America, the largest types of gas engines now observable are, so far as I am aware, of foreign origin. The Allis-Chalmers Company, of Milwaukee, has recently acquired, it is announced, the gas engine as produced by Vereingte Maschinenfabrik Augsburg und Maschinenbaugesellschaft Nürnberg A. G., and is prepared to manufacture engines of the Nürnberg origin of 1850 horse-power. This Nürnberg machine is like the Cockerill engine in general appearance, being of the horizontal two-cylinder tandem type. It has a length over all of 60 feet and an extreme breadth of 19 feet 4 inches. Its flywheel measures 18 feet in diameter, and when developing 1800 horse-power it runs at 90 revolutions per minute.

The firm of A. Borsig, Tegel, near Berlin, has recently undertaken to manufacture the Oechelhauser gas engine in sizes of 500, 1000 and 1750 horse-power. The Borsig firm is now working in connection with Julius Pintsch, of Berlin, the Pintsch firm undertaking to supply the gas producers. A Borsig installation shows a three-furnace gas producer in close proximity to the engine, and the area of the space occupied by the producer is but little larger than the space occupied by the engine itself. The Germans permit the gas producer to be placed within 18 inches of the wall partition, and the practice is observed of separating the engine room and gas producer merely by an ordinary partition. For an engine of 1750 horse-power, the Pintsch people install a gas producer capable of developing 2400 horse-power. No reservoir is employed; the gas passes direct from the furnaces through a washer to the engine.

When using anthracite coal of proper quality, the Pintsch people assert that there is no difficulty in developing 1750 horse-power on 1575 pounds of coal per hour; for periods when the engine is not in actual operation, as, say, between night and morning, 50 pounds of coal per hour is used merely to keep the furnaces warm. It will be seen from these figures that the Borsig engine combined with a Pintsch gas producer is capable of developing a horse-power on less than one pound of coal an hour.

The principal gas engine makers of Germany are included in the firm known as Gasmoterenfabrik Deutz, near Cologne. This firm probably turns out more gas engines than any other firm in the Fatherland, and its 900-h.p. engines have earned a splendid name. When the writer visited Deutz, during the past year, he was informed that the Deutz establishment expected to be able by 1905 to have in actual service a gas engine of 6000 horse-power.

The Deutz 900-h.p. engine is of the double-acting four-cycle type, and differs considerably in appearance from the usual form of gas engine, being in many respects more like a steam engine in its general arrangement, as an inspection of the accompanying engravings will show. Referring to the illustrations, the exhaust valves are indicated by the letter *E*, and the general inlet valves by *I*. The exhaust valves, as Fig. 2 plainly shows, are opened by the usual cam and link arrangement actuated from a secondary or lay shaft *S*, and are closed by means of

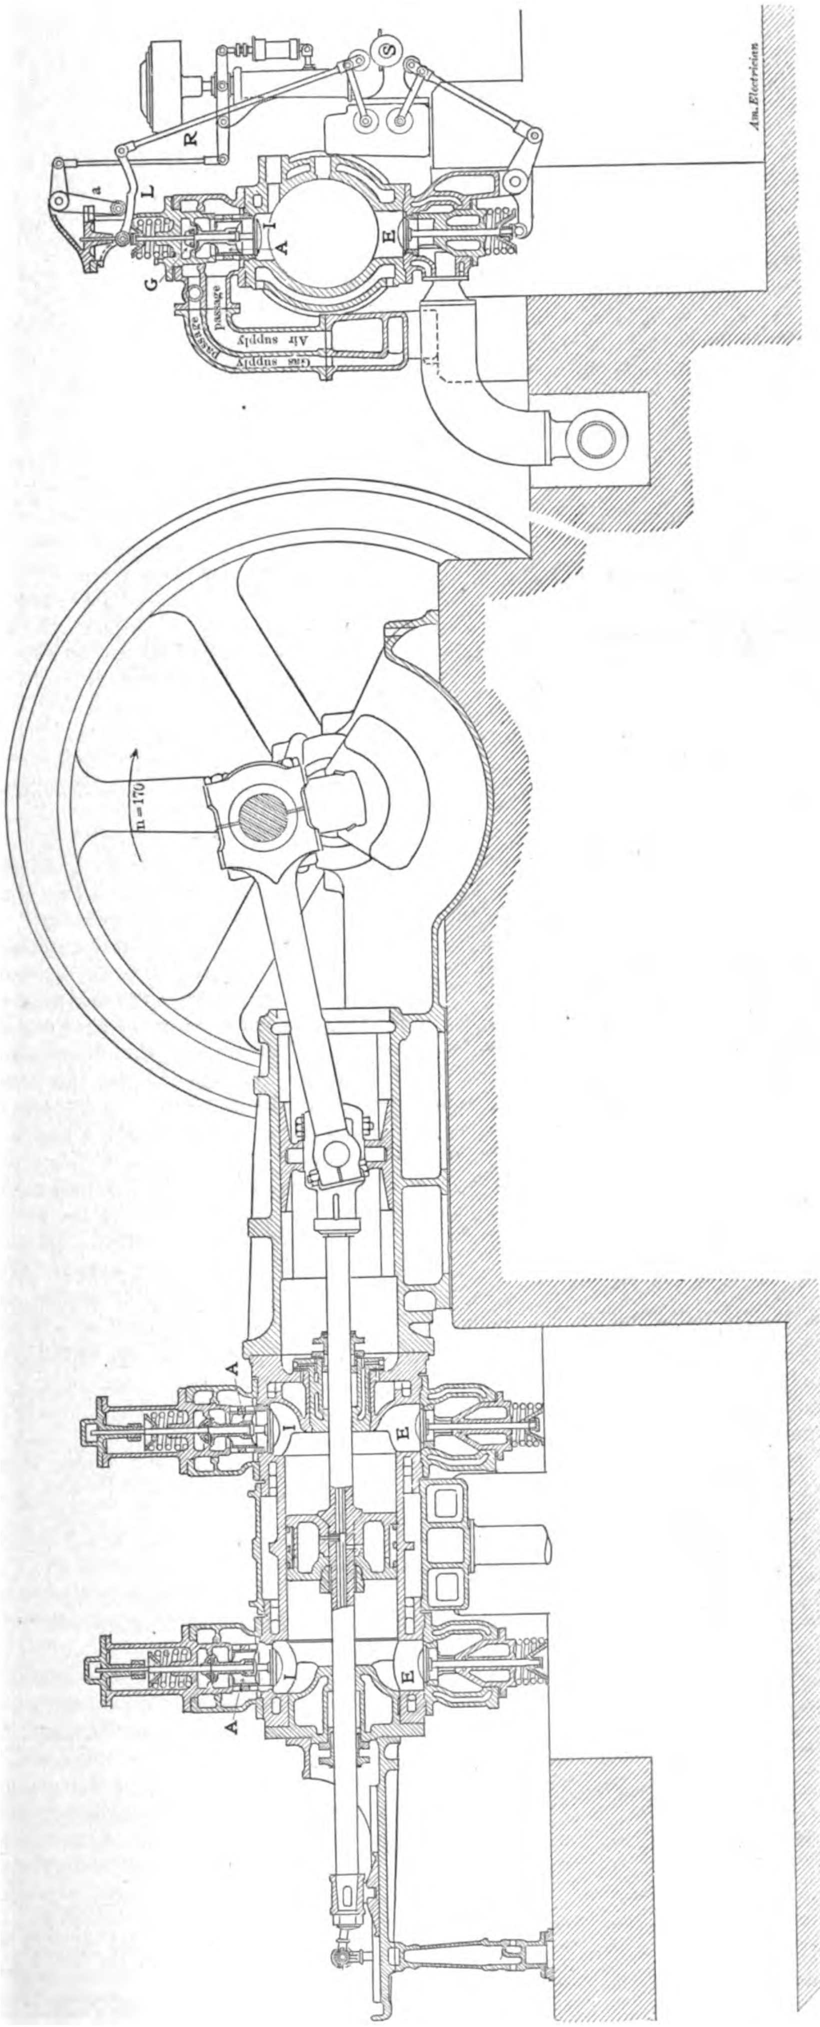

FIG. I.—ELEVATION AND END VIEW OF THE DEUTZ DOUBLE-ACTING FOUR-CYCLE GAS ENGINE—FIG. 2.

springs. The admission valves are similarly opened by cams and linkages, but their travel is varied by the governor through the medium of the bell-crank arm *a*, which carries a roller at its extremity, this roller serving as the fulcrum for the lever *L*, operated by the cam mechanism. Obviously, the position of the roller determines the ratio between the travel of the reach rod *R* and that of the admission valves, and therefore regulates the quantity of explosive mixture admitted to the cylinder. The admission valves are composite; the air valve *A* is of the piston variety and controls the entrance of air from the supply pipe in the usual manner. It carries at its upper end a poppet valve extension which controls the admission of gas through the port *G*, the gas and air being mixed in the valve chamber. It is stated that the action of the governor is so sensitive that the speed fluctuation does not exceed one-half of one per cent when the load is abruptly increased or decreased 25 per cent. The variation in speed between no load and full load is generally not more than three-quarters of one per cent.

The double-acting construction involves the use of stuffing boxes, which have been used very little heretofore in gas engine construction, and experience shows that these stuffing boxes, contrary to the general expectation prior to their actual use, cause no trouble whatever. Fig. 1 gives an excellent idea of the general construction of the engine. The piston is packed by rings of a special type, and the rod and piston are hollow, of course, to permit water cooling. The cooling is very carefully arranged; the cylinder and cylinder lid and the valve, discharging valve and discharging pipe receive separate cooling water so that the temperature can be regulated independently. A lever pump is employed to force the water through the jackets. The starting of the engine is effected by compressed air. These double-acting engines are turned out at Deutz in sizes of 150 horse-power per cylinder and upward. The two-cylinder machines are recommended.

Körting Bros., Körtingsdorf, near Hanover, are not building any engines of their type at the Körtingsdorf shops of more than 500 horse-power. The writer was informed at Körtingsdorf that the facilities of the shops there did not permit of work larger than this. The American rights for this engine are now being developed, and engines of considerably larger power are being manufactured.

In England the Crossleys, of Manchester, have turned out more than twenty thousand gas engines of all sizes; the majority being, however, very small units. The Crossleys are now going in for engines of considerable horse-power, and they, too, are employing poor gas. At Sandiacre, Birmingham, and at Reddish, the writer found shops turning out 500-h.p. gas engines. These sizes seem to be recognized as standard in the United Kingdom, and Mond gas and the Duffield and the Norris systems are now much in favor. The rights to manufacture Crossley engines in the United States, it is stated, have been acquired by local interests.

THE OECHELHAUSER GAS MOTOR.*

BY A. BORSIG.

During the past few years much attention has been devoted to the better utilization of the inferior fuel of low calorific value. This has particularly been the case since the discovery of the fact that the gases from blast-furnaces form an excellent agent for driving gas engines. To-day, therefore, every imaginable fuel is being tested as to its gas-producing qualities with the object of utilizing the gas obtained in explosive motors.

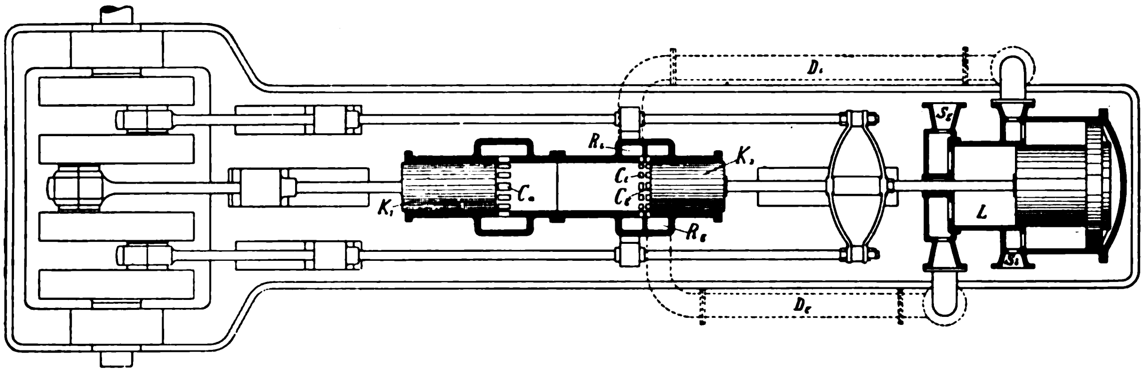

FIG. 1.—SEMI-SECTIONAL PLAN VIEW OF THE OECHELHAUSER GAS MOTOR.

Until a few years ago engineers had not succeeded in obtaining high efficiencies with a single cylinder. Attempts were made to adapt the various existing systems to the increased demands, the result being more or less complicated designs, for what proves successful experimentally is by no means found to be so when carried out on a large scale. The task still remained for the theorist and the practical engineer to conceive and construct an engine fulfilling all the requirements of trade industry; simple, safe in its working, and enabling large powers to be developed in one cylinder of not too large a size. To-day engines are being built, capable of producing continuously over 2000 horse-power in a single working cylinder.

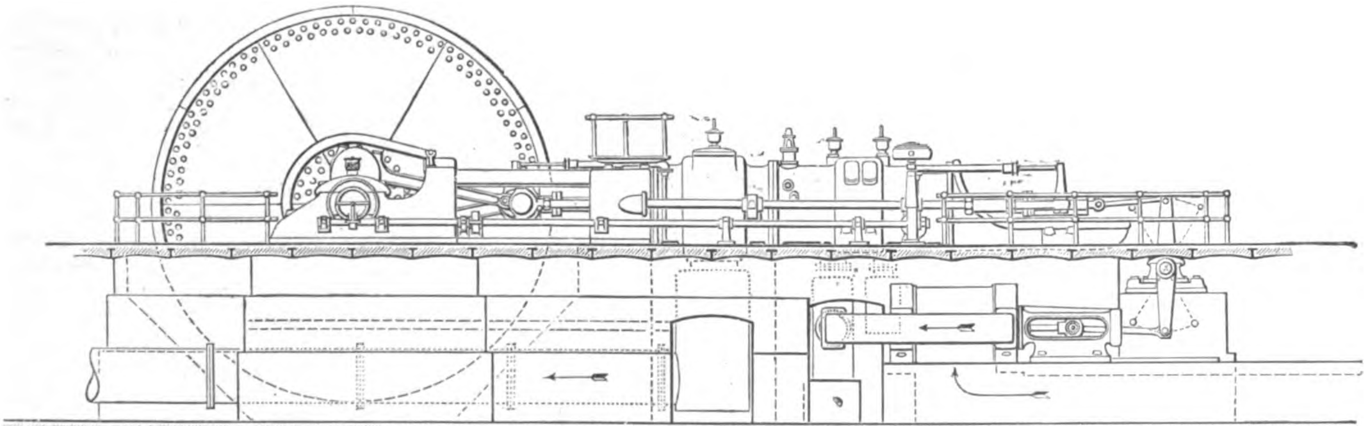

FIG. 2.—ELEVATION OF AN OECHELHAUSER GAS ENGINE.

Following upon the exhaustive investigations of Herr Fritz Lurmann and Professor E. Meyer many iron-workers are gradually displacing their steam engines by gas motors, the latter utilizing the furnace gases three times as well as the steam engines. The results obtained by the experimenters just mentioned show that if the whole of the gases is employed to drive gas engines, about 28 horse-power per ton of pig-iron per day is available for power purposes. The gases from coke-ovens may be similarly well utilized.

Smelting and coke-works, therefore, will in time constitute large central power stations, supplying light and power to the adjacent mines, rolling-mills and other works, and to the neighboring district generally.

Gas engines can also be driven by any kind of producer gas, and before long gas producers will be constructed capable of making a serviceable gas from fuels which are at present generally regarded as being too poor for profitable employment.

Among the numerous types of gas engines, the simplest is unquestionably W. von Oechelhauser's two-stroke cycle motor. As is shown in Fig. 1, two pistons, K_1 and K_2, work in opposite directions in a long cylinder open at both ends and provided with ports *Ca*, *Cl*, and *Cg*. During their motion in the outward direction the pistons uncover the ports consecutively, whereby the distribution is effected. The piston, K_1, first opens the longer ports, *Ca*, and allows the still compressed products of combustion to escape. As soon as the pressure of the latter has sunk to that of the atmosphere the piston, K_2, opens the ports, *Cl*, through which pure air enters the cylinder and sweeps out the waste gases. Hereupon the piston, K_2, opens the ports, *Cg*, allowing gas to enter the cylinder and mix with the air likewise streaming in, whereby the explosive mixture required for a new working stroke is formed. This mixture is compressed during the return strokes of the two pistons and on the cranks reaching their inner dead points it is fired by means of two magneto igniters. Thus a working stroke is obtained for every revolution of the crank-shaft.

The so-called charging spaces, *Rl* and *Rg*, for air and gas, respectively, are refilled during the compression and working strokes by means of a charging pump, *L*, located behind the cylinder, so that at the beginning of the stroke there is always a fresh charge under a low pressure (about 4 to 6 lbs. per sq. in.) ready to enter the cylinder.

In order to prevent gas from entering the exhaust ports the motor is so constructed that whilst air can enter the charging space for gas, no gas can enter the charging space for air. Furthermore, the dimensions of the cylinder are such that for the development of maximum power it is filled at most to about 70 per cent of its full capacity with the explosive mixture. The front piston acts direct upon the middle crank-pin of the three-throw crank-shaft while the rear piston acts upon the two outside crank-pins by means of a cross-piece and connecting-rods. The working of the engine is so regulated that the quantity of gas admitted, which is always exactly in proportion to the power required at the moment, is just sufficient to furnish an easily explosive mixture in the neighborhood of the igniting devices.

The chief advantages of the Oechelhauser motor are as follows: (1) The diameters of the cylinders are reduced and hence also the forces acting upon the driving parts. For instance, the cylinder of the 1700-1800-h.p. engine is only 1100 millimeters (43.3 inches) in diameter. (2) Owing to the pistons and driving parts moving in opposite directions, it is possible to almost exactly balance the reciprocating masses. (3) The whole power passes through the driving parts exclusively, so that the frame is subjected to no horizontal strain, which is often the case to a large extent with engines with rods working in one direction only, so that heavy foundations and strong holding-down bolts are necessary to secure the engine. A further feature, insuring absolutely safe working and great durability, is that the engine requires no valves. Valves in general, and more particularly those of the exhaust, are always liable to derangement, soon become dirty, bend through heat and thereby fail to keep tight. The only valve employed at all is the small one for starting the motor with compressed air, which, however, the moment the motor is running fairly, is closed and remains out of action. (4) The cylinder can be inspected and cleaned in a very short time. After removal of the short piston-rod which connects the rear piston, K_2, with the crosshead, this piston can be withdrawn at once, when the interior of the cylinder as far as the exhaust ports is entirely exposed for access. (5) The moving parts of the piston cooling apparatus are not removed for cleaning the cylinder, but only those pieces which connect the cooling pipe with the interiors of the pistons. All the parts are so arranged that withdrawal of the pistons is in nowise obstructed, while the stuffing boxes of the cooling pipes can be inspected and put in order during running. As the cylinder is open at both ends, there are no covers and no stuffing boxes to remove before cleaning is commenced. If it is desired to withdraw the front piston also, this can be done in the same manner as just described. (6) The combustion chamber is of very practical shape. It is a smooth cylinder without any projections and having no clearance spaces in which dirt might accumulate or waste gases of high temperature remain.

---

* Written for the St. Louis Exposition authorities, and published here for the first time by the courtesy of the Department of Machinery.

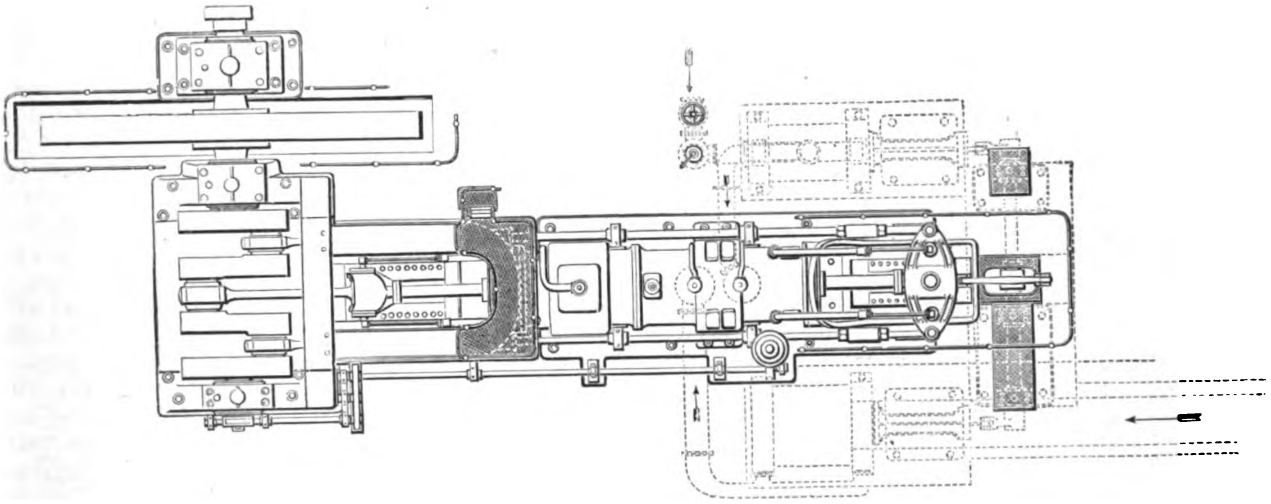

FIG. 3.—PLAN VIEW OF AN OECHELHAUSER GAS ENGINE.

The engine is fitted throughout with self-acting sight-feed lubricators. The standard sizes of the Oechelhauser engine are as follows:

Single cylinder.	Two-cylinder.	R.p.m.
250 h.p.	500 h.p.	150
300 h.p.	600 h.p.	150
400 h.p.	800 h.p.	150
500 h.p.	1000 h.p.	125
750 h.p.	1500 h.p.	125
1000 h.p.	2000 h.p.	94—100—107
1500 h.p.	3000 h.p.	94—100—107

The figures 94 and 107 in the third column refer to the driving of three-phase alternators.

The above figures express the nominal powers of the motors in brake horse-power; they may be overloaded 10 per cent in regular working, and will stand a temporary overload of 20 per cent above these figures. The 500-h.p. single-cylinder motor for instance has furnished as much as 700 horse-power when worked with blast-furnace gas containing less than 900 calories per cubic meter.

The engine is started by means of compressed air. A compressor coupled with an electric or gas motor supplies compressed air under a pressure of 20 atmospheres to a vessel communicating with the engine cylinder through a valve controlled by the engine itself. As soon as the first ignition has taken place the starting valve is closed and the gear disengaged by the attendant.

In order to remove the doubt still expressed by certain engineers as to the durability of the three-throw crank-shaft, I requested Professor E. Meyer, of Charlottenburg, to give an expert opinion on such a shaft. In his report, Professor Meyer first described the manner of calculation advocated by Mr. Max Ensslin, gave the results, and in conclusion stated: "My investigation shows that the crank-shaft made of Siemens-Martin steel, if carefully manufactured so that it may be considered as consisting of a solid piece, will satisfy all demands as to strength and resistance to deformation."

PRIME MOVERS AND ELECTRIC GENERATORS AT THE ST. LOUIS EXPOSITION.

From present indications it would appear that in the disposition of the exhibits of power converting and distributing machinery at the St. Louis Exposition the policy of those in charge of that part of the work will differ greatly from the plan which has hitherto been generally followed. Instead of placing exhibits of electrical machinery (in operation) in the Electricity Building, all such exhibits will be located in Machinery Hall where steam engines and other prime movers will be displayed, as usual. While this disposition of electric generators and motors will doubtless seem strange to those accustomed to find these machines amongst the electrical exhibits, the arrangement is really logical, and has the merit of avoiding the overshadowing of the smaller and purely electrical apparatus in Electricity Building by huge exhibits of large machinery.

The Machinery Building, with its annex, covers 12 acres of ground and is already completed externally. Foundations for the huge engines and other machinery are now being completed. A 40-ton electric traveling crane is installed and is already in use for hoisting huge foundation castings of engines into place, and a 60-ton crane is in course of erection. The eastern half of this building will be devoted to exhibits of machinery and tools, most of which will be shown in complete operation. In general the southern half of the east section will be devoted to wood-working machinery, and the northern half to metal working machinery. Power for all operating machinery will be furnished by motors attached direct to the machines. These motors receive current from generators driven by the engines in the power plant proper in the western half of the building. There will be no line shafts in the entire building, nor anywhere on the grounds.

The western half of Machinery Hall will contain probably the largest and most noteworthy exhibition of engines and generators ever brought together in one place. The larger engines are grouped in a row in the center with a line of smaller steam engines, generators and transformers along the northern wall, and internal combustion engines and water motors along the southern wall. The ground plan of this section is shown in Fig. 1; Fig. 2 is a map of the Exposition grounds.

The central bay of Machinery Hall is divided into four sections, the first of which, approaching from the east, will contain an Allis-Chalmers 5000-h.p. Manhattan type engine, with a 3500-kw. Bullock generator. The next section comprises the power plant of the Intramural railway. The third section contains the two greatest exhibits in engineering on the grounds—namely, a 3000-h.p. Cockerill gas engine and an 8000-h.p. Curtis steam turbine. The fourth section contains four 3000-h.p. Westinghouse engines, with two Westinghouse 2000-kw. generators and two of the same capacity made by the General Electric Company.

In the bay south of the Westinghouse engines will be shown among others the following: A 2250-h.p. vertical Hamilton Corliss engine, driving a 1500-kw. generator of the National Electric Company; a steam turbine driving a 1000-kw. Bullock generator; a 1000-h.p. Willans engine exhibited by the Bradley Manufacturing Company with 750-kw. Stanley generators; a 1000-h.p. Mülhausen engine with a 700-kw. generator; a 1500-h.p. Belleville-Delaunay engine driving a 1100-kw. generator.

One of the most noteworthy exhibits in the whole exposition is the 3000-h.p. gas engine built by Société Anonyme John Cockerill, Seraing, Belgium. This engine is of the double-acting tandem type, and will drive a 2000-kw. General Electric generator. This engine is referred to more in detail in an article elsewhere in this issue. Gas for this engine is produced in the Steam, Gas and Fuels Building several hundred feet away, by a producer gas plant made and installed by W. F. Mason & Co., of Manchester, England. The 2000-kw. General Electric alternator driven by the Cockerill engine will operate in parallel with three alternators of the same rating installed by the same company. Another noteworthy gas engine, the Borsig, is referred to further along in connection with the Intramural plant, of which it forms a part.

The largest steam turbine ever put on exhibition will be located next to the Cock-

FIG. 2.—MAP OF ST. LOUIS EXPOSITION GROUNDS.

erill gas engine. This is the Curtis turbine mentioned before. It will be rated at 8000 horse-power, and is being built by the General Electric Company. It is built on the same plans and specifications as the ten turbines being constructed by the same works for the Commonwealth Electric Company, of Chicago, and the eight turbines for the New York Central Railroad's New York power house. While its rating is nominally 8000 horse-power, it is guaranteed to deliver 12,000 horse-power with safety.

The length of the Intramural electric railway is approximately 10 miles. The power plant for this railway occupies a space approximately 100 feet square in the Machinery Building, and comprises the following engines and generators: A 1750-h.p. Borsig gas engine (described on page 6 of this issue) direct connected to a 900-kw. generator; a 900-h.p. Lane & Bodley steam engine direct connected to a 600-kw. generator; a 750-h.p. Murray Iron Works engine coupled to a 500-kw. generator, and a 600-h.p. Harrisburg engine coupled to a 400-kw. generator. All of the generators are of Crocker-Wheeler manufacture. The plant also includes a 500-h.p. Abner Doble tangential water-wheel driving a Crocker-Wheeler generator. This wheel will be operated by water forced through the delivery pipes by artificial pressure, of course, the pressure at the nozzle to be 300 lbs. per square inch. The wheel will run at 900 r.p.m.

What the Corliss engine was to the Centennial Exposition of 1876, the Allis-Chalmers Manhattan type of steam engine will be to the St. Louis Exposition. While the Curtis steam turbine exceeds it in power, the Allis-Chalmers engine will be the largest piston prime mover on the grounds. Its rating is 5000 horse-power, and it is known as the Manhattan type because it is built on the lines of the engine furnished by the same builders for the Manhattan Railway system of New York. It occupies a floor space 35 by 45 feet, and is 54 feet high, of which 34 feet will be above the floor. Its weight, with the Bullock generator which is coupled to it, is over 600 tons. The foundations for this engine are now about completed. The generator field magnet is, of course, mounted on the main shaft of the engine, and will run at 85 revolutions per minute. A 300-h.p. Ide engine with a 200-kw. Bullock generator will be located in the same bay with the Allis-Chalmers engine.

Altogether, over 45,000 horse-power is represented in the engines which will be in operation in the western end of Machinery Hall, of which 1200 horse-power will be required for electric lighting, 6000 horse-power for the Cascade pumping station and the balance for exhibits and general purposes. Steam for the engine and turbines comes to Machinery Hall through a huge underground steam pipe from the boilers in the Steam, Gas and Fuels Building, which adjoins Machinery Hall to the west.

The Steam, Gas and Fuels Building is almost in the geographical center of the grounds. It is built of steel and cement, and covers a space 300 by 326 feet; it is about 100 feet high. In it will be grouped the best known types of boilers, both European and American. The pressures will range from 125 to 300 pounds per square inch. The building will also contain gas producing plants for supplying the gas engines in Machinery Hall, and briquetting plants, water purifying and softening systems for the water supply and mechanical draft plants for supplying the boiler furnaces.

The southwestern quarter of the building will be devoted to the gas producers, the largest unit being the 3000-horse-power Duff-Whitfield system installed by W. F. Mason & Co., of Manchester, England. Adjoining this will be a 2000 horse-power plant installed by R. D. Wood & Co., of Philadelphia. Both these systems will deliver their gas into tanks or holders. A noteworthy gas producer is that of Julius Pintsch, of Berlin, of 2400 horse-power capacity, which requires no receivers or reservoirs. The Société Anonyme John Cockerill will exhibit a gas scrubber.

The pumping plant of the Cascade is situated underneath the easternmost or left-hand spillway. It consists of three Worthington centrifugal pumps, each of which will deliver 30,000 gallons of water per minute against a double head of 159 feet. These are said to be the largest individual pumps ever built. They are 36-inch. single stage and each is to be driven by a 2000 horse-power alternating-current motor. The water before being pumped will be subjected to filtering and purifying processes and will be used over and over again with only a sufficient additional intake through the purifiers to compensate for leakage and evaporation. A unique feature of this Cascade is that it is to be made useful as well as ornamental. It is to serve as a cooling tower for the steam plants in the Machinery Building and its annex, 3000 feet away. The exhaust steam from the engines, after being condensed, will be pumped through a line of piping to the Cascade pumping plant, and after dashing down the Cascade and passing a mile or two around the grand canal the water will be pumped from a low point in the canal near Machinery Hall westwardly to the boiler feed-water heaters in the power plant. The piping for the Cascade is both spiral riveted and the ordinary construction.

◆◆◆

Utilization of Waste Gas.—Henry G. Morris, in a paper on the gaseous fuel problem read before the Engineers' Club of Philadelphia, says, "the rapidly increasing use of gas engines of high powers is an evidence of the desirability from an economical standpoint of the use of gaseous fuel, opening up a wide field of problems which the engineer will be called upon to solve in the near future. As an example, it is probable that fully 20,000 tons of coke is made per day in the Beehive Ovens, within a short distance of the line of the Pennsylvania Railroad between Altoona and Pittsburg, from which about 100,000,000 cubic feet of gas is discharged into the air or wasted, which if converted into power through gas engines would represent 5,000,000 horse-power-hours, or the effort of about 104 gas engines of 2000 horse-power each."

TELEPHONE ENGINEERING.

Erection of Messenger.

BY F. J. DOMMERQUE.

Before attempting to pull any messenger up on a pole line, the entire line must be firmly anchored and guyed. The methods of anchoring and guying will be discussed later. Also messenger supports must be provided upon the pole by which the messengers are to be held. The designs of such supports are various. The one shown in Fig. 1 is much used for messenger wire and very small strand; for $^{5}/_{16}$-in. strand and larger sizes, the so-called L bracket, illustrated in Fig. 2, is favored. The bracket consists of two parts, one of which is attached to the pole by one bolt and one lag screw or by two lag screws, and the other clamps the strand by two ⅜-in. bolts. The clamp shown in Fig. 1 needs only one lag screw to clamp the messenger and hold the support to the pole. For two cables on one pole, two of the described supports can be used, one on each side of the pole.

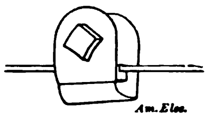

FIG. 1.

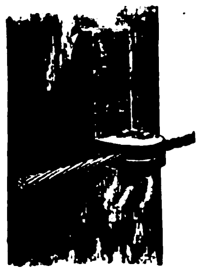

FIG. 2.

For more than two cables on a pole it is customary to use an angle-iron cross-arm attached to the pole in or below the lowest gain. The angle-iron arm is usually arranged for four cables, as that is the limit for aerial cable construction in all cases; in fact, that is hardly ever reached. The angle itself is of 4-in. x 3-in. stock and 32 inches long. It is drilled as shown in Fig. 3 for two cross-arm braces, which are in this case attached to the pole above the arm. The distance of 16 inches between the two cables nearest to the pole may be made greater when it is desirable to allow more space for a lineman to pass in climbing the pole. In some cases where the strain is very severe, a strap is put around the pole in addition, as shown in Fig. 4. Figs. 3 and 4

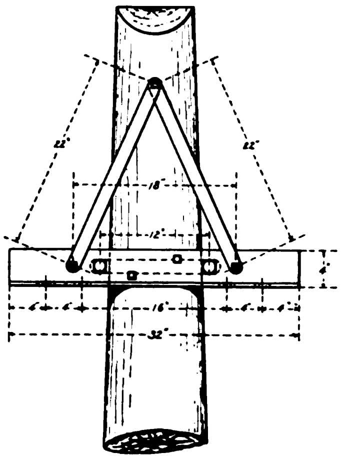

FIG. 3.—ANGLE-IRON CROSS-ARM.

show the holes supplied for the bolts that hold the messenger. These holes are either square or round. When ¼-in. carriage bolts are used to hold the messenger, the holes are cut square to fit the square heads of the bolts. When U-shaped clamps are used, such as that illustrated in Fig. 5, the holes are round, 9/16 inch in diameter. In both cases the strand is clamped between the angle and a strap held by two nuts. On places where heavy strains are encountered, two angles may be placed back to back. In this case the other angle would take the place of the strap in Fig. 4, and would be provided with bolts the same as the first arm for holding the messengers.

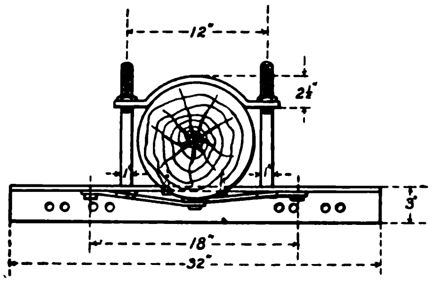

FIG. 4.—ANGLE-IRON CROSS-ARM.

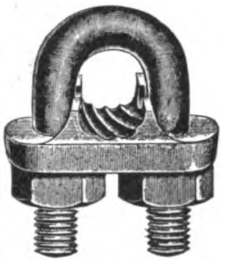

FIG. 5.—CLAMP.

The messenger is lifted up to the poles like ordinary wire and clamped to the supports temporarily but tightly. The terminal of the messenger must be fastened securely to an anchor pole. It is better not to start the messenger from the same pole that the cable starts from, but from the pole ahead, so as to leave the cable pole free from anchors. It is advisable not to use the beginning of the messenger as a guy, but to terminate the messenger on the anchor pole and to use a separate guy for anchoring. The end of the messenger should be wrapped three times around the pole and then brought back so as to form an eye at least eight inches long, and then it should be clamped to the strand with two strand clamps, each clamp consisting of a U-shaped piece and a strap, or of two parts which are clamped together by two or three ⅜-in. bolts. Such clamps are illustrated in Figs. 6 and 7. To prevent the messenger from cutting into the pole, a row of galvanized iron strips 1 inch wide and 6 to 8 inches long are preferably set vertically around the pole with about an inch space between them, the messenger being prevented from slipping off these strips by a spike driven into the pole. The strips are nailed to the pole before the strand is wrapped around them. When more than one messenger terminates upon the same pole, they are fastened one above the other.

After the messengers are firmly secured to the starting pole, the tackle for tightening them is attached at the end of the messenger; one messenger is tightened at a time. If this is done by hand three pairs of pulley blocks are needed, the first one fastened to the pole at which the messenger is to terminate, the second one fastened to the next pole in line, and the third one fastened to a stub or bar some distance farther out, as shown in Fig. 8. The first pair of blocks is attached to the pole at the same level with the messenger supports, and is provided at its free end with a clamp to grip the messenger. With this pair a ¾-in. rope is used about 200 feet long. The men first pull the messenger tight with this pair, after the support clamps have been loosened to allow the messenger to slide freely. When they have pulled it as tight as they can, the messenger is cut off leaving the end long enough to go three times around the pole and form a long eye. Then the end of the pulley rope is fastened to the second pair of pulley blocks, which is attached to the next pole about midway between the ground level and the level of the messenger supports, and which is provided with a ¾-in. rope about 100 feet long. The messenger is pulled as tight as it will go with this second pair, and finally the third pair is brought into action. This pair needs only a ⅝-in. rope about 100 feet long. With this pair the messenger is pulled until it has the proper deflection. Then all supports are tightened again, this time permanently, and the messenger is wrapped three times around the pole and fastened by two strand clamps, the same as at the beginning.

The pole on which this messenger terminates is preferably the next behind the one upon which the cable terminates. In cases where another cable starts upon a pole only a few poles further along, and the messenger for the first cable is short enough to leave a sufficient length for the second cable, it is advisable not to cut the messenger but to run it right through to the end of the next cable.

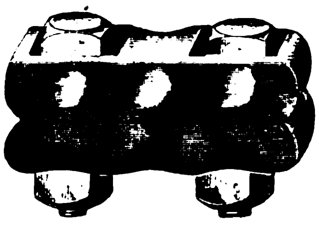

FIG. 6.—GUY CLAMP.

If more than one messenger is to be tightened, the first one is pulled up and clamped down, but not fastened to the end pole. The other messengers are then pulled tight in the same manner as the first one. When the second one has been pulled tight, it will be noticed that the first one has become slack again on account of the line yielding to some extent to the additional pull. This slack has to be taken up, and then the first cable can be secured permanently. The others are then pulled up to the same deflection as the first one, and permanently fastened. It is possible to pull a messenger around a smooth curve, but not around a corner. In the latter case the messenger must be cut and the two ends fastened to the corner pole. When a capstan is used to pull a messenger tight, only one set of pulley blocks is required.

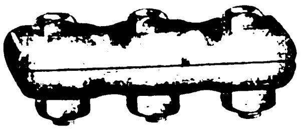

FIG. 7.—GUY CLAMP.

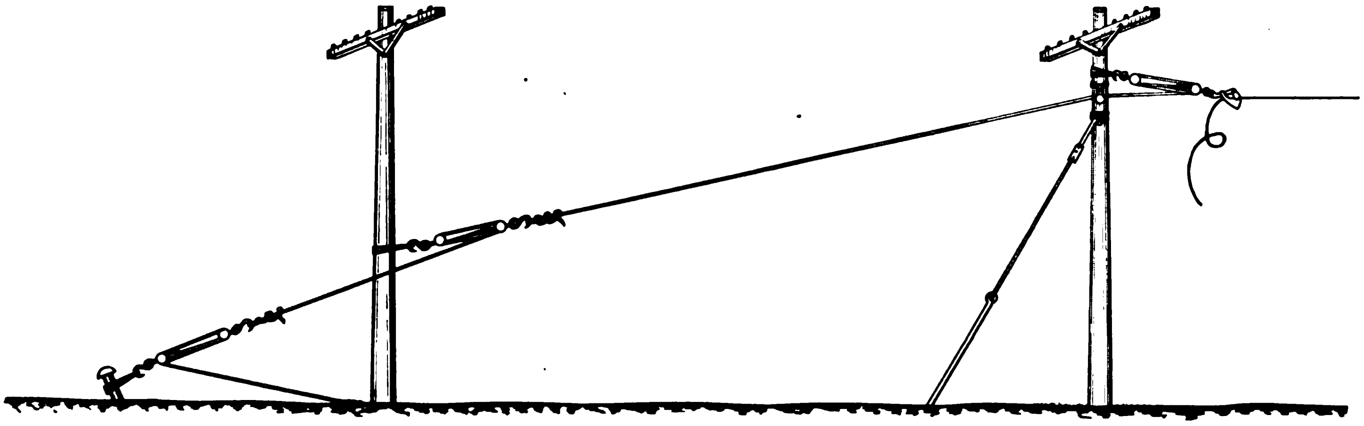

FIG. 8.—METHOD OF TIGHTENING MESSENGER WIRE.

◆

Heating Value of Acetylene and Coal Gas—The heat units developed per cubic foot of acetylene and coal gas are 1850 and 630, respectively. One quart of water was brought to boiling from 50° Fahr. in 8½ minutes with acetylene and in 10½ minutes with coal gas; the burner of the former consuming two cubic feet of gas per hour, while that of the latter consumed 16 cubic feet per hour.

THE EFFICIENCY OF MODERN TELEPHONE EQUIPMENT.

BY M. A. EDSON.

The engineering problems of the transmission of speech have for the last twenty years occupied the time and inventive genius of a large number of engineers and involved an enormous financial expenditure, not only in actual construction, but in some purely experimental exchanges involving every actual condition to be met in operation and maintenance. After all, there are instances where exchanges planned with every feature carefully worked out on a basis of 10 years' service have been radically changed at large expense before being put in operation, on account of some engineering or operative improvement.

After reviewing all these changes and evolutions can it be said that the actual efficiency of the plant for purely conversational purposes, after the desired connection has been made, is any higher to-day than it was twenty years ago? The answer may be made in several ways. A general statement is that the local transmission is only a little better, but the long-distance transmission is greatly improved, not in any one part particularly but as a whole.

The increase in the efficiency of a long-distance telephonic transmission system is 50 per cent in the line and 20 per cent in the transmitter. Conversation may be carried on over these improved lines with a Blake transmitter with good results, but it lacks power and clearness, due to several faulty elements in the mechanism for transforming the energy of the sound waves into electrical undulations. This mechanism has been one on which more work has been done in proportion to the results than any other part of the plant. It is true that there is today the all-carbon transmitter with the low-wound induction coil. This transforms the sound energy into electrical undulations of better form for transmission; that is, the wave form is better, conforming to the sound waves and avoiding the sharp peaks due to the reactance of a high-wound secondary and the undamped inertia of the transmitter parts.

The principal inefficiency in the modern transmitter has two elements: The loss in the mechanical transformation of sound energy into mechanical pressure on the carbon and the loss due to maintaining a supply of electrical energy which is varied between the rather narrow limits of one-tenth to fifteen-hundredths of an ampere as an average for common battery and one-tenth to four-tenths of an ampere for local battery systems. The exact measurement of sound energy at a point six inches from the mouthpiece of the instrument has been tried, but the results are not uniform, and most of the methods are open to serious errors introduced by the direct action of the air pressure on the instruments. The use of vibrating strings has so far proved the most satisfactory, but is open to the objection that two very heavy piers are necessary in order that the vibrations may not reach the measuring diaphragms by mechanical conduction. These strings in the recent experiments have been piano strings on separate mountings electrically maintained by a fine platinum wire at a nodal point dipping into mercury, the wire at this point vibrating between the poles of a powerful permanent magnet.

In this connection a frequency of 125 to 750 cycles per second should be used and the most common constant is 750, but when the frequency is raised to 1200 some phenomena develop in the iron which would seriously interfere with transmission efficiency if they occurred at a lower frequency. Fortunately there are only a few singers that can reach a note as high as 1100 and experiments made at these frequencies (750 to 1200) are more interesting than useful.

Th general tendency of late years is toward the use of transmitters having a low fundamental note, as such transmitters will give greater volume and rate of variation of the primary current per unit of sound energy; lower fundamentals also lessen the tendency of the transmitter to amplify certain tones which are near that of the diaphragm. The efficiency of the subscriber's station equipment from an engineering point presents more difficulty than that of the central office if exact measurements are to be made, but from recent tests the transmitter changes sound energy into electrical undulations at an efficiency of 50 per cent in common battery plants and 75 per cent in local battery. In common battery work the efficiency is still further reduced if the loss in the line is considered, which should be the case as it is a part of the primary circuit. These figures are only for the transmitter, and do not include the induction coil or other inductive devices.

Another uncertain element in the efficiency of the common battery transmitter is the distance from the exchange. It is evident that greater distance from the exchange means less current, as it is not the modern practice to vary the battery or conductor resistance for different lengths of line. The consequence is that an instrument in the exchange building may receive three-tenths of an ampere through the transmitter while another receives one-hundredth of an ampere through four miles of cable, which is about as far as it is safe to go without repeating coils and trunk lines. The average limit is usually set at 350 ohms per line for 24 and 40-volt systems. The line efficiency at two miles from the exchange is 80 per cent, and may go as high as 90 per cent for common battery systems, but for local battery the line is used only for the high voltage variable telephone current and the efficiency is higher. The average value is 95 per cent for aerial copper metallic circuits and 85 per cent for standard underground cable.

In relation to the receiver very little improvement has been made in the original arrangement of a permanent magnet and diaphragm, with a soft iron cored pair of electromagnets, but any improvement that may be made will not materially affect the efficiency, which is about 85 per cent. Receivers, like transmitters, should be made for frequencies of about 750. The most efficient instrument should have a range of 250 to 2000. The acoustic properties of the receiver may be improved in several ways, principally in the shape of the cavities around the diaphragm. The efficiency of the exchange proper can be considered as a means for connecting the subscribers together in pairs, and the efficiency not only depends on the speed with which the connections are made but the cost and accuracy of operation.

The engineering elements which enter into the construction of a modern telephone exchange may be divided into three elements :(1) the power plant, (2) the switching mechanism proper and the distributing and testing boards, (3) the various toll, trouble and supervising desks.

From test runs on five common battery exchanges of 1000 to 5000 lines equipment the mean of all tests shows a power-plant efficiency from the supply mains to the various switchboard distributing points of 50 per cent. This is distributed as follows: Motor-generator combination, 67.5 per cent; charging mains, 94.3 per cent; motor-generator and battery leads, 63.5 per cent, and batteries, 72 per cent. The percentage of total energy delivered to the switchboards, therefore, averaged 52 per cent. The ringing dynamotors have a 24-hour efficiency of 40 per cent, operated with lamps in the ringing circuits.

Results obtained in a recent test of protection devices showed that 98 per cent of the spools were properly protected and 2 per cent injured by charging, but the latter would not have caused a fire; the general efficiency of the protection and distributing boards was 95 per cent. The toll desks or switchboards are generally equipped with the least apparatus so as to interfere as little as possible with transmission. In the average modern toll board, the equipment is only about the same as the system under which the main exchange is installed, except in the case of the automatic system and then it becomes a separate element and its efficiency may be low in comparison. Trouble desks are of a special nature, and are not subjected to the same demands as an exchange equipment. They may be considered a separate element. The supervisory desks are also treated as a separate element, but their efficiency is to be combined with the switching element proper as their work as a connective source increases the general efficiency of the system.

In considering the efficiency of the switching element proper, we may go back to the subscribers' station and lay down the requirements for a connection. These are: (1) Good transmission, by which is not meant great loudness, but strong, clear conversation, entirely free from annoyances, such as clicks, cross talk, inductive disturbances, and other people or operators cutting in on the line; in other words, the *equipment must talk and nothing else.* (2) Speed in getting the other subscriber. This must be attained without a sacrifice of accuracy, and the only delay must rest with the called subscriber. (3) After the conversation is finished, no time of either subscriber, calling or called, should be taken up with manipulating the equipment; it should absolutely be self-restoring. (4) The equipment must be economical of power and expensive supplies, low in mechanical maintenance and long-lived as to the most-used parts. The item of first cost is not entered into in this discussion as the problem is viewed more from the engineering standpoint without regard to first cost.

Under the first requirement the efficiency will be, we will assume, 100 per cent between two subscribers with no exchange and local battery. To compare this with a 5000-line exchange on the central energy manual switchboard and starting at the terminals of the battery, the first piece of apparatus is the retardation coils; since these coils are a necessary part of all large common battery systems, it only remains to determine the most efficient arrangement. In the first arrangement, the coils are both retardation and repeating coils, and in the same circuit is included disconnecting relays as a separate element, also lamps. In the second, the retardation coils, resistance and disconnect relay are one, with the addition of condensers between the coils in the well known way. The efficiency of the first combination is 40 per cent; that of the second combination is 50 per cent, as it is less influenced by leakage and contains the signaling element in one combination; the use of condensers is also an advantage in reducing the inductive losses in the coils. In the exchange with local battery only, a high impedance and high resistance bridge is across the circuit, and the transmission efficiency is 95 per cent after all connections are made. This refers only to speed transmission and the best switchboard construction for local battery, electromechanical signal call and disconnect magneto signaling systems not being included in this discussion as they are obsolete for large exchanges. In the first combination, the repeating coil system is inefficient for the reason that it is very susceptible to unbalanced conditions of lines and leakages and the difficulty of constructing coils which will have a high efficiency under such load variation as 0.3 ampere to 0.01 ampere; also because of the loss in the auxiliary relays, lamps and similar devices. Second requirement: Speed in getting the called subscriber. It is generally conceded that the best types of modern central energy manual switchboards require the same number of operations for large exchanges. The operations may be enumerated thus: 1, subscriber takes the receiver off the hook; 2, subscriber's individual signal lights up above the pilot lamp, involving a double operation, as the relay must first make the contact and the lamp filament must then be located; 3, operator inserts answering plug, which involves three movements from a military point of view, *i.e.*, pick up plug, locate jack, insert plug; 4, operator sets listening key; 5, operator asks number; 6, subscriber gives number; 7, operator repeats number; 8, operator picks up plug and locates jack in multiple; 9, operator test for busy; 10, operator inserts plug; 11, operator rings called subscriber; 12, operator restores listening key; 13, operator notes when called subscriber's lamp goes out in cord circuit; 14, called subscriber answers; 15, called subscriber hangs up receiver; 16, connecting cord lamp lights; 17, calling subscriber hangs up receiver; 18, operator removes answering plug; 19, operator removes calling plug.

If trunking is necessary, the following sequence must be substituted for the last twelve operations: 8, operator selects order wire key; 9, operator gives order to incoming trunk operator; 10, incoming trunk operator repeats number; 11, incoming trunk operator gives trunk number; 12, first operator picks up plug, locates trunk jack and inserts plug; 13, incoming trunk operator tests line of called subscriber for busy; 14, incoming trunk operator inserts incoming trunk plug in called subscriber's jack; 15, incoming trunk operator sets automatic ringing key; 16, automatic key rings subscriber; 17, called subscriber takes up receiver and restores key automatically; 18, calling subscriber hangs up receiver; 19, supervisory lamp at first operator's position lights up; 20, called subscriber hangs up receiver; 21, second supervisory lamp lights up; 22, first operator pulls out plugs; 23, disconnect lamp on incoming trunk cord lights up; 24, incoming trunk operator pulls out trunk plug.

In all manual boards there is very little variation in this cycle of operations. Visual mechanical signals are used instead of relays and lamps, and different methods of trunk operation are devised without materially increasing the efficiency. The efficiency of operators as a part of the system is one of the most variable quantities with which we have to deal in the manual system; one operator may work eight hours at an efficiency of 80 per cent. This is based on the principle that the operator has 100 per cent of work to perform, and 80 per cent of the work is done correctly and 20 per cent is unnecessary errors and delays. As a result of numerous tests on modern common battery equipment, a general efficiency of 75 per cent was obtained.

The third requirement, the disconnection of all apparatus, is performed in a way to leave little to be desired at present, as indicated in the foregoing discussion of the cycle of operations for each call.

Fourth requirement: Power economy and long life of apparatus. The low power cost for a local talking battery central signaling battery switchboard places it at an efficiency in this respect of 75 per cent. This is due to the fact that current is used only when the signals are operated and no cut-off relays used. In the most efficient common battery combination, the retardation coil-relay-condenser system, with visual electro-mechanical signals, consumes less energy in the all-day operation of the equipment; this may reach an efficiency of 60 per cent. The common battery repeating coil-relay system, with lamp signals throughout, works at an average efficiency of 50 per cent. All of these efficiencies refer only to the switching equipment and do not include lines, power plant or subscribers' equipment.

Under the first requirement the operation of an automatic equipment is very efficient, as such a system is free from the interference of operators, busy test clicks, cross talk, and reasonably free from inductive disturbances. The line is bridged by high impedance high resistance coils, and has about the same efficiency as the local battery board with one clearing out drop, but the complexity of the plant must be considered; 90 per cent efficiency is about the average at present. Speed of operation is one of the main features of the system, and will reach 95 per cent of the theoretical requirements.

The establishment of a connection and clearing of the lines are reduced from 19 and 24 operations to from 6 to 9 in calling any number from 1 to 9999; this is divided thus in the automatic exchange: 1, subscriber removes receiver from hook; 2, subscriber rotates dial for thousands; 3, subscriber rotates dial for hundreds; 4, subscriber rotates dial for tens; 5, subscriber rotates dial for units; 6. subscriber pushes ringing button; 7, called subscriber answers; 8, calling subscriber hangs up receiver and thereby clears the line; 9, called subscriber hangs up receiver. If the number is under 10, the second, third and fourth operations are eliminated.

The third requirement of clearing lines is included in the foregoing cycle, as it was in the discussion of manual operation.

The power required is a little less than in the common battery, and the efficiency of the power plant is the same. Maintenance (mechanical) is less than with the common battery system, and the life of the plant is greater, as it can be built on heavy lines from an engineering standpoint, requiring no special refinements in the way of woodwork and finish.

In conclusion, the efficiency of exchange equipments is affected in so many ways that it is difficult to compare one plant with another. The local conditions under which one plant operates may be such that another could not do the work with half the efficiency due to the methods of operating which are necessary to the public service; the all-day efficiency is variable and is modified by the class of service given, whether measured service or flat rate.

The telephone industry has passed through three periods of evolution, the eighties, when the apparatus used included the magneto series and Blake transmitters; the period of the nineties of multiple bridging, granular carbon transmitters, all metallic circuits, etc., and the period of 1900 of central-energy automatic signals and better lines. We are now entering on the fourth period, involving automatic central energy telephony, and with high hopes of increasing the all too small efficiency of the modern telephone equipment.

[The foregoing is an abstract of a paper read last month before the Chicago Electrical Association.]

American Internal Combustion Engines

In view of the remarkable development of the gas engine as to point of magnitude of output per unit and closeness of speed regulation, which has brought this type of prime mover up from the level of a driver of coffee grinders and remote pumping or hoisting outfits to a serious competitor of the Corliss and similar types of steam engine, a presentation of American practice in gas engine construction will doubtless be of interest. And as much serious and notable engineering work has been done on internal combustion engines using oil as fuel, that form of engine has been included in this article.

It is doubtless well known that there are two general methods of securing speed regulation in gas and oil engines, namely, the throttling method and the "hit-and-miss" method. Throttling is used in all engines of large output and practically all engines for driving dynamos, for the reason that it gives a more nearly uniform rate of speed than the "hit-and-miss" method. It usually consists in varying the amount of explosive mixture admitted to the cylinder according to the requirements of the load, exactly as the quantity of admitted steam is varied by the governor of a throttling steam engine, although there are many builders who prefer to throttle the gas or oil supply only, allowing the total quantity of mixture to remain constant. This latter method obviously regulates the power of the engine by regulating the calorific value of the mixture and thereby the force of the explosion, or more scientifically, the initial pressure due to combustion. The throttling of the gas or oil alone has the merit of maintaining constant compression, whereas throttling the whole mixture causes the compression to vary with (not proportionately to) variations in the load. It seems to be the opinion of the majority of gas engine designers, however, that it is better to keep the richness of the mixture unchanged, after adjusting it so as to secure maximum combustion efficiency, and to vary the quantity of mixture admitted, than to vary the quantity of gas or oil and thereby impair the combustion efficiency of the mixture.

The "hit-and-miss" method consists in suspending admission of either the fuel alone or of the mixture of fuel and air when the speed becomes excessive. The governor of an engine of this class will skip a charge every now and then, when the engine is running on less than its full load, the frequency of the "misses" depending, of course, upon the proportion of full load being carried. On very light loads, several admissions will be omitted consecutively; then there will follow a single admission and explosion which "boosts" the speed above normal to such an extent as to cause several admissions to be skipped again, and so on. It is obvious that under such conditions anything near a uniform rate of angular speed is out of the question. At points near full load, however (or the load which will require relatively few misses) the "hit-and-miss" method yields excellent speed regulation, and it has the advantage that the cylinder is occasionally swept out by pure air, if it is the fuel delivery alone which is cut off and not the air and fuel both.

Almost all engines of considerable output are operated on what is commonly termed the "Otto" cycle, and more accurately but less frequently referred to as the "Beau de Rochas" cycle; the cycle was originated by Beau de Rochas, but Otto was probably the first engineer to apply the cycle in a practical manner. The cycle requires four single strokes of the piston; on the first stroke (assumed to start with the piston in the position nearest the cylinder head) the explosive mixture is drawn into the cylinder; then the piston returns, compressing the charge; when it reaches the starting position, the charge is ignited and the expansion of the heated gas forces it forward again; at the outward end of the stroke the exhaust port is opened, and as the piston returns again to its starting position it sweeps out the inert gases produced by the combustion of the charge. Thus the piston traverses the length of its stroke four times in each complete cycle. Engines operating thus are commonly but inaccurately termed "four-cycle" engines; "four-stroke cycle" would obviously be more descriptive.

Many small engines and a few large ones are operated on the two-stroke cycle, and

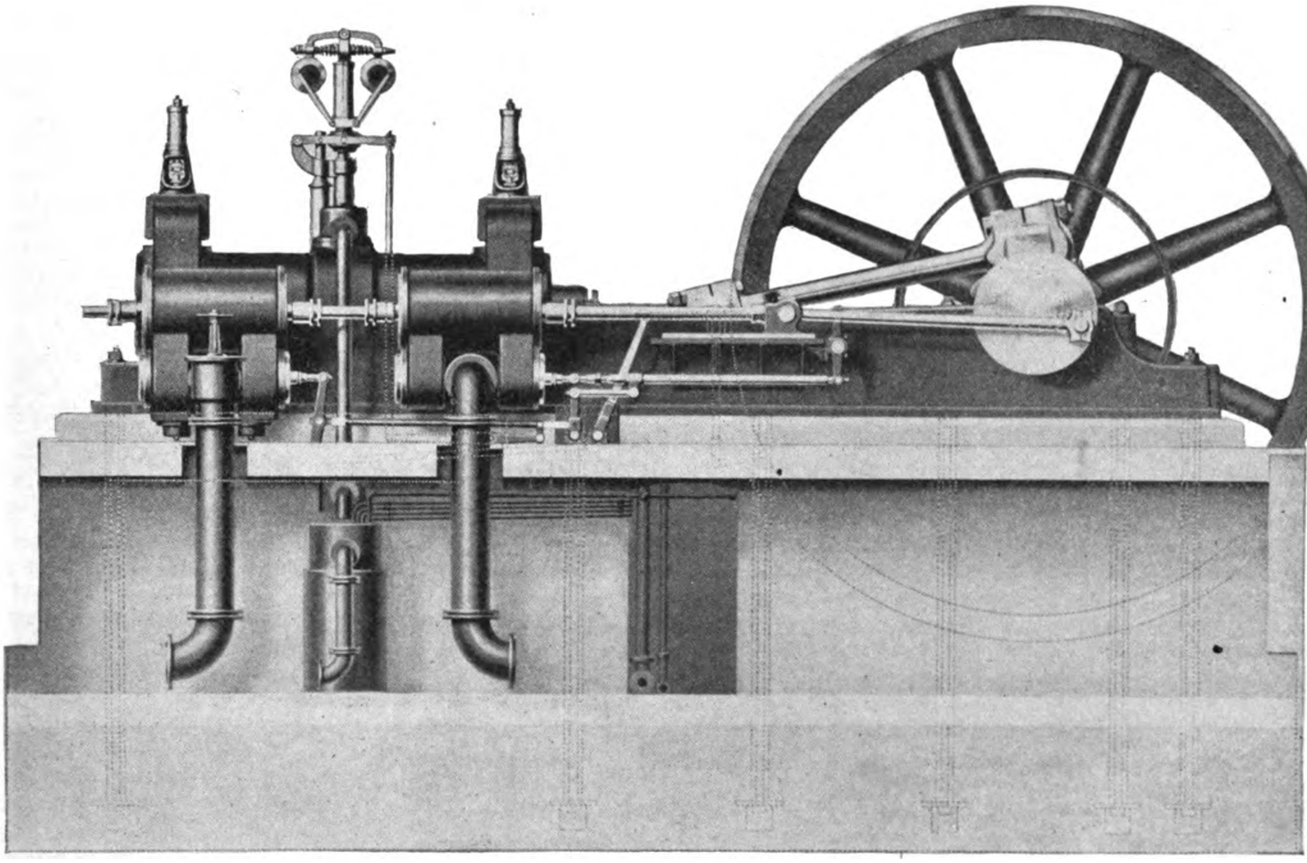

FIG. I.—SIDE ELEVATION OF THE KOERTING DOUBLE-ACTING, TWO-STROKE CYCLE GAS ENGINE.

are known as "two-cycle" engines. In the two-stroke cycle a separate receiving chamber and a pump for drawing in and slightly compressing the charge are necessary; in small machines the engine is always single-acting, and the front of the cylinder is commonly combined with the crank-case to form a receiving chamber, the front side of the piston acting as a pump. The cycle is easier to describe starting from the moment of ignition. The piston, at this moment, is at the "inner" end of its travel, of course, and a charge of the mixture is contained in the cylinder behind it, while another charge has just been drawn into the receiving chamber. As the expanding gases drive the piston forward it compresses the charge in front of it; at the end of the stroke, the exhaust port is opened on one side of the cylinder, and an instant later a port on the other side of the cylinder leading to the receiver chamber is also opened, so that the exhaust gases escape on one side while the fresh charge, which has been slightly compressed, enters on the opposite side of the cylinder; the piston returns, further compressing the charge now behind it, and drawing in another charge into the receiving chamber. This brings the engine back to the beginning of a cycle. The two-stroke cycle is obviously open to the objection that either some of the entering charge must be carried out along with the exhaust gases or else some of the inert gases which should be exhausted must remain in the cylinder and contaminate the fresh charge. In some cases, the exhaust port is opened considerably in advance of the opening of the admission port, and a third port is opened simultaneously to admit pure air under compression, the air serving to sweep out the inert gases and form a barrier between the exhaust port and the incoming fresh charge when the latter is admitted. This practice is observed in the operation of almost all two-stroke cycle engines of considerable output.

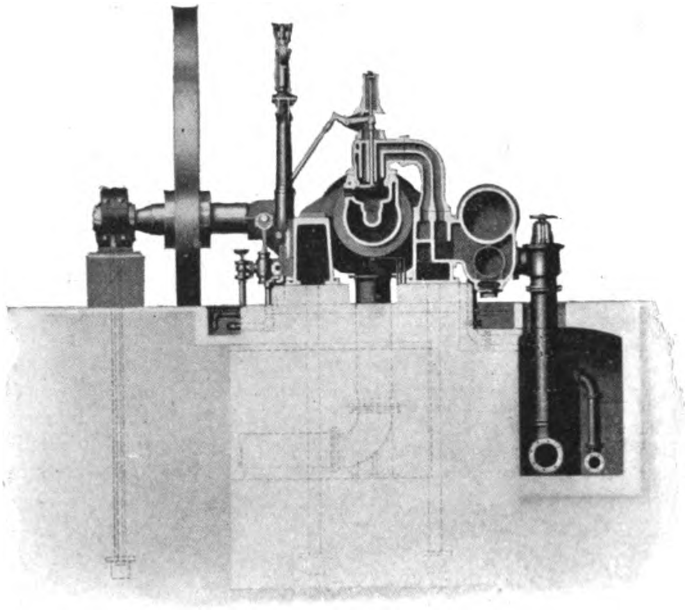

FIG. 3.—SECTION THROUGH SUCTION VALVE OF KOERTING GAS ENGINE.

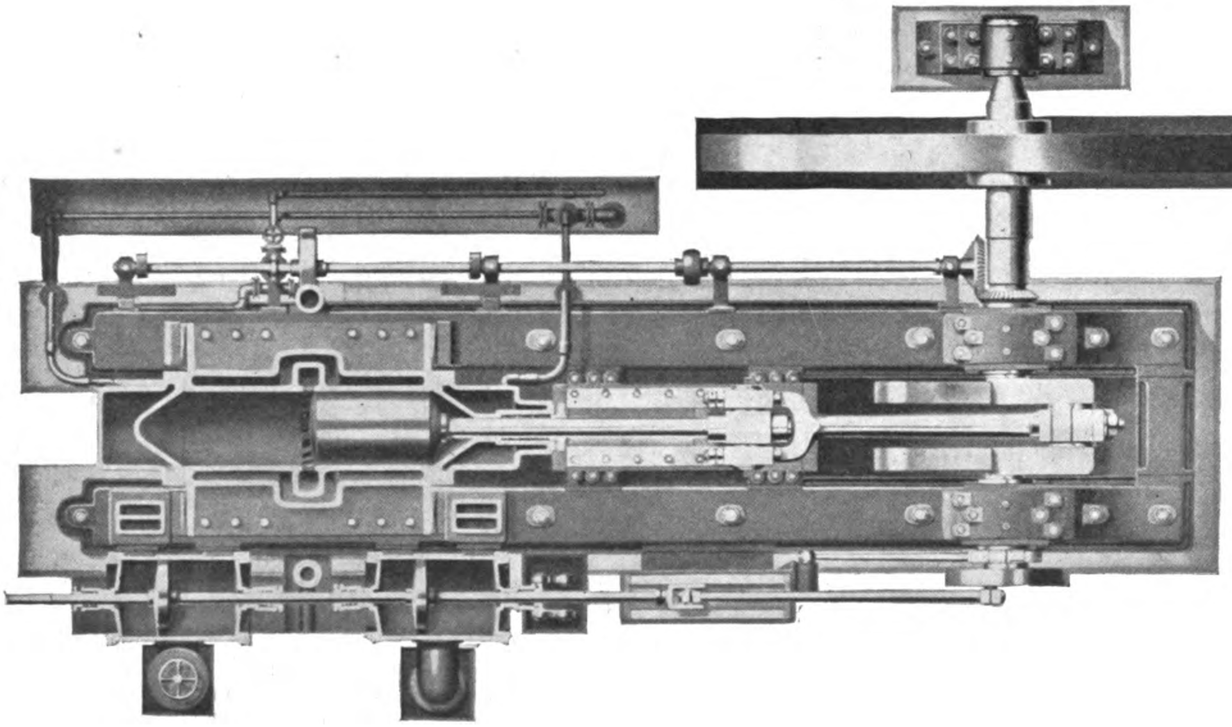

FIG. 2.—SECTIONAL PLAN VIEW OF THE KOERTING TWO-STROKE CYCLE GAS ENGINE.

So far as the writer is aware, the only American builder of two-stroke cycle engines of large size is the De La Vergne Refrigerating Machine Company, New York. This company builds the Körting design of engine, originated by the German firm of Körting Brothers, Körtingsdorf, near Hanover. Fig. 1 is a side elevation of the Körting engine; Fig. 2 is a sectional plan view, and Fig. 3 is a transverse section through the cylinder, admission valve chamber and gas pump. Individual pumps for gas and air are used, as indicated by Fig. 1, but a single rod drives both pistons. The pump rod is actuated from a crank disc on one end of the main crank shaft, and the valves of both pumps are actuated by an eccentric on the main shaft through a system of reach rods and rocker arms; this gearing is clearly shown in Fig. 1. This engine is double-acting, and has no exhaust valves; the exhaust ports are in the center of the cylinder, and are covered and uncovered by the piston, as shown by Fig. 2. The piston, therefore, is made of a length equal to the stroke minus the length of the exhaust ports.

Admission valves of the poppet type are used, as shown by Fig. 3; these are opened by cams on a secondary shaft running parallel with the cylinder and driven by equal gears from the main shaft. This secondary shaft also drives the governor. Referring to Fig. 2, it will be seen that the piston is at the crank or "inner" end of its travel, having just uncovered the exhaust ports and allowed the products of combustion to escape. Immediately upon the opening of the exhaust ports, the air pump (at the crank end of the cylinder) delivers a stream of air to the cylinder which drives out the remnant of burnt gases and forms a barrier between the exhaust ports and the charge of mixed gas and air which is admitted an instant later. The mixture of gas and air is effected in the passages leading to the admission valve (see Fig. 3.) The charge is compressed, of course, together with the scavenging air by the piston upon its return stroke, ready for firing. The compression pressure ranges from 150 to 175 pounds per square inch. The pressure to which the air and gas are compressed by the pumps before delivery to the cylinder is about 9 pounds.

The governor controls the valves of the gas pump and also controls a throttle valve in a by-pass between the delivery ports of the pumps and the compression channels leading from the pumps to the admission valve chamber. The action of the governor is to delay the delivery of gas as the load is reduced, thereby reducing the total quantity sent into the cylinder; this is a refinement of the second method of throttling mentioned at the beginning of this article. With high compression pressures employed in the Körting engine, the variation in the ratio of gas to air in the cylinder is not of so much importance, especially as there is no variation in the quality of the charge proper; the proportion of gas to air delivered to the admission valve after the first delivery of air alone to drive out the exhaust gases is not changed, but the quantity of air first sent into the cylinder is larger, and the quantity of mixed gas and air delivered afterwards smaller, as the load on the engine decreases. It is stated by the builders that the body of air used for scavenging and the body of the charge of combustible mixture remain practically distinct in the cylinder.

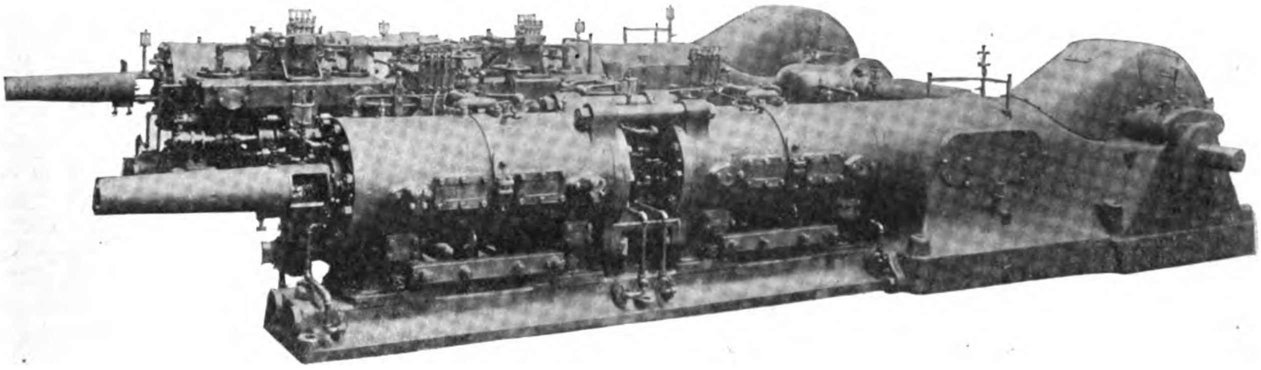

FIG. 4.—WESTINGHOUSE DOUBLE-CRANK FOUR-STROKE CYCLE GAS ENGINE.

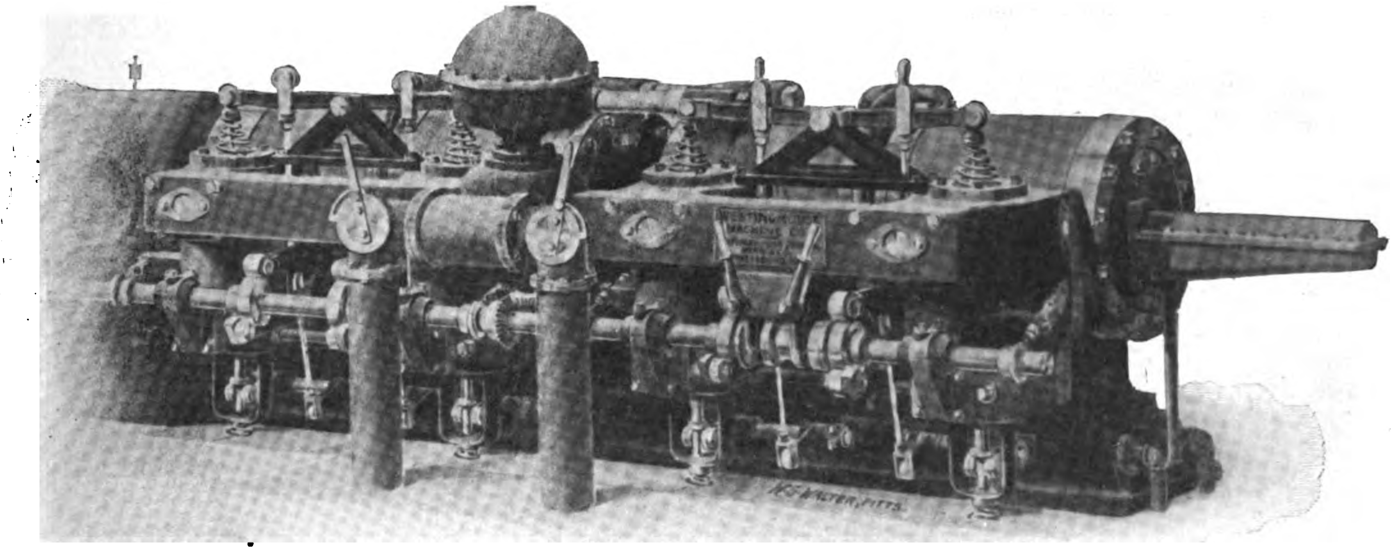

FIG. 5.—VALVE GEAR OF THE WESTINGHOUSE SINGLE-CRANK FOUR-STROKE CYCLE GAS ENGINE.

Electric ignition is employed, and the igniter mechanism is actuated through a gear which is so mounted on the shaft that its angular position with respect to a fixed point on the shaft may be adjusted; consequently the time of ignition may be adjusted to suit the quality of the gas used. Lean gases require ignition considerably in advance of the point of ignition for rich gases.

The engine is started by means of compressed air, and the air inlets for this purpose are so arranged that the compressed air does not enter at the extreme ends of the cylinder where the charges are being compressed during the process of starting, so that these charges are not weakened appreciably by the air used for starting. A double-acting piston valve driven from the secondary shaft by an eccentric controls the admission of compressed air for starting, exactly as the ordinary slide valve controls the admission to a steam engine cylinder. Two charges of compressed air usually suffice to start the engine to running regularly.

The working cylinder is, of course, water-cooled, and the piston and piston rod are also cooled, but to a greater degree than the cylinder barrel. The object in keeping the piston and rod temperatures below that of the cylinder is, of course, to avoid difficulty due to disproportionate expansions.

The largest four-stroke cycle gas engines built thus far in this country are those of the Westinghouse Machine Works. The vertical single-acting Westinghouse gas engine is very generally familiar to those interested in the subject. The general features of built-up cranks enclosed in a housing, adjustable concentric journals, cam and roller valve-gear, and compressed-air starting arrangement characteristic of the vertical design described fully in the technical papers a few years ago, have all been retained. The entire upper cam shaft has, however, been dispensed with, a single cam shaft, which is mounted within the housing, serving to actuate all of the valves. It is driven by single reduction gearing directly from the main shaft, and upon it are mounted two sets of cams, one for the exhaust valve and the other for the admission valve and the igniters. A single cam for each cylinder is employed instead of two, as formerly, to operate both the admission valve and the igniter. The exhaust mechanism is provided with an auxiliary cam of opposite throw at the side of the main exhaust cam, which is also engaged at the starting of the engine, thereby opening the valve at each stroke. Compressed air for starting is then admitted to one cylinder by a special double-throw cam mounted on the end of the cam shaft, thereby allowing this cylinder to operate for the time being as an air motor. During this operation both the admission valve and the igniter from this cylinder are thrown out of service by a clutch operated automatically by the compressed air system.

The governor is mounted at the end of the engine on a short vertical shaft, driven from the main shaft, as shown in Figs. 7 and 8. It is of the fly-ball type, the main fulcrum pins being knife edges, and the motion is transmitted through roller contacts; it is housed in an iron casing. Adjustment of the spring tension, and hence the speed of the engine during operation, is provided.

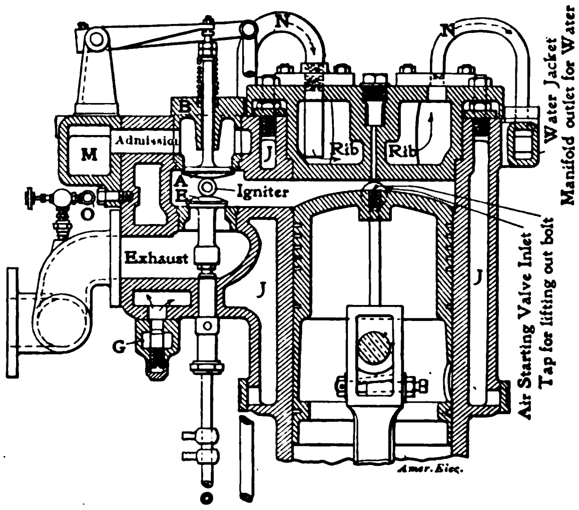

FIG. 6.—DETAILS OF WESTINGHOUSE VERTICAL GAS ENGINE.

Formerly the cylinder casting contained only the exhaust valves and chambers, while the cover or head contained both the admission valves and igniters, and was bolted to the upper face of the castings by long stud bolts. In the new design, shown in section in Fig. 6, the main cylinder casting contains all of the valves and the igniters, while the cover is simply a plain cylinder head cored out for circulating water. This permits the removal of the piston without dismantling the upper works of the engines.

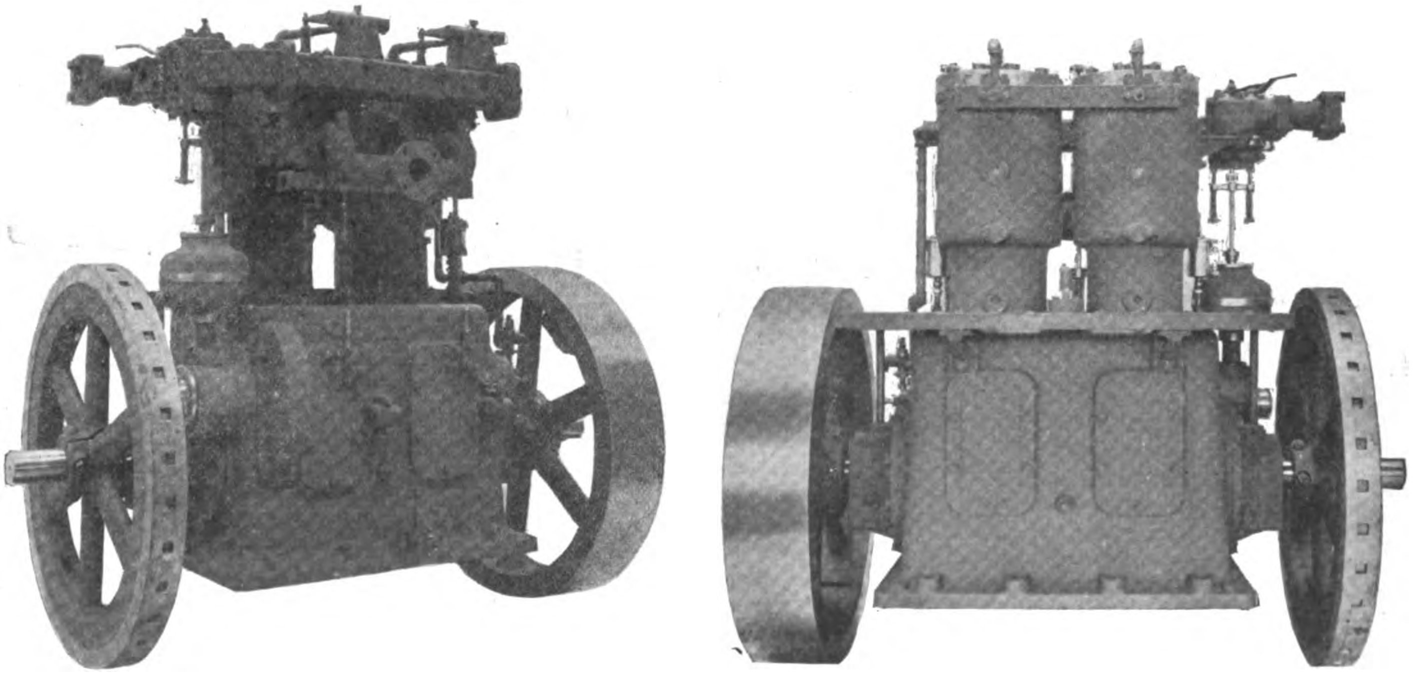

FIG. 7.—FRONT AND BACK VIEWS OF THE WESTINGHOUSE TWO-CYLINDER VERTICAL GAS ENGINE.—FIG. 8.

Gas and water manifolds (*N*, Fig. 6) separate from the cylinder casting and bolted on at opposite sides are provided to connect the different chambers, so that without increasing the complexity of the cylinder casting, the upper part of the engine has been largely cleared of working parts.

A feature of the new design is the relative location of admission and exhaust valves, *A* and *E*. These seat vertically in opposite directions, and are held on their seats by spiral springs. They are both removed through the same opening in the casting. The admission valve *A* is mounted in a cast-iron bonnet *B*, and the entire part may thus be removed without dismantling. This leaves sufficient room for taking out the exhaust valve *E*, and its seat if necessary. Formerly a special opening was provided for the removal of the exhaust valve. The arrangement of the valves has been largely instrumental in reducing the working temperature of the exhaust valve, as the cool mixture entering the cylinder flows directly across the exhaust-valve head. This has made it possible to use uncooled valves on larger sizes of engine than formerly. Water-cooled valves are, however, employed in sizes above 125 horse-power, and on smaller sizes when used with special gases. The valves are of forged steel and are bored throughout their length for the reception of a small copper water tube. This conducts cold water to the valve head where it discharges into a recess and returns through the annular space between the tube and spindle bore. In locations where the cooling water is obtained from artesian wells and contains acid impurities, cast-iron valves are used, of the construction shown in Fig. 6. Cooling water circulates first around the combustion and exhaust chambers, these being the parts subjected to the greatest heat, then around the cooler parts.

Two forms of mixing valves are used, according to the character of fuel gas. With natural or illuminating gases which are quite free from solid or viscous impurities, a two-section piston valve is employed, directly controlled by the governor to increase or decrease the port opening of each section in proportion to the load on the engine, while the mixture proportion is secured by rotating the valve on its axis in the valve casing, which has ports nominally registering with those of the valve. These two mixing valve sections are each controlled by a separate lever, so that the ratio of gas to air can always be adjusted and constantly maintained with accuracy. With producer or other lean gases a double-beat poppet valve is employed and the proportion secured by independent plug valves, each having graduated ports.

The vertical type is built in sizes ranging from 10 horse-power to 200 horse-power, the larger engines of this group having three cylinders instead of two. For outputs above 200 horse-power double-acting construction is employed, and for very large outputs, the engines are built in the horizontal form, with two tandem cylinders, as indicated in Fig. 5, which shows the valve-gear side of the cylinders of such an engine. Fig. 4 illustrates the twin tandem horizontal type built for outputs up to 4000 horse-power (1000 horse-power per cylinder).

In general construction, the double-acting engines embody the essential characteristics of the single-acting type, together with many established features of modern steam engine practice. For example, in the horizontal design, from the crank-shaft to the cylinders the construction is that of a horizontal steam engine, suitably strengthened in proportion to the increased maximum pressures involved. The design of the cylinders, pistons and valves, of course, departs materially from steam engine practice. The cylinders are double walled with the outer walls split peripherally to permit of independent expansion and contraction when subjected to heating and cooling in operation, and to relieve cooling stresses in casting. The two tandem cylinders are united at the top by heavy tie rods and at the bottom by a cast iron distance piece. Both inner cylinder heads are split diametrically and held together by bolts; the seam is a ground fit no packing being used. Straight ports at the end of each cylinder communicate with the combustion chambers, which are cast integral with the cylinder.

The relation of admission and exhaust valves is quite similar to that of the single-acting type shown in Fig. 7, and the entire cam mechanism is but an adaptation of that of the vertical to the horizontal engine. The mixture is adjusted in the same manner as in the vertical type and controlled by a governor of similar construction positively driven from the cam shaft, which receives its motion from the main shaft through helical gearing. The combustion chambers and exhaust passages are all water cooled, as are also the pistons and piston rods, all the horizontal engines being double-acting. The pistons are fitted with spring packing rings and have babbitted bearing surfaces. They are secured in position on the rods by internal keys and present plain convex surfaces to the burning gases. Circulating water is admitted to the pistons through the piston rods; it enters at the cross-heads through flexible pipe connections provided with swinging joints. It then flows through the hollow piston rod to the front and rear pistons successively, through which it circulates, eventually emerging through a bronze tail rod which extends through the rear cylinder head, and emptying into a cast-iron jacket piped to the discharge main.

The cylinder oiling is accomplished automatically by multi-plunger pumps driven from the valve mechanism. The engine is started by compressed air in the same manner as the vertical type.

The method of ignition in all types is electric, at either high or low voltage, as may be desired. In plants where lighting current is available, current is taken directly from the mains, passing through incandescent lamps, both for the purpose of limiting the current to the amount required and for indicating the continuity of the supply. The igniter is of the standard make and break type. It is removable in one piece in the form of a plug, and is operated by a vertical rod from the cam shaft. The igniter enters the side of the combustion chamber, as shown in outline in Fig. 6, where it profits by the cooling effects of the entering gases.

In the twin tandem, double-crank engine shown, the cranks are placed at 90 degrees, giving four impulses per revolution, and a crank effect corresponding to that of the cross-compound, double-acting steam engine.

Using a mixture of gas and air of unvarying quality initially proportioned according to the nature of the gas used, and increasing or decreasing the quantity by the governor according to the load, obviously necessitates variable compression, but the builders state that the difference in theoretical economy due to the lower compression at light loads is more than compensated for by maintaining the mixture of gas and air constant in the best proportion for perfect combustion.

The pressures usually obtained with natural gas are approximately 350 lbs. explosion pressure, 120 lbs. compression pressure, and 30 lbs. exhaust. This exhaust pressure at full load is comparatively low and decreases in proportion as the load falls off, so that the necessity for elaborate mufflers is obviated.

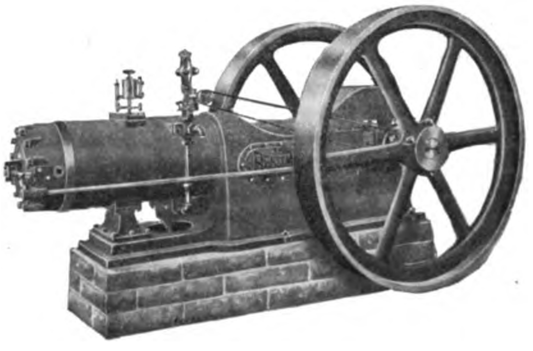

FIG. 9.—BESSEMER GAS ENGINE.

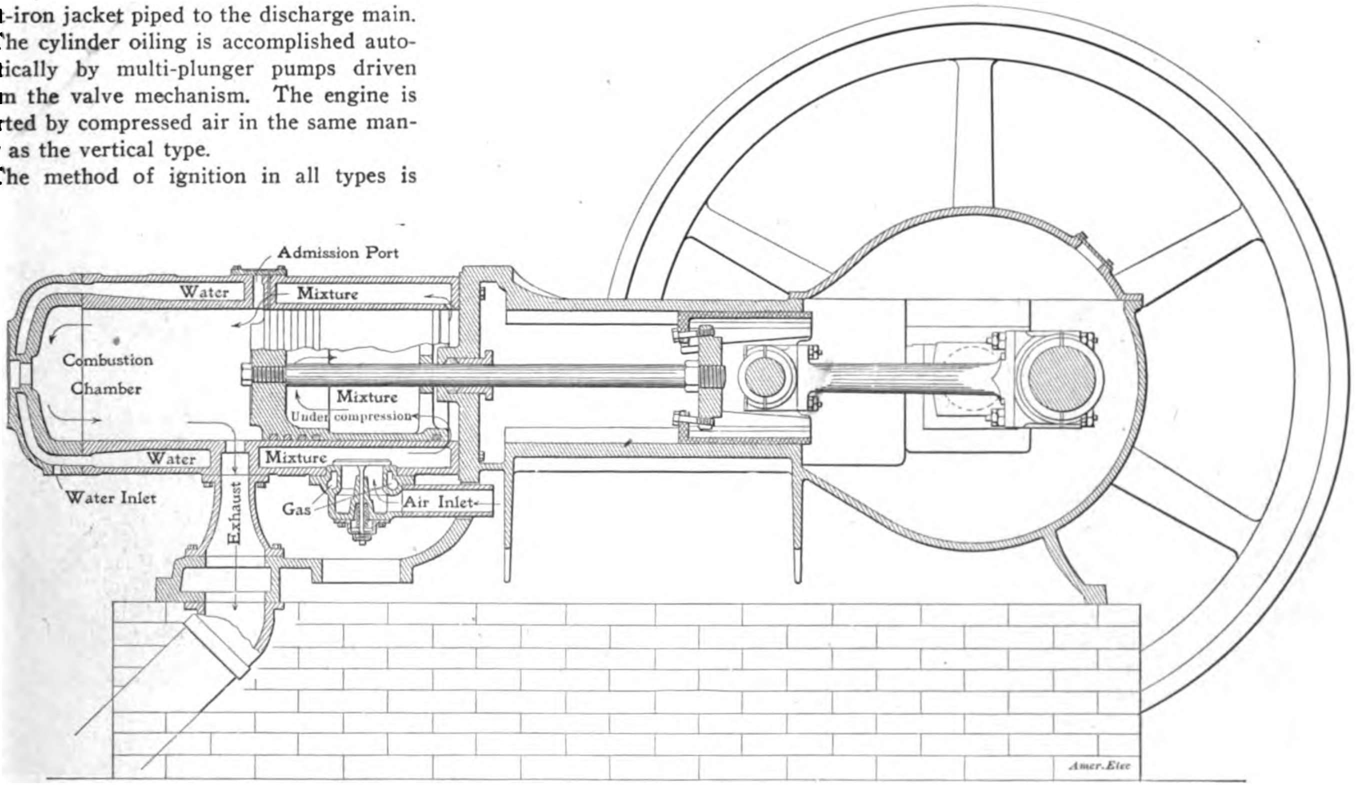

FIG. 10.—SECTIONAL ELEVATION OF BESSEMER GAS ENGINE.

The Bessemer gas engine, illustrated by Figs. 9 and 10 is a compact two-stroke cycle machine of the type referred to in an earlier paragraph. The front part of the cylinder is a pump and receiver for the combustible mixture; the admission port is in the top side of the cylinder and the exhaust port is in the bottom side, both being covered and uncovered by the piston. Starting from the position of parts shown in Fig. 10, the cycle is as follows:

A charge having just been admitted to the working cylinder from the receiver in front of the piston, as indicated by the arrow in the admission port, the piston is carried back towards the cylinder head, closing the admission and exhaust ports and compressing the charge behind it; at the same time it draws gas and air into the receiver end of the cylinder structure through the single poppet valve beneath the cylinder, the valve being lifted by atmospheric pressure. When the piston reaches the end of its stroke the compressed charge behind it is fired, and as it is driven forward it compresses the receiver charge in front of it. It uncovers the exhaust port before it reaches the admission port, and when the latter is passed, the slightly compressed mixture in the receiver rushes into the cylinder and is deflected toward the rear by the curved recess in the piston head so as to prevent it from passing straight across to the exhaust outlet.

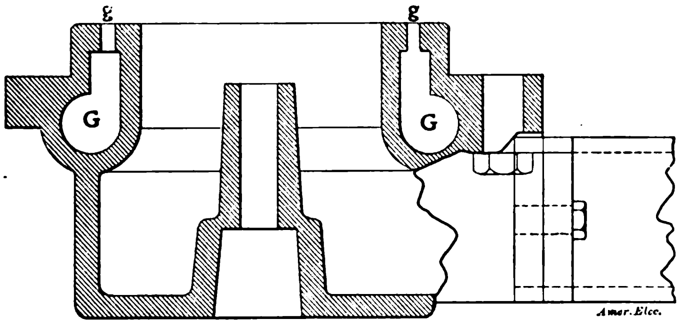

FIG. 11.—DETAIL OF BESSEMER INTAKE VALVE.

The one valve on the engine controls the delivery of both gas and air to the mixing and receiver chamber; gas is delivered to an annular chamber, *G*, Fig. 11, in the valve casing, whence it escapes through small holes *g*, when the valve is raised by atmospheric pressure through the air inlet. Governing is accomplished by throttling the supply of gas and thereby varying the quality of the mixture. Ignition is electric, the igniter mechanism being actuated by a small secondary shaft shown lying parallel with the cylinder and bed in Fig. 9. These engines are built by the Bessemer Gas Engine Company, Grove City, Pa. The single-cylinder engines are built up to 75 horse-power, and double-cylinder engines up to double that output, of course.

A compact two-stroke-cycle engine is also built by the Capital Gas Engine Company, Indianapolis, Ind., but only in small sizes. Fig. 12 is a sectional elevation of this machine, in which *A* is the inlet valve for the receiver; *T* is a throttle valve controlling the quantity of mixture passed through the admission port when it is uncovered by the piston; *D* is a deflector plate on the piston head for directing the incoming charge to the upper part of the cylinder, and *E* is the exhaust port. The operation of the engine is similar to that of the Bessemer engine just described. The exceptions are that the crank chamber serves as the receiver, no cross-head is used (the engine being built for small outputs), and the igniter is actuated by a pin, *p*, set in the piston head, so that no secondary shaft is required. A relief cock is screwed into the opening *R*. The throttle, *T*, is controlled by a flyball governor mounted on the main shaft. *G* represents a sight-feed for gasoline when that is used as fuel. This little engine is known as the "Hoosier."

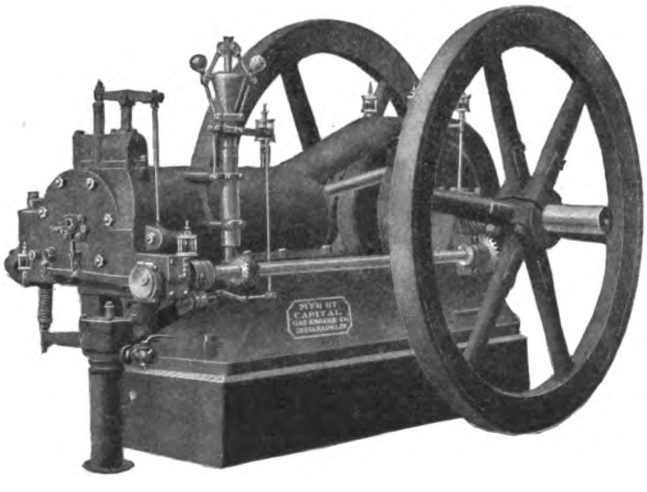

FIG. 13.—CAPITAL GAS ENGINE.

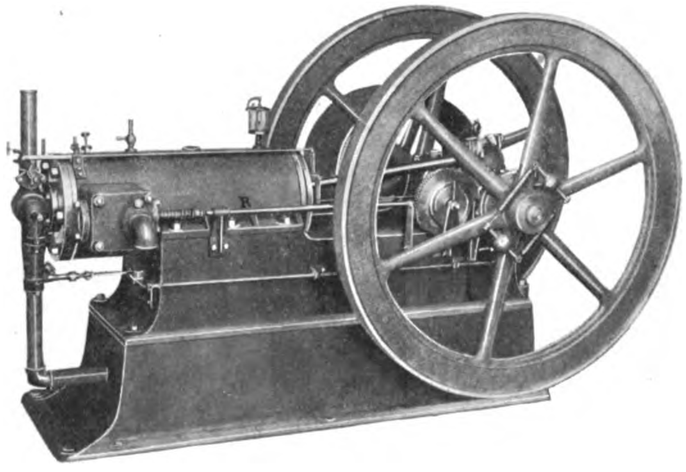

FIG. 15.—CHARTER GAS ENGINE.

The chief product of the Capital Company, however, is a four-stroke-cycle engine of the horizontal type, which is built in sizes up to 150 horse-power per cylinder; the modifications in the larger sizes are in frame and base construction chiefly. As Fig. 13 shows, the secondary shaft, characteristic of all four-stroke engines, is driven through helical gears from the main shaft and drives the governor through similar gears. Regulation is by throttling of the complete mixture; a butterfly valve in the delivery passage is operated by the governor to this end. Fig. 14 shows the arrangement of this valve and the other valves of the engine. The gas and air are mixed in the chamber marked "Mixer," and the butterfly valve *B* controls the passage of the mixture to the admission valve *A*, which is opened by a cam on the secondary shaft *S* and seated by a spring, as usual. The exhaust valve, *E*, is similarly opened and closed. The igniter plug is set into the center of the cylinder head, where it is swept by the entering charge; the igniter is operated by an eccentric on the end of the secondary shaft, as shown in Fig. 13. Capital engines are also built with "hit-and-miss" regulation.

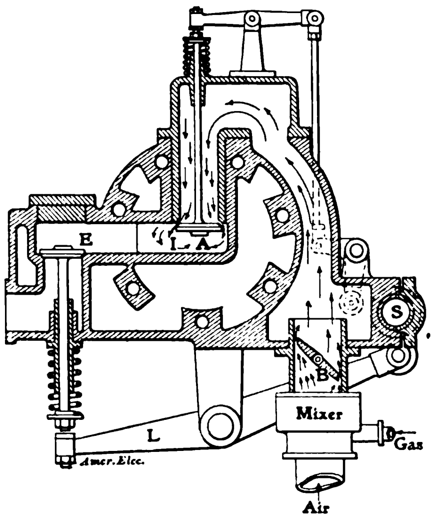

FIG. 14.—VALVES OF CAPITAL GAS ENGINE.

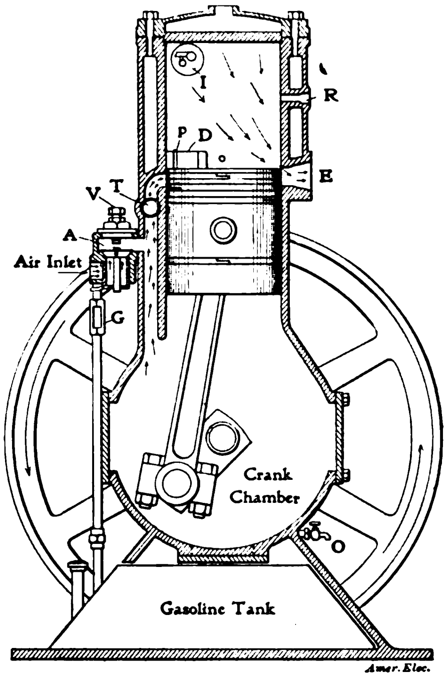

FIG. 12.—HOOSIER GAS ENGINE.

The Charter engine, Fig. 15, is of the hit-and-miss four-stroke-cycle class. It embodies the somewhat unusual features of a shaft governor and a very short secondary shaft lying parallel with the crank shaft. The missing of a charge when the speed is excessive is accomplished by cutting off the supply of gas and allowing the cylinder to be filled with air only, during the suction or charging stroke. The gas valve is actuated by the small rod shown parallel with the base of the engine in Fig. 15, and indicated by *r* in Fig. 16. The end of this rod near the shaft carries a thin blade of steel, the end of which is normally in alignment with the end of a rocking lever which is moved to and fro by a cam on the secondary shaft. The lever strikes the end of the blade and pushes the gas valve open regularly so long as the speed is normal; an increase of speed causes the governor to swing the end of the valve rod to one side just enough to cause the lever to miss the end of the thin blade carried by the valve rod, thereby allowing the gas valve to remain closed.

The rod *R*, Figs. 15 and 16, opens the exhaust valve and is actuated by a cam on the short secondary shaft, of course. The admission or intake valve *I*, Fig. 16, is opened by atmospheric pressure from without when the piston goes forward and creates a partial vacuum behind it after the exhaust stroke of the preceding cycle has been completed. Ignition is usually electric, although the Bunsen tube is furnished when desired. Firing is accomplished by means of an individual rod lying along the top of the cylinder (see Fig. 15) and reciprocated by a cam on the secondary shaft. The Charter engines are built by the Charter Gas Engine Company, Sterling, Ill.; they are fitted to use gasoline as fuel when desired.

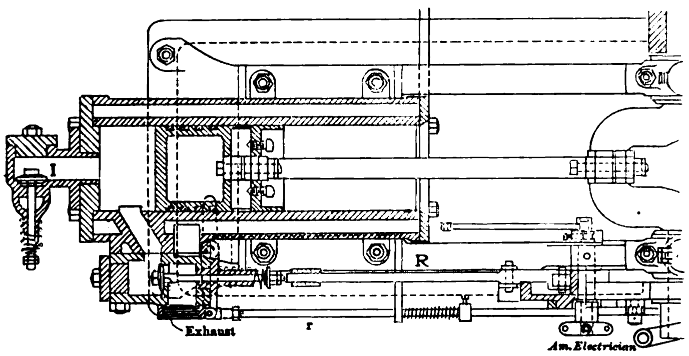

FIG. 16.—DETAILS OF CHARTER ENGINE.

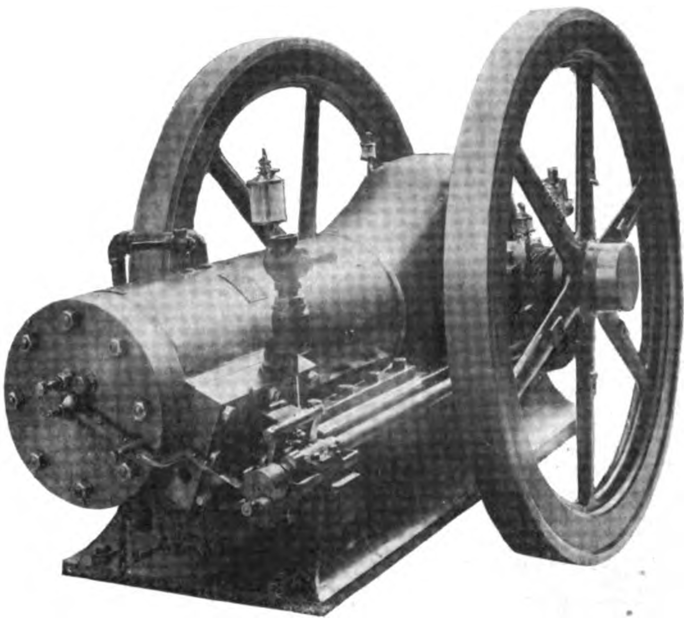

FIG. 17.—FAIRBANKS GAS ENGINE.

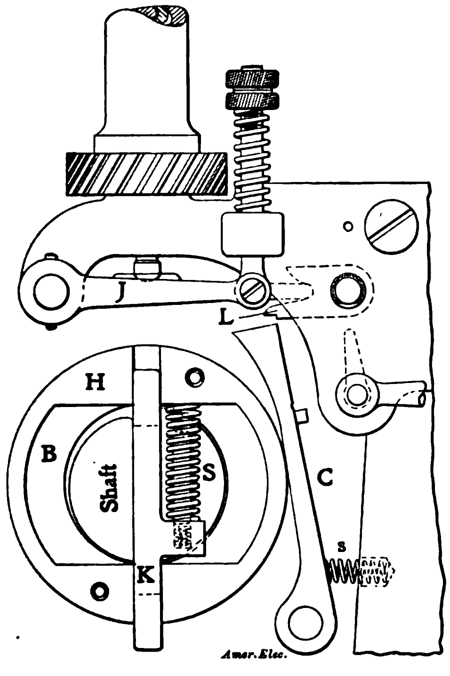

FIG. 19.—DETAILS OF FAIRBANKS GOVERNOR.

An engine of the "hit-and-miss" class which embodies several notable features of recent design is the Fairbanks machine, shown in perspective by Fig. 17. Both the admission and the exhaust valves are positively opened by cams on the secondary shaft and seated by helical springs; they are of the poppet type, as usual. Both valves are mounted in a single chest bolted to the side of the cylinder, and the chest, valves and tappets are all removable, together with the mixing chamber and gas valve, as indicated by Fig. 18, which shows this group of parts. The tappets are interposed between the valve stems and the cams on the secondary shaft for the purpose of obviating the side thrust on the valve stems which is unavoidable when the cams impinge against the valve-stem heads. The left-hand tappet in Fig. 18 opens the admission valve and also the gas valve, located in the mixing chamber bolted to the upper edge of the main valve chest.

The engine is water-cooled, of course, and in order to insure cool, smooth-working valves, the jacket water passes first into the jacket of the valve chest, then around the valves, and thence to the main cylinder jacket.

The engine works on the four-stroke cycle, and the method of omitting an explosion when the speed is excessive is remarkably simple and applied by mechanism just as simple and notably compact. Reference to Figs. 19 and 20 will facilitate the explanation of this apparatus. The head, *H*, mounted on the end of the secondary shaft is driven continuously by helical gears from the crank shaft, and as long as the sliding key *K* remains in the position shown in Fig. 19 the secondary shaft revolves with the head, being driven by the key; the spring *S* tends to hold the key in the operative position shown. A lever cam, *C*, is normally pressed lightly against the periphery of the head *H* by the spring *s*; this latter spring is much weaker than the spring *S*, so that when the projecting end of the key *K* comes around to the point of contact between the head *H* and the cam *C*, it knocks the latter away and continues to hold the secondary shaft locked to the revolving head *H*. When the speed exceeds the normal rate for which the governor is adjusted, the outward movement of the governor balls depresses the central spindle and thereby forces the end of the lever *J* downward; the latch *L* is thereby lowered until it catches the upper end of the lever cam *C*; when the end of the key *K* next comes around to the cam lever it is pressed inward by the face of the cam and the secondary shaft is thereby released and consequently it stops revolving. The key is mounted in a block, *B*, on the end of the secondary shaft, so that it stops with the shaft and keeps the latter unlocked from the revolving head as long as the cam *C* is held against it by the latch *L*. When the secondary shaft is in this arrested position, the exhaust valve is wide open and the gas and admission valves are closed, of course, so that the piston simply draws in air through the exhaust port and drives it out again until the speed falls enough for the governor to release the latch *L*. The rate of speed is adjusted by adjusting the tension of the spring which tends to draw the end of the arm *J* upward. The mechanism works with remarkable smoothness, sensitiveness and certainty.

The engine shown by Fig. 20 is not of the simple "hit-and-miss" type; it is regulated by a combination of the "hit-and-miss" and the throttling methods. The governor lever, indicated in Fig. 19 by *J*, latches the lever cam *C* directly, and is extended to a bell-crank and reach rod mechanism

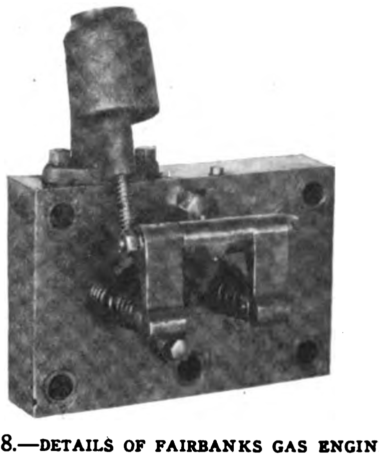

FIG. 18.—DETAILS OF FAIRBANKS GAS ENGINE.

through the medium of which it controls the quantity of fuel admitted to the cylinder, within a certain range. Beyond that range, the "hit-and-miss" mechanism comes into play. This obviously gives a refinement of control which eliminates most of the spasmodic character of the "hit-and-miss" method alone.

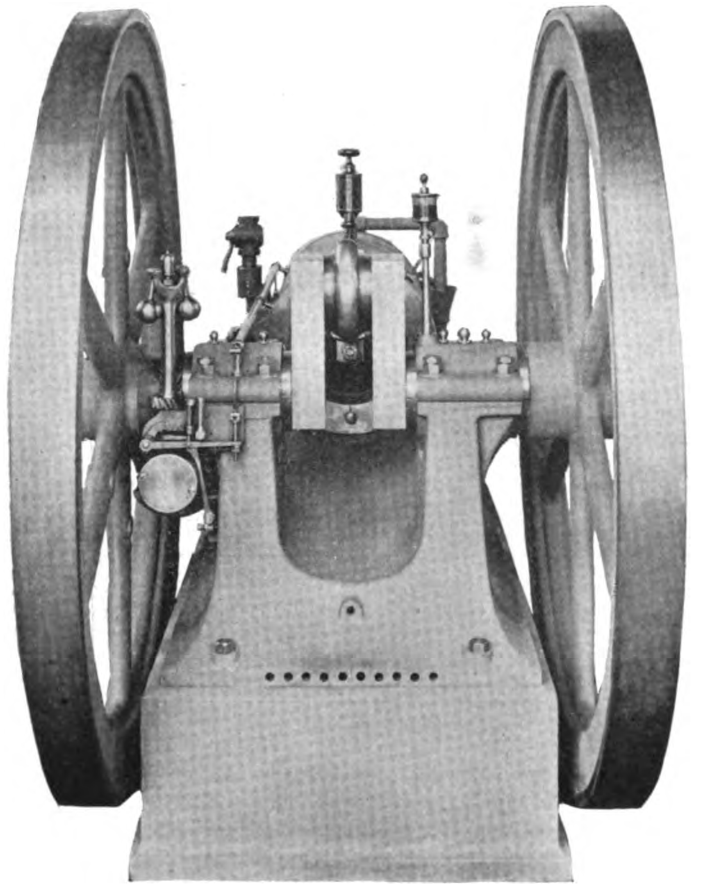

FIG. 20.—END VIEW OF FAIRBANKS GAS ENGINE.

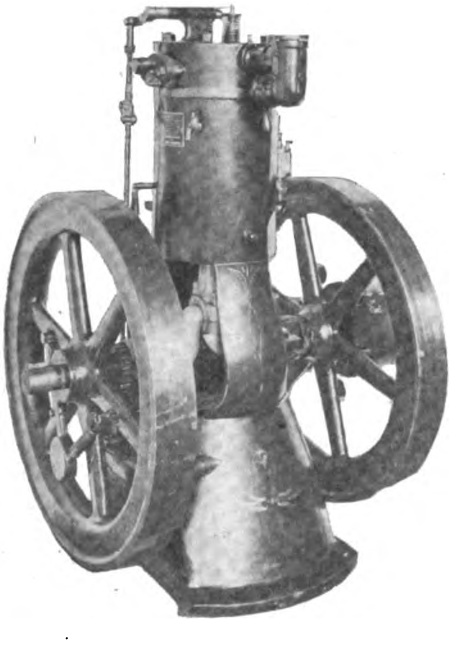

FIG. 21.—FAIRBANKS VERTICAL GAS ENGINE.

Fig. 21 illustrates the vertical engine built by the same company (The Fairbanks Company, New York). The valves are mounted directly in the cylinder head, and the method of regulation is practically the same as that described in connection with the "hit-and-miss" horizontal engine, though the mechanism is different. A shaft governor is employed, and the secondary shaft is a very short one, parallel with the main shaft, as in the case of the Charter engine. A cam on the secondary shaft pulls the valve rod downward through the medium of a rocker-arm and a helical spring, the upper end of which shows just above the near flywheel rim, pulls it upward. When the rod is in the lowest position the exhaust valve is open, and when the speed exceeds the normal, a cam controlled by the governor catches the valve rod rocker-arm and holds it down until the cam on the secondary shaft comes around again. The rocker-arm on top of the cylinder serves to actuate both the admision and the exhaust valves.

The ignition is electric on all of these engines. The vertical engines are equipped with the usual form of make and break igniter, and the igniter arm is caught by a latch on the valve rod. The igniter mechanism used on the horizontal engines, however, is new and highly ingenious. It is the Goodson magneto igniter and spark plug, and is described fully under the head of Igniters farther on in this article.

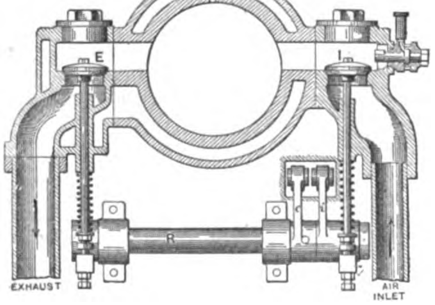

FIG. 24.—VALVES AND VALVE MECHANISM OF FOOS ENGINE.

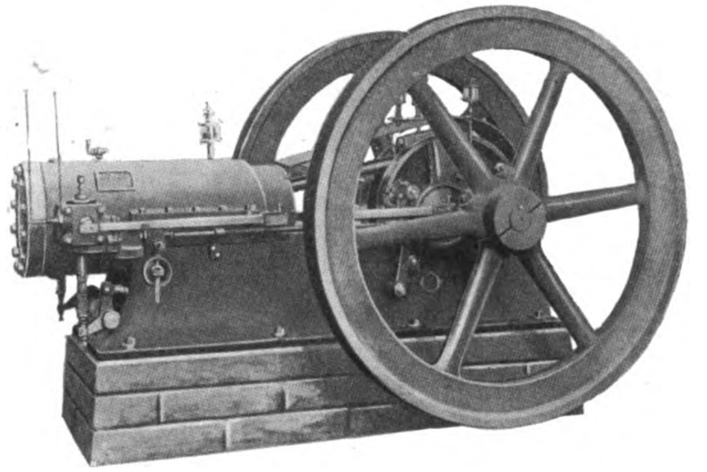

FIG. 22.—FOOS GAS ENGINE.

Another "hit-and-miss" engine having positively opened gas and admission valves is that manufactured by the Foos Gas Engine Company, Springfield, Ohio, and illustrated by Fig. 22. Like the Charter and Fairbanks engines, this one has a short secondary shaft driven by plain spur gears; it operates on the four-stroke cycle. Fig. 23 shows the secondary or cam shaft, and also shows the means for adjusting the time of ignition. The igniter driving rod is driven by a crank-pin set in a disc or plate which is bolted to the gear wheel of the cam shaft, and the bolt holes are arc-shaped slots, so that the igniter crank-disc may be set ahead or backward with relation to the cam shaft, and the ignition thereby made early, normal or late, according to the requirements of the fuel gas used.

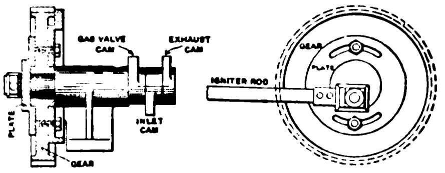

FIG. 23.—SECONDARY SHAFT OF FOOS ENGINE.

The admission and exhaust valves are opened and closed regularly by means of cams, reach rods and rocker-arms, regardless of speed or load, but the governor acts to cut off the supply of gas when the speed exceeds the normal. Fig. 24 shows the ad-

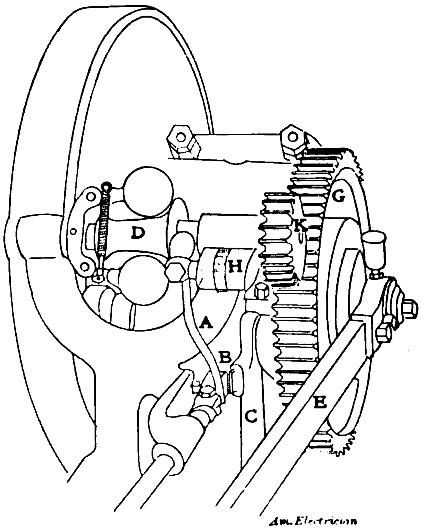

FIG. 25.—DETAILS OF FOOS GOVERNOR.

mission and exhaust valves and the valve mechanism at that end of the engine; the admission valve *I* is opened by the rocker-arm *i*, which is oscillated by a reach rod extending through the engine base to the cam shaft near the main shaft; a cam on the cam shaft (inlet cam, Fig. 23) pushes the reach rod back, and the spring on the valve stem returns it. The exhaust valve mechanism is exactly the same. The gas cam oscillates a rocker-arm, *C* in Fig. 25, the upper end of which carries a "pick" blade which normally engages a block, *B*, pivoted on the end of the gas-valve rod. When the speed exceeds the proper rate, the governor balls slide the spool *D* to the right, and the base of the spool presses against a roller on the upper end of the arm *A*, which is pivoted to the bracket *H;* the lower end of the arm *A* is thrown inward and justifies the pivoted block *B* out of the path of the pick blade on the rocker-arm *C*, so that the gas valve remains closed and the engine takes in air only. This air, however, is taken in through the admission valve and not through the exhaust valve, so that it is pure and therefore highly effective as a scavenging and cooling charge.

The ignition is electric, but the igniter contacts are different from the usual butt contracts; the stationary electrode is a spring and the moving electrode is oscillated by the igniter rod so as to make a wiping contact on the spring electrode and thus maintain clean contact surfaces. The larger sizes of engine are provided with compressed-air starting apparatus.

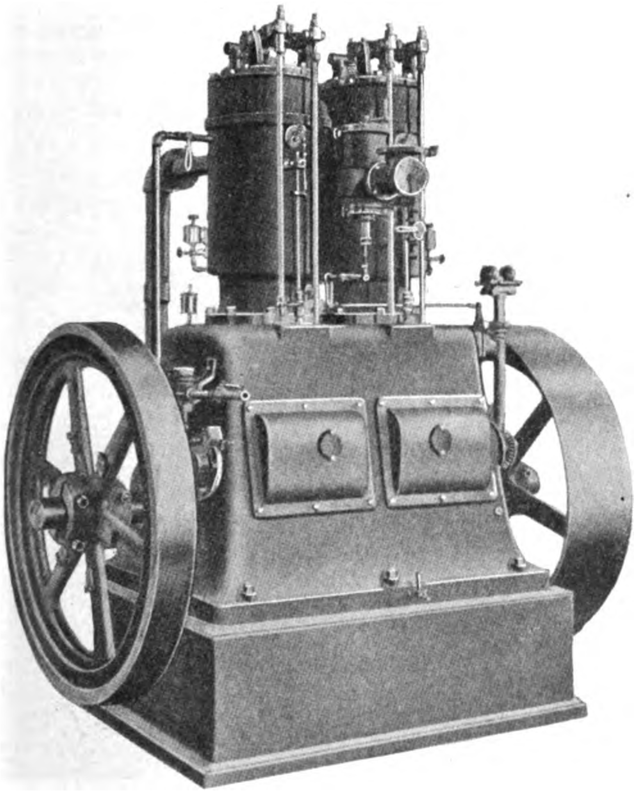

FIG. 26.—TWO-CYLINDER WALRATH GAS ENGINE.

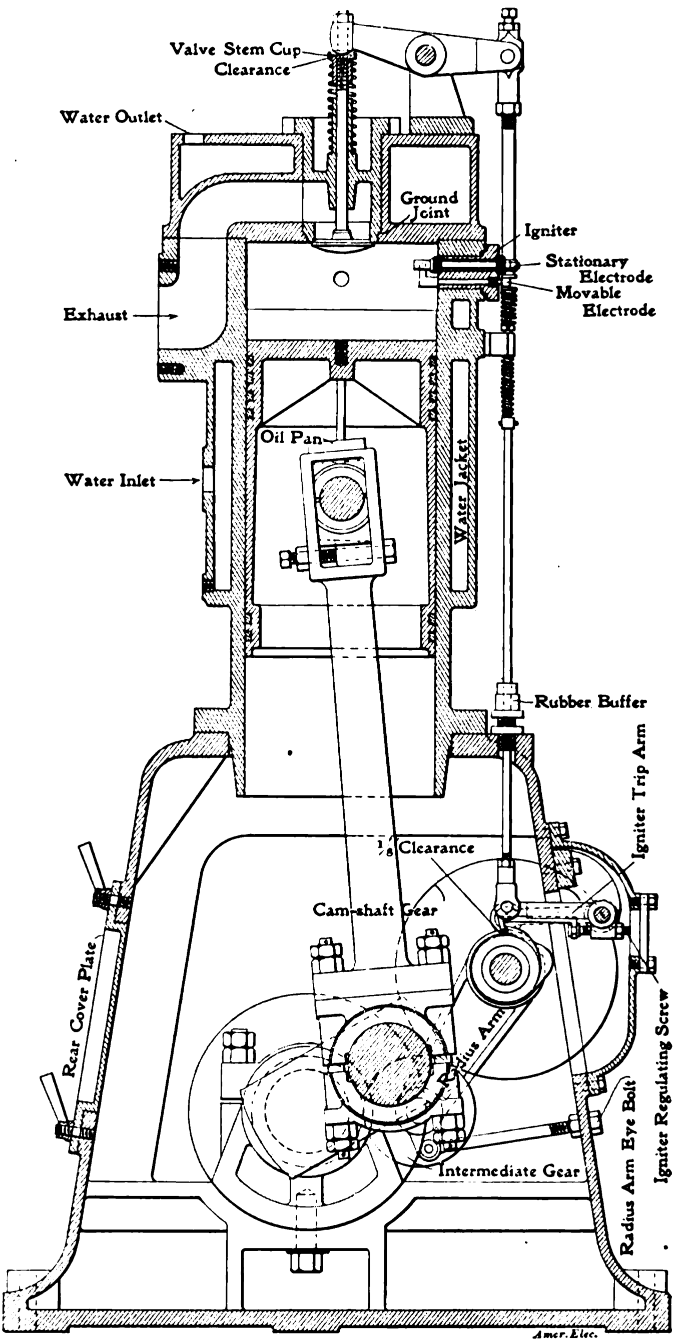

FIG. 27.—SECTIONAL ELEVATION OF WALRATH GAS ENGINE.

The Marinette Iron Works Manufacturing Company, Marinette, Wis., builds only vertical engines, operated on the four-stroke cycle. These are known as "Walrath" engines, and are built with one, two and three cylinders, according to the output. Fig. 26 shows a two-cylinder 60-h.p. engine, and Fig. 27 is a sectional elevation of one cylinder and its mechanism. The admission and exhaust valves are positively opened by means of vertical reach rods and cams on the secondary shaft; the latter is located within the crank housing, as shown by Fig. 27, and is driven through an intermediate gear journaled in the end of a swinging arm which the makers term a "radius" arm. By adjusting the nuts on the end of the "radius" arm eyebolt (Fig. 27) the meshing of the gears may be made as snug as desired, or the cam shaft may be disengaged from the main shaft entirely and its static position adjusted with relation to that of the main shaft.

The igniter is of the electric type and is actuated by an individual rod which is raised and lowered through the medium of a rocker-arm designated the "igniter trip arm." This is adjustable, as indicated in Fig. 27, so that the time of ignition may be regulated.

The governor controls a throttle valve between the mixing chamber and the admission valve-chamber which regulates the quantity of explosive mixture admitted to the cylinder. The mixing chamber and governor linkage are clearly shown in Fig. 26. The proportion of gas to air is adjustable, of course; a single valve in the mixing chamber determines the quality of mixture. As the illustration indicates, only one mixing chamber and valve are used on the two-cylinder engine; two are used on the three-cylinder engines.

The horizontal engine of the New Era Iron Works Company, Dayton, Ohio, is of the "hit-and-miss" class. A general view of the engine is given by Fig. 28, from which it will be noticed that the valve-gear is particularly compact. The familiar cam shaft parallel with the bed is employed, and this actuates the exhaust valve admission valve and igniter. The governor controls the gas valve so as to keep it closed when the speed exceeds the normal. The igniter is operated by means of a spring arm in the path of a cam on the secondary shaft, shown as in Fig. 29. Fig. 30 is a sectional view of the admission valve chamber and mixing chamber; the right-hand valve controls the admission of gas into the mixing chamber at the bottom and the left-hand valve admits the mixture to the cylinder when it is opened by the cam on the cam shaft. The gas valve here shown is the one controlled by the governor.

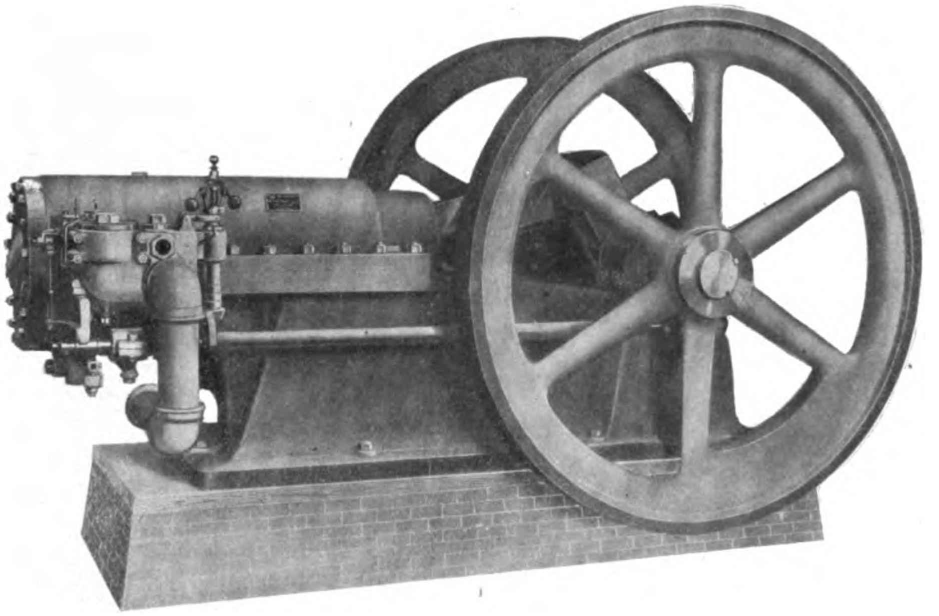

FIG. 28.—NEW ERA GAS ENGINE.

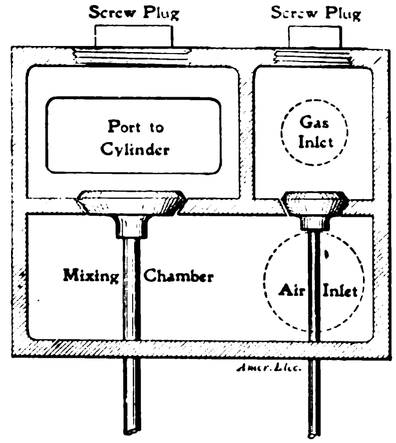

FIG. 30.—VALVE CHAMBERS OF NEW ERA ENGINE.

This engine has the unusual feature of two exhaust ports, one of which is uncovered by the piston just before the cam shaft opens the exhaust valve at the head of the cylinder. This relieves the pressure in the cylinder so that the exhaust valve mechanism has much less work to do than if the valve had to be opened against the full terminal pressure in the cylinder. The main exhaust port is connected to the exhaust-valve chamber by means of an external piece of pipe, as shown in Fig. 31, where *B* is the exhaust-valve rocker-arm; *C*, the exhaust-valve chamber; *D*, the connecting pipe, and *E*, the outlet of the main exhaust port.

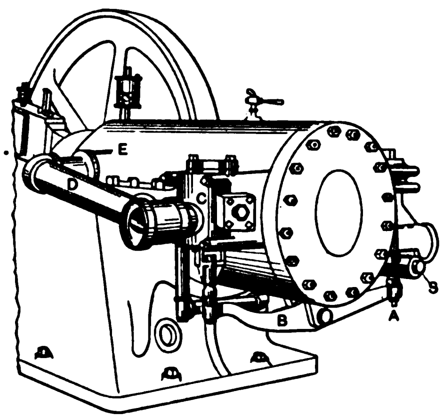

FIG. 31.—EXHAUST SIDE OF NEW ERA ENGINE.

The New Era Company has added to its line a comparatively new line of vertical throttling engines, the 50-h.p. size of which is illustrated by Fig. 32. Fig. 33 is a sectional elevation showing the arrangement of the cylinders and valves. Both the admission valves, *A*, *A*, and the exhaust valves, *E*. *E*, are opened by cams and rocker-arms and closed by springs. The cam shaft is mounted in bearings bolted to the sides of the cylinder heads and is driven by a vertical shaft through bevel gears; this latter shaft is shown to the left in Fig. 32. The governor is mounted opposite the space between the cylinders, and is driven from the cam shaft, as shown. It is located here in order to control the valve in the mixing chamber more directly than it could if mounted near or on the vertical lay shaft. The mixing chamber is on the opposite side of the engine, and a lever extends from the governor straight to the throttle valve stem, being pivoted on a support between the cylinders; this pivot is shown at *F* in Fig. 33.

The vertical engines are provided with an auxiliary exhaust port connected to the main exhaust outlet, exactly as in the horizontal engines. The connecting pipes are shown in Figs. 32 and 33.

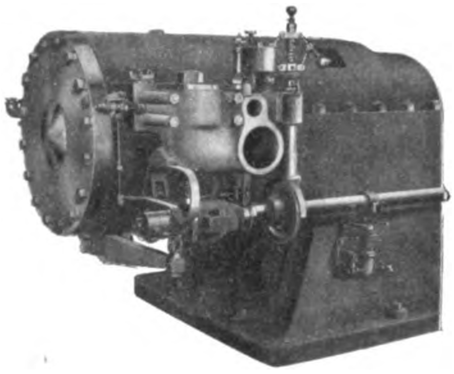

FIG. 29.—DETAIL VIEW OF NEW ERA GEAR.

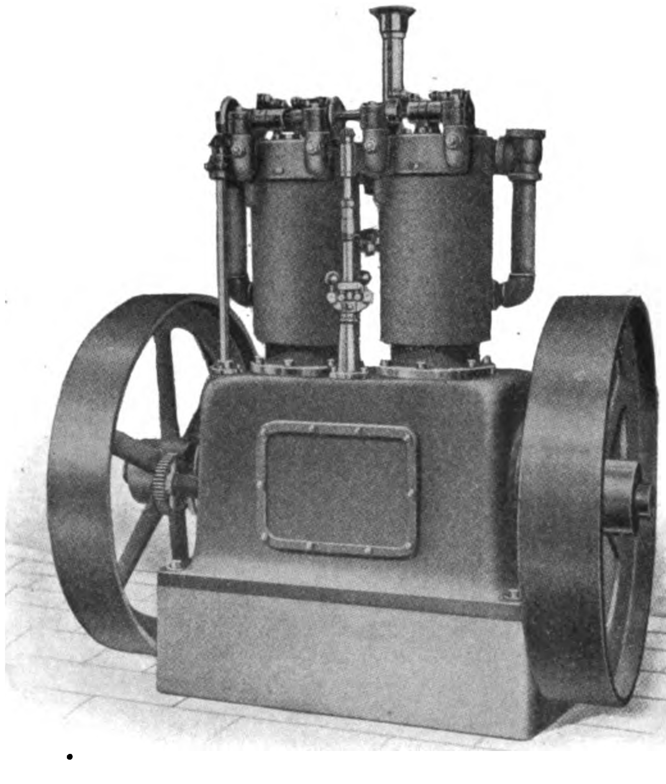

FIG. 32.—NEW ERA TWO- CYLINDER VERTICAL ENGINE.

The engine illustrated by Fig. 34 is that of the Olds Gasoline Engine Works, Lansing, Mich. Notwithstanding the name of the company, the engine here described is built to operate with gas as fuel; the same engine is adapted to use gasoline by merely adding a gasoline pump and connecting pipes and omitting the gas valve and its connection. The Olds engine is of the "hit-and-miss" type, and regulates by holding the exhaust valve open when an explosion is to be missed. The valve mechanism is unique. No secondary or cam shaft is used, although the engine works on the four-stroke cycle. A slide is reciprocated directly from the main shaft, and it carries a star-shaped cam wheel, *C*, Fig. 35, which is rotated by a pawl, *P*, pivoted on a stationary part of the engine. This action causes a tooth of the cam wheel to be brought opposite the nose, *n*, of the exhaust valve stem during one backward stroke of the slide, and a space between two teeth to be brought opposite the nose during the next backward stroke of the slide, the wheel being shifted by the pawl during each forward stroke of the slide. Consequently, the exhaust valve is opened once in every four strokes, or two revolutions, of the engine, so long as the speed remains normal or less than normal. Should the speed rise beyond normal, the governor throws the spring finger *f* inward, pushing the latch button *b* into the path of a collar, *c*, on the end of the exhaust valve stem and preventing the valve from closing after the star wheel has opened it. The relation of the button *b* to the collar *c* is more clearly shown by Fig. 36, which shows the relative positions of the valve-stem nose, the button *b*, and a tooth *C* of the cam wheel when the valve is closed; Fig. 37 shows the positions of these parts when the valve is open. Fig. 38 is a plan view of the mechanism.

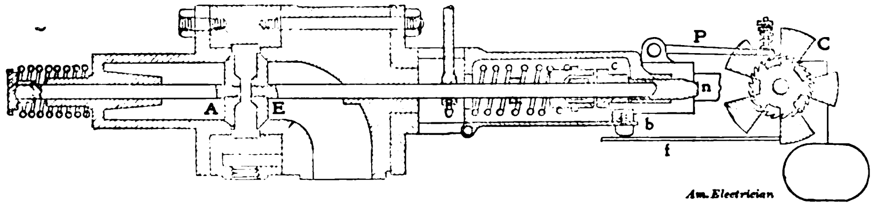

FIG. 35.—DETAILS OF OLDS GOVERNOR MECHANISM.

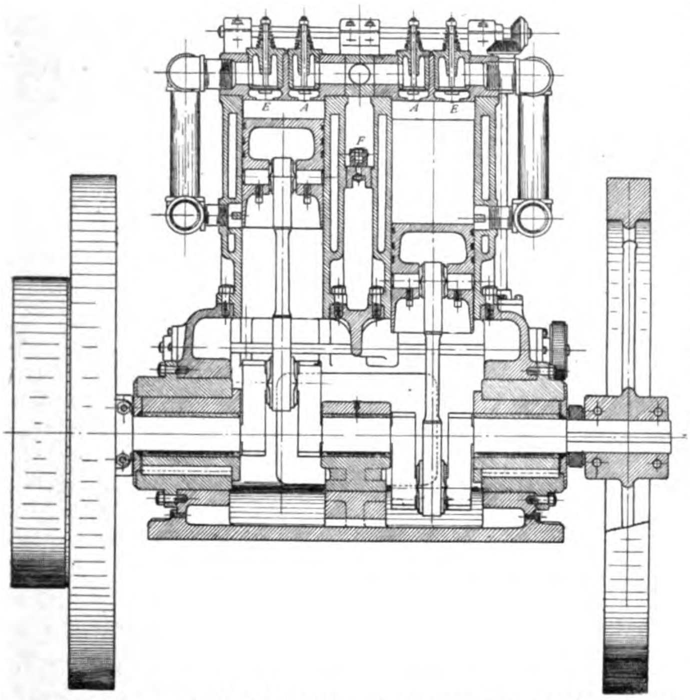

FIG. 33.—SECTIONAL ELEVATION OF NEW ERA VERTICAL ENGINE.

The Otto engine, illustrated by Fig. 39, is one of the oldest gas engines built. It is manufactured in this country by The Otto Gas Engine Works, Philadelphia, Pa., in sizes up to 140 horse-power in a single cylinder, and is of the "hit-and-miss" type. The admission valve, *A*, Fig. 40, is opened by atmospheric pressure and a gas valve which delivers gas to the passage *G* is opened by a cam on the secondary shaft so long as the speed is not above normal. The exhaust valve, *E*, Fig. 40, is opened by the usual rocker-arm and cam, and the igniter, *I*, is actuated by a pin cam and spring finger, as indicated in Fig. 39.

The admission-valve chest is indicated by *B* in Fig. 41, and the gas-valve chest by *H*. The gas valve is opened by the vertical rocker-arm *K*, Figs. 40 and 41, which is on one end of a rock-shaft; on the other end of that shaft is a horizontal rocker-arm carrying at its outer extremity a roller, *r*, which is adapted to slide along its spindle *s* under the control of the governor. When the speed is not above normal, the roller *r* is in the path of the cam *c* on the secondary shaft, and this cam opens the gas valve by raising the roller *r* and with it the end of the rocker-arm on which it is pivoted. Excess of speed causes the governor to slide the roller *r* out of alignment with the cam *c*, allowing the gas valve to be held shut by its spring; the roller *r* is shown in this position in Fig. 41. In the larger sizes, the admission valve is positively opened by means of a cam and rocker-arm, like the exhaust valve. These engines are adapted to use gasoline by making a slight change in the admission valve and providing a pump to deliver the gasoline. Fig. 42 shows the very compact and substantially built gas engine manufactured by the Pierce-Crouch Engine Company, New Brighton, Pa., and known as the Brighton engine. Fig. 43 is a semi-sectional elevation, and Fig. 44 a plan view of the engine.

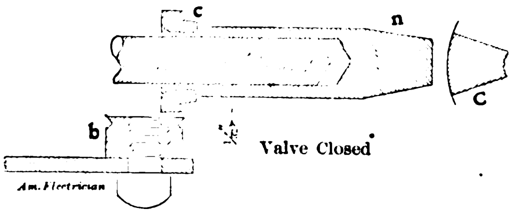

FIG. 36.—DETAILS OF OLDS GEAR.

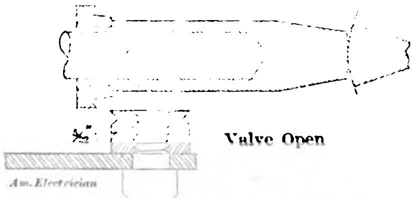

FIG. 37.—DETAILS OF OLDS GEAR.

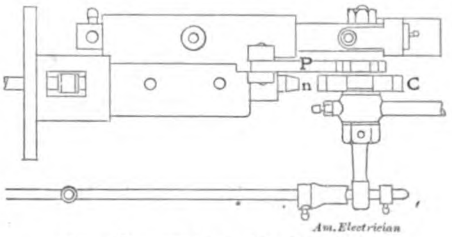

FIG. 38.—DETAILS OF OLDS GEAR.

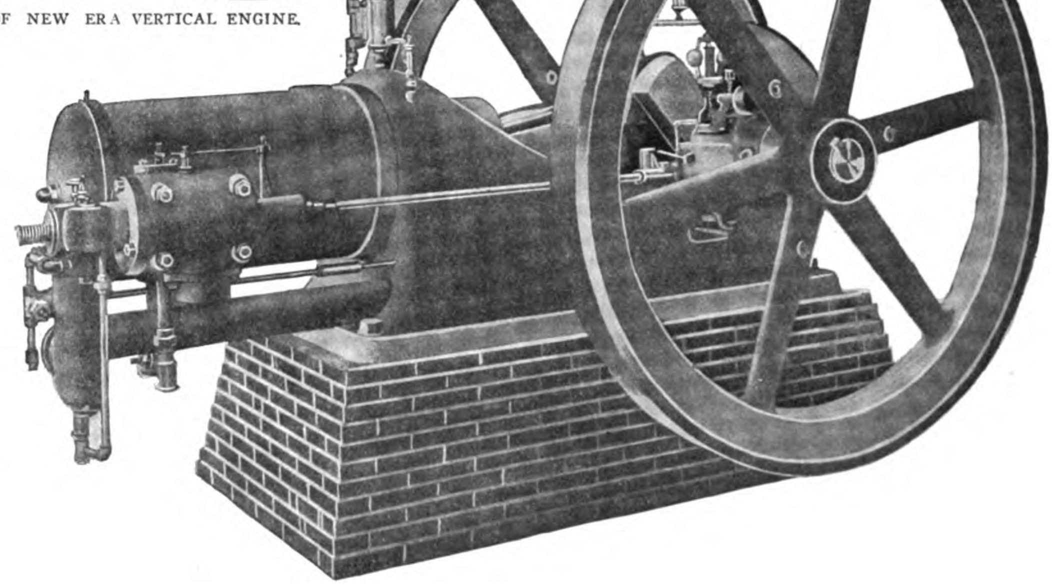

FIG. 34.—OLDS GAS ENGINE.

The engine is of the four-stroke-cycle type. As the first view of the engine shows, it is of very simple and massive construction. The crank-pin discs form the central portions of the flywheels, and the strain between the cylinder and the main bearings is resisted in a straight line by the sides of the engine bed. The bearings are of the self-oiling type, with chain oilers. The crank-pin is oiled through a straight duct of ample size, leading from a circular groove in the hub of one of the flywheels, to which groove oil is supplied by a sight-feed lubricator mounted on the cap of one of the main bearings.

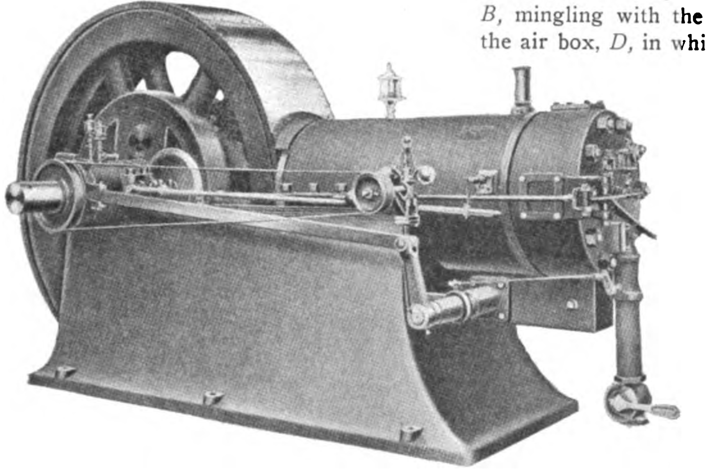

FIG. 42.—BRIGHTON GAS ENGINE.

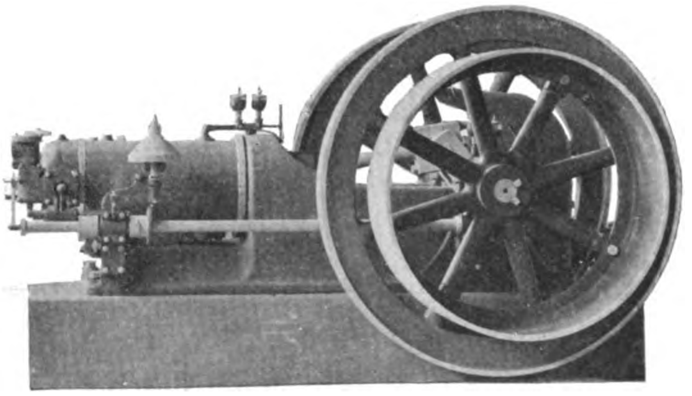

FIG. 39.—OTTO GAS ENGINE.

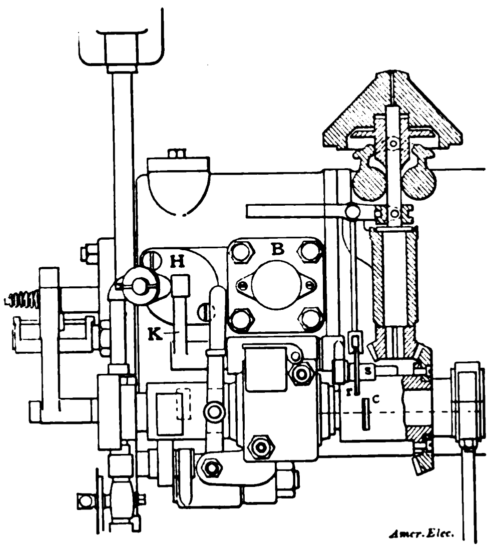

FIG. 41.—VALVE CHESTS OF OTTO GAS ENGINE.

The engine is provided with an auxiliary exhaust port, like the New Era, but the arrangement of valves is very unusual. The poppet valve, *A*, Fig. 45, which is opened by means of a rocker arm, shown in Fig. 44, serves the double purpose of admitting the charge and also releasing a part of the exhaust products. Most of the burned gases pass out through the main exhaust port, which is uncovered by the piston at the end of its forward stroke, as illustrated in Fig. 43. The remainder passes out at the valve, *A*, Fig. 45, and at this moment the piston valve, *C*, is in its lowermost position, so that the gases pass above it to the exhaust pipe. Fig. 45 shows the main piston and the valves during a charging stroke, when gas is admitted by the small poppet valve, *B*, mingling with the air supplied through the air box, *D*, in which the rocker arm, *F*, operates, and passing through the port of the poppet valve, *A*. During the return or compression stroke the valves, *A* and *B*, are, of course, closed, and it is immaterial where the positively-driven valve, *C*, may be. At the proper moment for exhaust, the valve, *C*, is drawn down low enough to connect the exhaust passage with the port of the poppet valve, *A*, and this valve is again opened, releasing that portion of the exhaust gases which did not pass out of the main port uncovered by the piston. The valves, *A* and *C*, therefore, perform the double function of admission and exhaust valves.

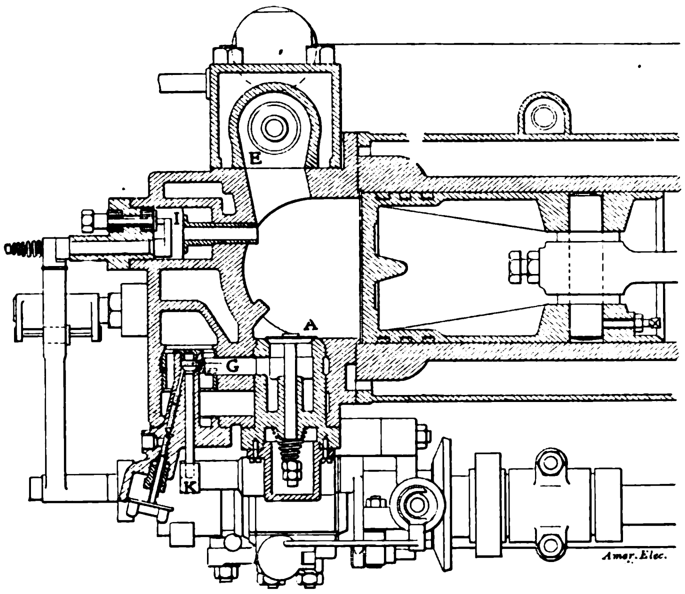

FIG. 40.—DETAILS OF OTTO GAS ENGINE.

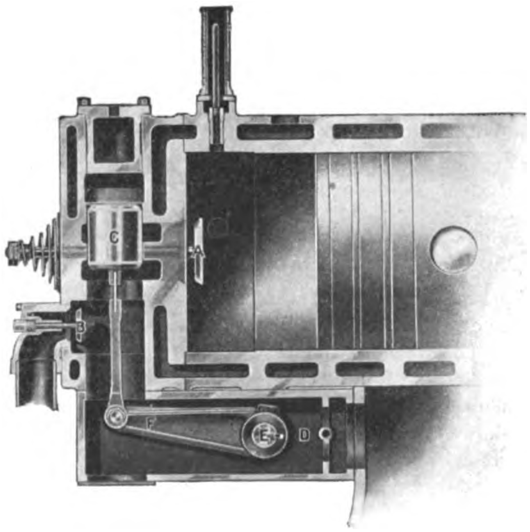

FIG. 45.—CYLINDER HEAD AND AIR BOX OF BRIGHTON GAS ENGINE.

The gas valve, *B*, is opened positively from the secondary shaft against the force of a spring as the piston starts forward on the charging stroke. The poppet valve, *A*, is opened from the same shaft, which is geared to the main shaft in the ratio of 1 to 2, as usual. The rock shaft, *E*, through which the piston valve, *C*, is driven, receives its motion, however, from an eccentric on the main shaft.

The larger sizes of this engine are equipped with either throttling or "hit-and-miss" governors. The "hit-and-miss" governor connects and disconnects the valve rod. The governor is of the ordinary flyball type, arranged to control two balanced butterfly valves, one in the air inlet and the other in the gas inlet. The electric igniter is of the butt contact type, the movable contact within the cylinder being mounted on a spindle to the outer end of which the flat spring, shown in the engraving, is attached. The igniter spindle is rocked by a beveled trip mounted on a reciprocating rod, which receives its motion from the secondary shaft. The ignition points are tipped with iridium. The trip, coming in contact with the spring, throws the points together, and they are snapped apart suddenly by the release of this spring when the trip has passed beyond its reach.

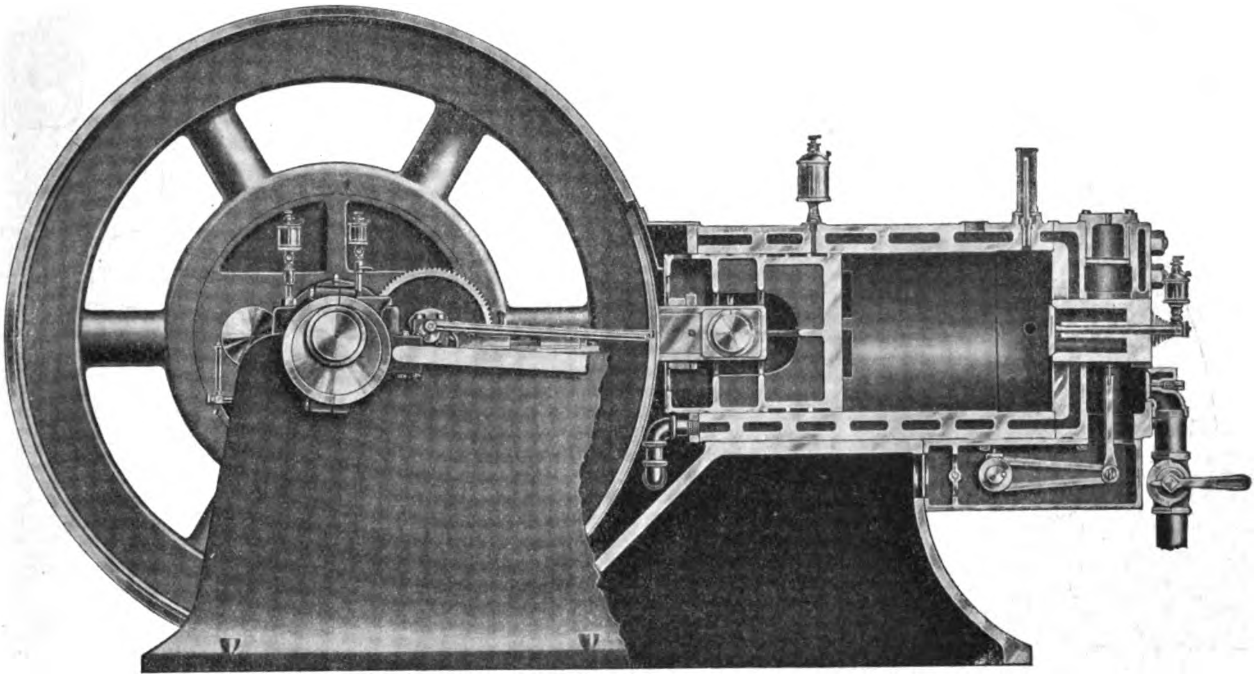

FIG. 43.—VERTICAL LONGITUDINAL SECTION OF THE BRIGHTON GAS ENGINE.

The automatic starting arrangement used in connection with this engine is interesting. The arrangement includes a small storage tank for compressed air, which is connected up to the cylinder of the engine through a special inlet. The pipe connecting the tank with the cylinder is provided with a small cup similar to the old-fashioned lubricator cups used on pumps and plain slide-valve engines many years ago. Before starting, about a spoonful of gasoline is poured into this cup, and the gasoline is delivered into the air-delivery pipe by turning the cock. A throw of the starting valve handle then admits a small quantity of compressed air to the connecting pipe, which vaporizes the gasoline and carries it into the cylinder, where it is ignited, giving the first impulse to the piston. This impulse is sufficiently strong to carry the piston through a complete double stroke, and the engine then begins its regular cycle of operations. One start, it is said, reduces the pressure in the air tank only a few pounds, so that a single filling of the tank suffices for several starts. To restore the pressure in the tank it is only necessary to shut off the gas supply from the engine, open the sealing valve between the cylinder and the pipe leading to the air tank, and raise the starting valve handle. The power stored in the flywheels is sufficient to recharge the air tank to the desired pressure.

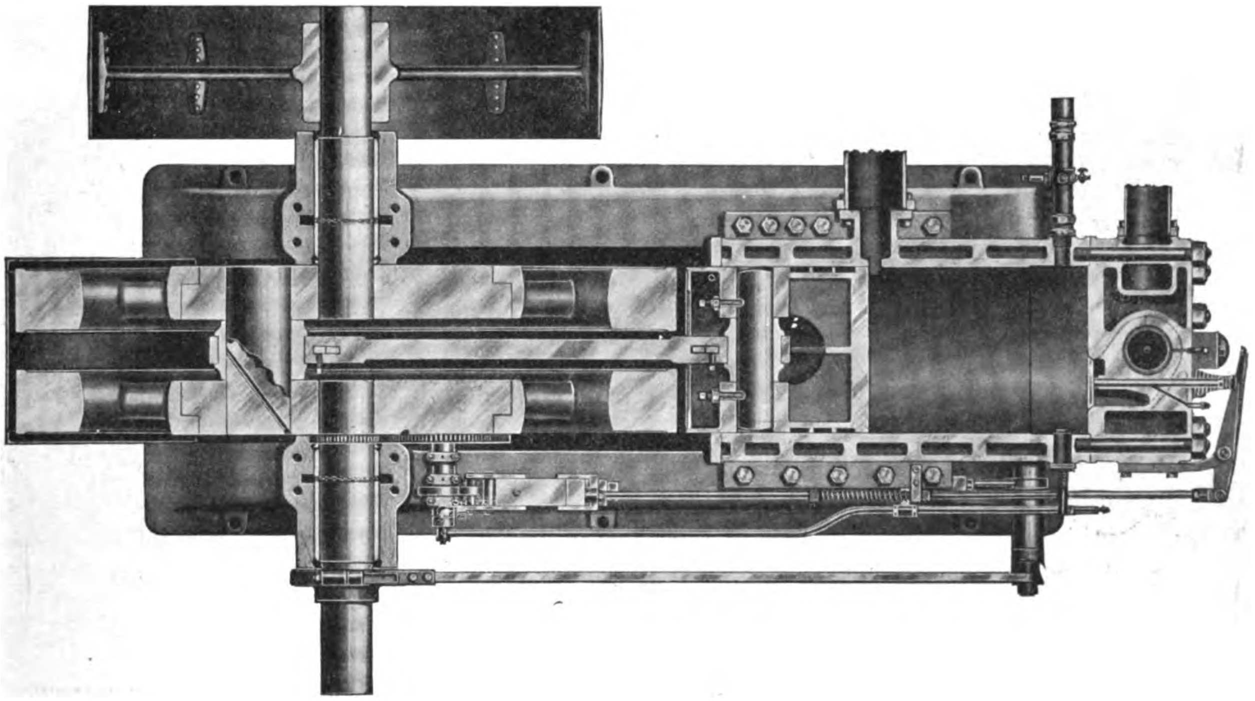

FIG. 44.—HORIZONTAL LONGITUDINAL SECTION OF THE BRIGHTON GAS ENGINE.

These engines are also built with an attachment for operation with gasoline, consisting of an adjustable mixing valve and a small pump operated from the engine shaft. No atomizer or carbureter is used, the gasoline being delivered directly into the engine cylinder.

Fig. 46 gives a rear view of the Advance engine built by the George D. Pohl Manufacturing Company, Vernon, N. Y. It happens that this engraving illustrates an Advance engine equipped for operation with gasoline, but as the only difference is a slight change in the arrangement of the mixer and the addition of the pump, the engraving will apply just as well to the gas engine. This engine is of the throttling class especially adapted for driving electric generators, and it operates on the usual four-stroke cycle. Fig. 47 is a sectional view showing the valve and governor arrangements. The admission valve, *A*, is opened by atmospheric pressure from without when the piston goes forward during the charging stroke; *B* is the starting valve, and *C* the regulating throttle valve controlled by the governor by means of the vertical arm *D* and the linkage, *H*. A detail of this linkage is shown to the right, giving a view of it from the side. The fuel enters through the small pipe, *G*. The exhaust valve, *E*, is opened by a rocker-arm pivoted beneath the cylinder and extending from the secondary shaft across to the exhaust valve stem, as shown in Fig. 46. The spaces marked *J* are, of course, the cooling water chambers, for which *I* is the inlet and *O* the outlet. The end of the secondary shaft is indicated in Fig. 47 by the letter *S*. The governor spindle revolves in a fixed position vertically, the external sleeve, *K*, being drawn up by the governor balls through the medium of the lifting collar, *Z*; the spring, *s*, opposes the action of the governor balls in the usual manner and the adjustment of its tension regulates the speed of the engine.

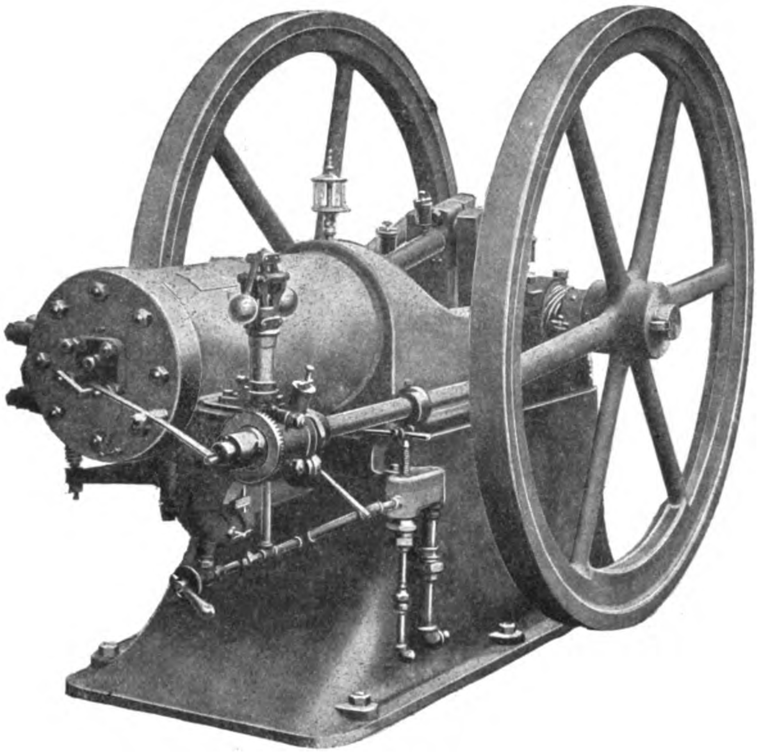

FIG. 46.—ADVANCE GAS ENGINE.

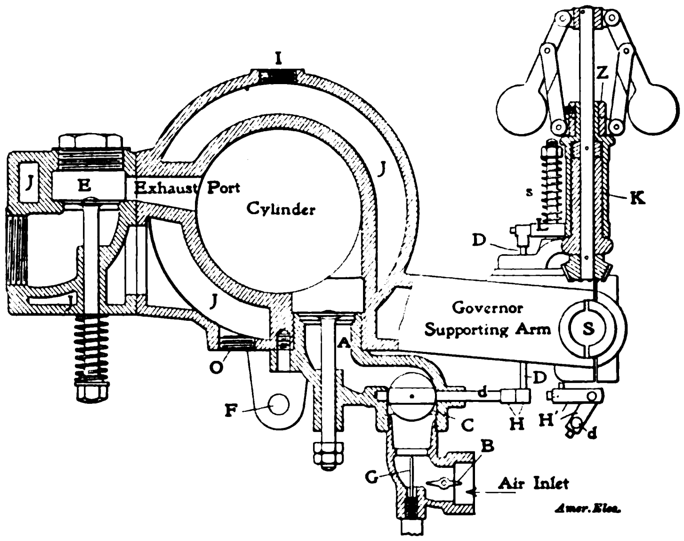

FIG. 47.—VALVE AND GOVERNOR ARRANGEMENT OF ADVANCE GAS ENGINE.

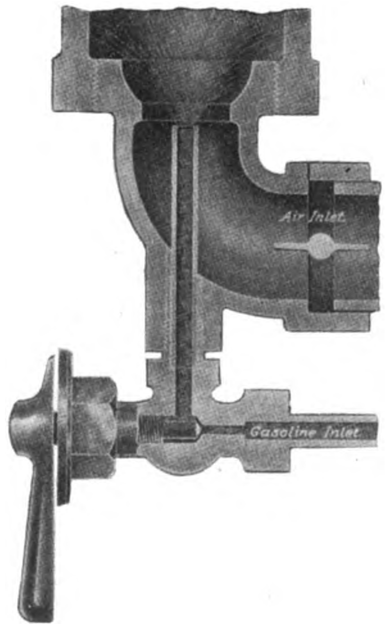

FIG. 49.—ADVANCE MIXER.

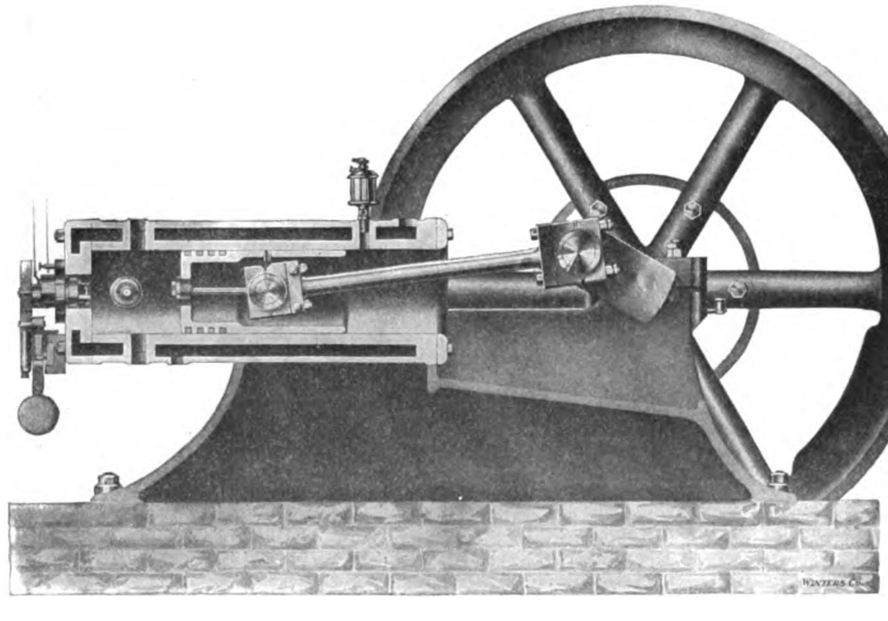

FIG. 50.—VERTICAL SECTION THROUGH CENTER OF SPRINGFIELD ENGINE.

The igniter is actuated by a spring lever and a pin cam on the secondary shaft, as shown in Fig. 46. Fig. 48 gives plan and end views of the igniter plug, which, it will be seen, is very simple and compact. The spring arm just referred to impinges against the pin in the end of the crank-arm mounted on the igniter spindle. The points of the igniter are made of platinum and may be unscrewed and replaced when necessary.

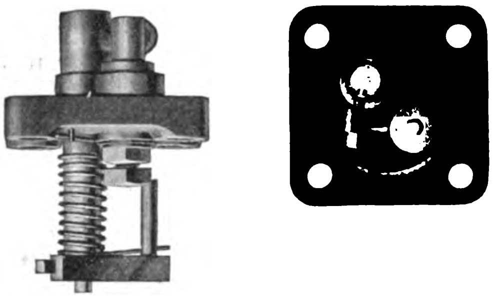

FIG. 48.—ADVANCE IGNITER PLUG.

When gasoline is used as fuel the mixing arrangement illustrated by Fig. 49 is employed. When the engine is at rest the gasoline fills the stand-pipe (which is indicated by *G* in Fig. 47) not quite level with the top, and when the engine is in operation the current of air drawn in by the suction of the piston draws the gasoline out of the stand-pipe in the form of spray. The quantity of gasoline is adjustable, of course, by means of the pin valve shown at the bottom of the mixer, to which it is delivered by the pump shown on the side of the engine base in Fig. 46.

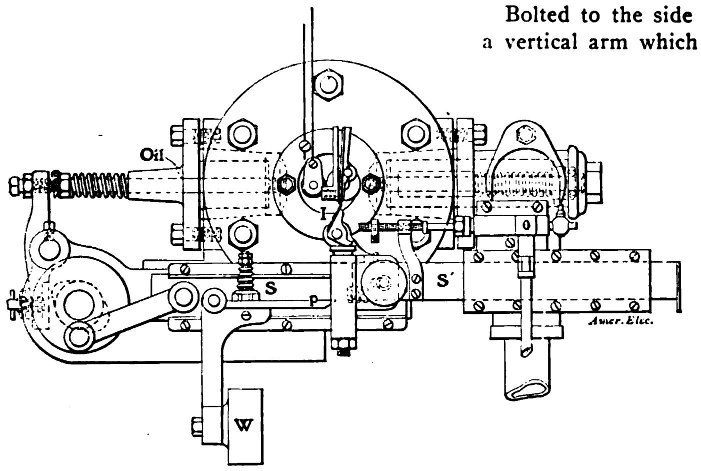

FIG. 52.—DETAILS OF SPRINGFIELD GOVERNOR, IGNITER AND GAS VALVE.

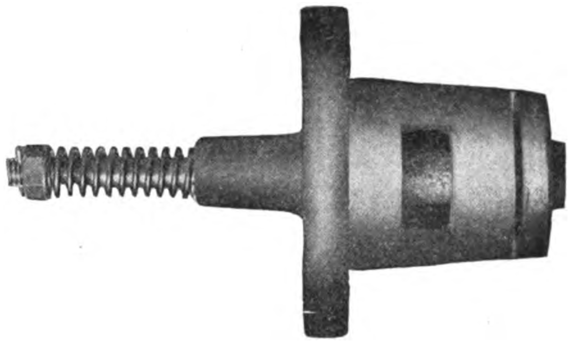

FIG. 53.—SPRINGFIELD VALVE.

The gas engine built by the Springfield Gas Engine Company, Springfield, Ohio, and illustrated by Figs. 50 and 51, is the only one of the group described in this article in which a centrifugal governor is not employed. This engine works on the four-stroke cycle, and is regulated by the "hit-and-miss" method. Fig. 52 is a rear view showing the details of the governor, igniter and fuel valve control, and while this view has a rather complicated appearance at first glance, the mechanism is really very simple.

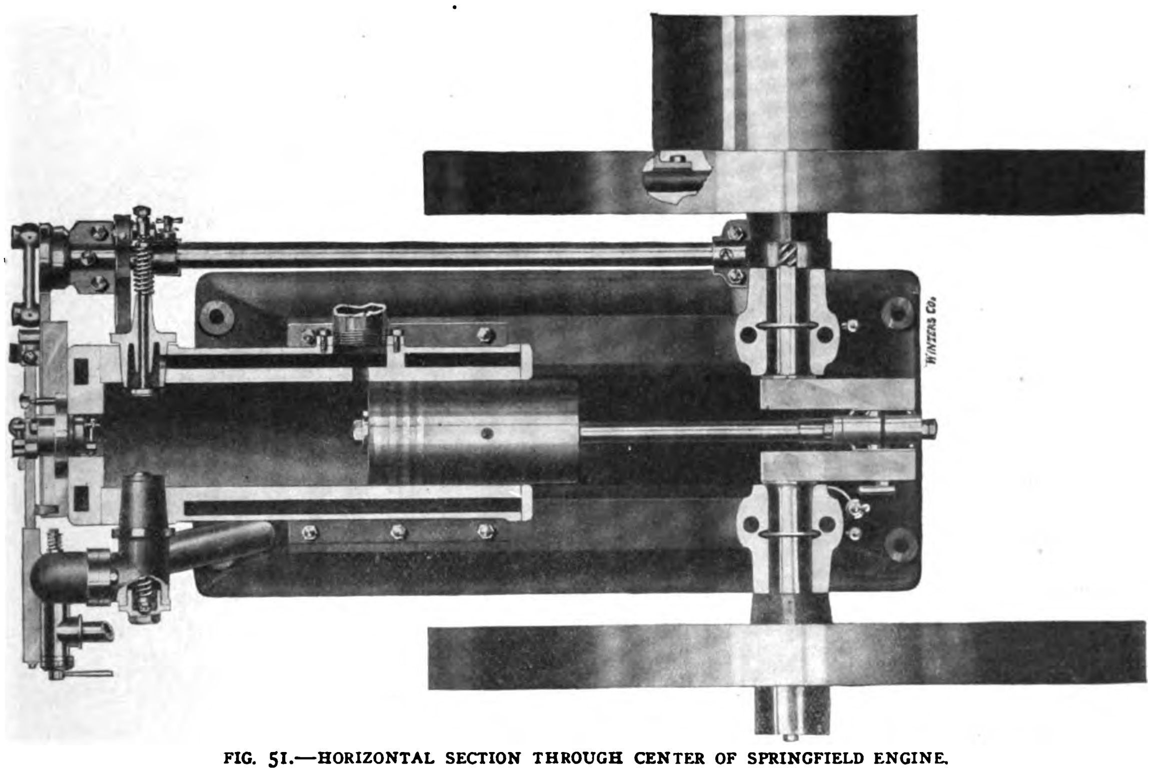

FIG. 51.—HORIZONTAL SECTION THROUGH CENTER OF SPRINGFIELD ENGINE.

The secondary shaft lies on the left-hand side of the engine, as shown in Figs. 51 and 52, and opens the exhaust valve through the medium of a cam and the rocker-arm shown on the extreme left in Fig. 52. On the end of the secondary shaft is a crank-disc; a pitman extends from the crank-pin to a wrist-pin on the slide, *S*. Pivoted on this slide is a bell crank to the vertical arm of which is bolted a weight, *W*, and to the horizontal arm a pick-blade, *p*. The end of this pick-blade is normally in alignment with a buffer block on the slide, *S'*.

Bolted to the side of this second slide is a vertical arm which is shown slightly offset in Fig. 52, and which engages at its upper end with the stem of the gas valve. At normal speed the end of the pick-blade, *p*, engages the buffer block over it, and the slide, *S*, moves to the right so that the slide, *S'* is similarly pushed over in the right-hand direction, opening the gas valve. The mechanism is such that when the slide, *S*, is drawn back by the secondary shaft it pulls the slide, *S'*, back with it. Any increase in speed above the normal rate causes the pick-blade, *p*, to be thrown downward on account of the inertia of the weight, *W*, so that the end of the blade misses the buffer block on the slide, *S'*, and the gas valve remains closed. The helical spring, shown just to the right of the letter *S* in Fig. 52, is for the purpose of adjusting the governor and thereby the rate of speed.

As Fig. 51 clearly shows, the main admission valve is mounted in the side of the cylinder, directly opposite the exhaust valve; it is opened by atmospheric pressure, so that when the governor cuts off the gas the admission valve is opened just the same and pure air admitted to the cylinder. The admission and exhaust valves are mounted in individual casings which are readily removable from the cylinder each in a single unit, as shown by Fig. 53. The valves are of the poppet type, of course, but instead of having beveled faces the faces and seats are flat, their plane being at right angles with the axis of the valve stem. This arrangement was adopted in order to facilitate regrinding and to give a larger area of opening with a given movement of valve. As in the case of two of the engines previously described, the Springfield engine has a second exhaust port near the front end of the cylinder, which is uncovered by the piston, as shown in Fig. 51. The main exhaust outlet is directly opposite this port, so that it is practically the principal exhaust port, rather than an auxiliary one. The port opened by the exhaust valve is more properly an auxiliary exhaust port, its function being merely to allow the residual products of combustion to be swept out by the piston on its back stroke after most of the burning and burnt gases have escaped by means of the forward port.

The igniter, *I*, Fig. 52, is actuated by a trip mounted on an arm bolted to the rear end of the slide, *S'*. The engraving shows the trip just in the act of operating the igniter; the rotational direction of the secondary shaft, viewed from the rear as in this engraving, is clockwise.

Fig. 54 illustrates the special electric light engine built by the St. Mary's Machine Company, St. Mary's, Ohio. Both the admission valve and the exhaust valve are positively operated by cams and rocker-arms. The engine is of the throttling class; a throttle valve in the mixing chamber on the left-hand side of the cylinder head being controlled by the governor through the horizontal rocker-arm pivoted to the face of the cylinder head. The ignition is electric, as the engraving clearly indicates, the usual butt-contact igniter being employed and actuated by a spring lever and a pin-cam on the end of the secondary shaft. This company also builds a line of "hit-and-miss" engines for general service in sizes ranging as high as 60 horse-power, but all engines of 75 horse-power and over are of the throttling type here illustrated. The valves, of course, are of the poppet type and are contained in individual valve cases, which may be removed without disturbing any other parts of the engine or any of its adjustments. This engine is adapted to use gasoline as well as gas, and it can be adapted to use kerosene or crude oil for fuel by the addition of a vaporizer, which is heated by the exhaust gases of the engine.

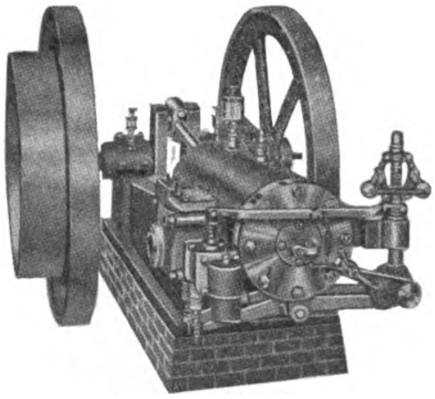

FIG. 54.—ST. MARY'S GAS ENGINE

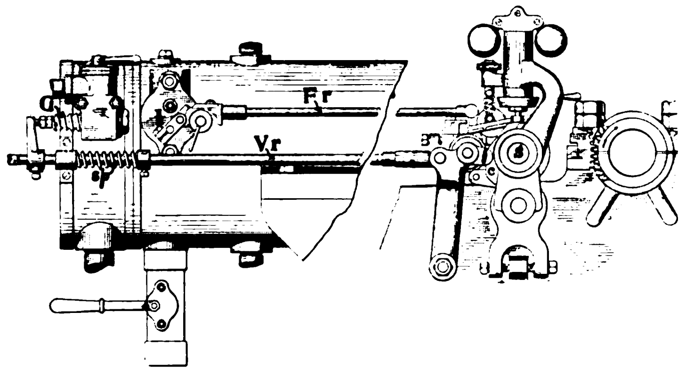

FIG. 55.—FT. WAYNE CONTROL MECHANISM.

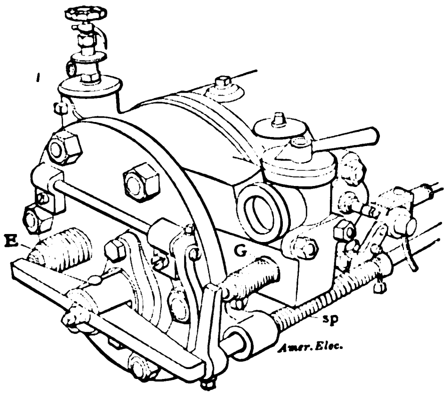

FIG. 56.—FT. WAYNE GAS ENGINE DETAILS.

Fig. 55 illustrates most of the control mechanism of the gas engine built by The Ft. Wayne Foundry & Machine Company, Ft. Wayne, Ind. This engine is of the four-stroke-cycle class, governed by the "hit-and-miss" method. Fig. 56 gives a diagonal view of the rear end of the cylinder and the mechanism mounted thereon, and Fig. 57 is a horizontal sectional view through the cylinder and the admission and exhaust valve chambers. The secondary shaft, *S*, Fig. 55, is a very short one, and lies parallel with the main shaft, which is shown just to the right of it in this engraving. The cam *c* on the secondary shaft throws to the left the rocker-arm to which the valve rod, *Vr*, is connected, and the spring *sp* returns the valve rod when the cam releases it. This rod opens the exhaust valve (*E*, Figs. 56 and 57) when it is thrown back by the cam, and opens the gas valve (*G*, Fig. 56) when released by the cam and thrown forward by the spring *sp*, this spring being much stronger than the seating spring on the gas-valve stem. The gas valve delivers fuel to the cage of the admission valve, *A*, Fig. 57, and this valve is opened by atmospheric pressure.

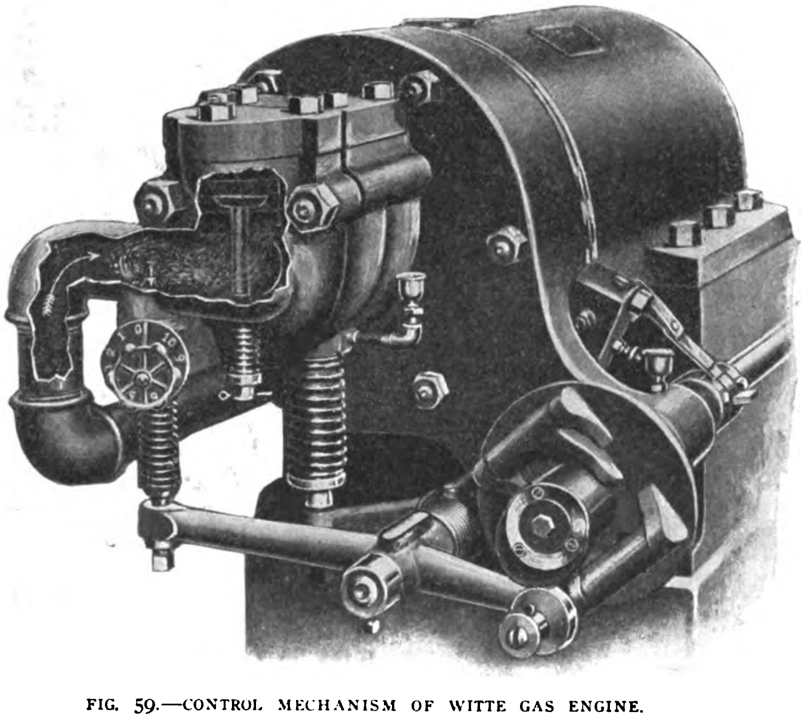

FIG. 59.—CONTROL MECHANISM OF WITTE GAS ENGINE.

During a normal charging stroke, the valve rod *Vr* is, of course, entirely released by the cam *c* on the secondary shaft so that it holds the gas valve open. During the compression stroke, the cam *c* holds the valve rod in an intermediate position where it releases the gas valve, but has not begun to open the exhaust valve. This position is, of course, maintained during the working stroke also, but at the end of that stroke the cam on the secondary shaft pushes the valve rod all the way back and thereby opens the exhaust valve. This cycle of actions goes on regularly so long as the speed is not excessive. Abnormally high speed

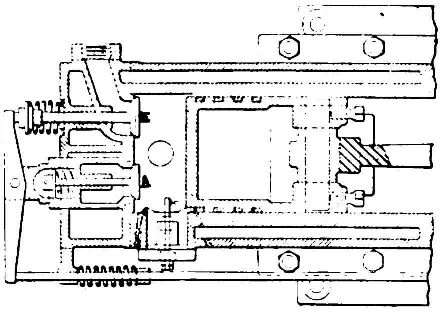

FIG. 57.—CYLINDER AND VALVE CHAMBER OF FT. WAYNE ENGINE.

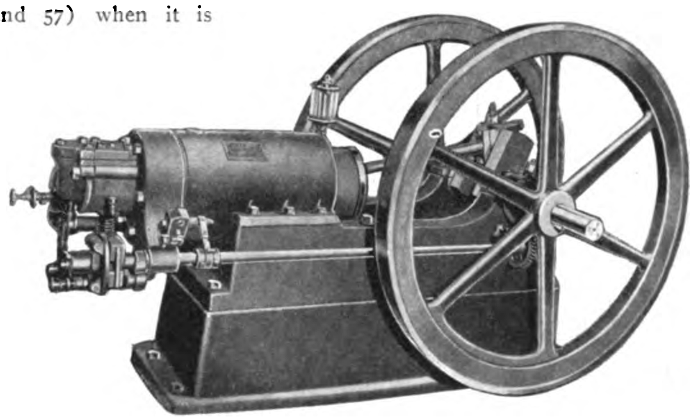

FIG. 58.—WITTE GAS ENGINE.

causes the governor to raise the end of a latch into interference with a lug on the rocker-arm to which the valve rod *Vr* (Fig. 55) is pivoted. This action holds the valve rod after it has been released by the cam on the secondary shaft and thus prevents the gas valve from being opened. The engine takes air through the admission valve during this idle stroke, as in the case of several of the other engines previously described.

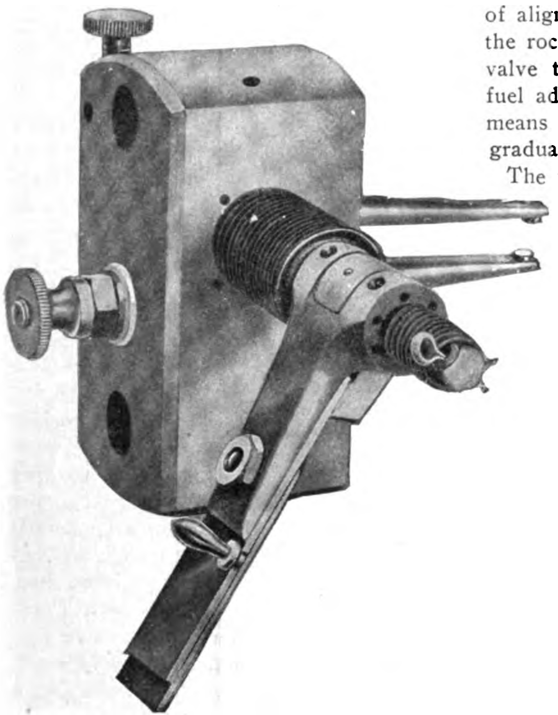

FIG. 60.—WITTE GAS ENGINE IGNITER.

The Witte engine, illustrated by Fig. 58, and built by the Witte Iron Works Company, Kansas City, Mo., has the very unusual qualification of being able to operate equally well with gas, gasoline, kerosene or distillate, without any change whatever in any of its parts; it also has the unusual feature of having its governor mounted directly on the secondary or cam shaft, and arranged to control the admission of fuel without the intervention of any mechanism beyond the rocker-arm which operates the gas valve. The engine works on the four-stroke cycle, and is regulated by the "hit-and-miss" method. Fig. 59 shows all of the control mechanism. The head of the governor is shown in the lower right-hand corner of the engraving. It caries the cam which actuates the rocker-arm of the gas or gasoline valve, and when the speed exceeds the proper rate it draws the cam out of alignment with the roller on the end of the rocker-arm and thereby allows the fuel valve to remain closed. The quantity of fuel admitted by this valve is adjusted by means of the hand wheel shown over the graduated plate near the air inlet pipe. The main admission valve is located between the fuel valve and the exhaust valve, and is opened by atmospheric pressure. It is shown lifted in the engraving. The exhaust valve is opened by a rocker-arm pivoted on the same stud with the fuel-valve rocker-arm and oscillated by a cam on the secondary shaft between the governor and the shaft bearing.

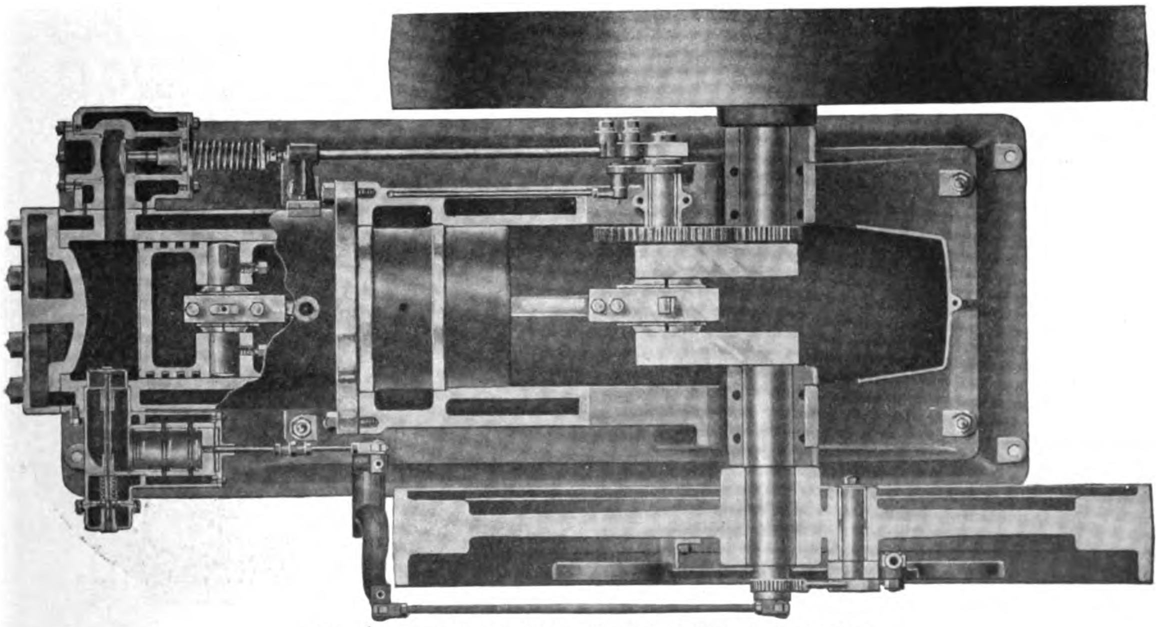

FIG. 61.—SECTIONAL VIEW OF THE BURGER GAS ENGINE.

As both of the engravings indicate, the valve and mixing chamber is in two parts, one of which is cast integral, with the cylinder head and the other bolted on; the fuel and admission valves are contained in the removable part and the exhaust valve is mounted in the part which is integral with the cylinder head. Each part is provided with a removable cap, as shown in Fig. 59, so that access to any of the valves is possible without removing the outer half of the valve chamber.

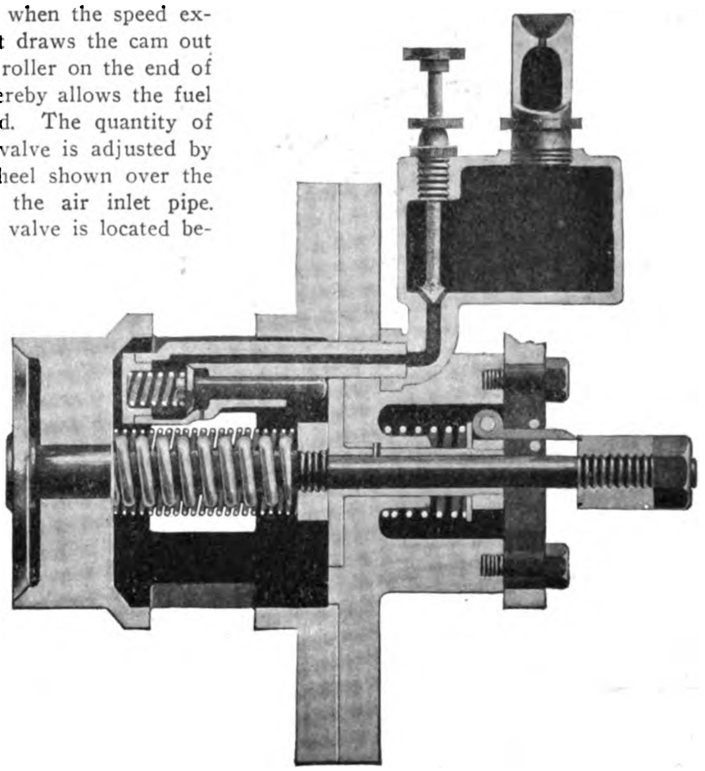

FIG. 63.—BURGER AIR AND GASOLINE VALVES.

The igniter is of the butt-contact type, operated by a spring arm, one end of which is attached to the igniter spindle; the other end is lifted by the flat pin cam shown in Fig. 59 beyond the cam-shaft bearing.

The spring arm of the igniter is of composite construction. Referring to Fig. 60 it will be evident that this arm is composed of two thin plates (of steel) bolted to a lug projecting from the hub. The bottom plate of these two is longer than the upper one, and is pivoted on the bolt shown in the end of the lug. For starting up, this bottom plate is left in the position shown in Fig. 60, with its end projecting beyond the end of the upper plate. The cam on the secondary shaft, therefore, cannot release the igniter arm until it has gone far enough to allow the end of the long plate to snap back. This times the ignition so that the charge cannot explode before the crank passes the inner dead center. After the engine has been started up, the longer plate of the igniter arm is thrown outward by means of the small handle shown, so that the cam engages with the shorter spring plate, and releases the igniter contacts earlier.

The Burger automatic engine, illustrated by Fig. 61, and built by the Woolley Foundry & Machine Works, Anderson, Ind., has the distinction of being the only one, so far as the writer's knowledge extends, on which the Rites governor is used. Fig. 62 shows the governor wheel. The weights oscillate a small rack about the pivot on which the weight arm is hung, and this rack meshes with a gear on a little crank disc, the crank-pin of which gives a reciprocating motion, by means of rods and rocker-arms, to a valve determining the quantity of explosive mixture admitted to the cylinder chamber. At maximum load the ports are open during the entire charging stroke, and at loads less than maximum the supply is cut off before the completion of the charging stroke, the point of cut-off varying according to load requirments, the quality of the charge being unaffected by the governor.

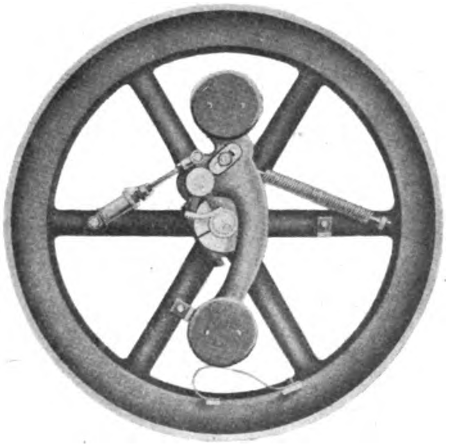

FIG. 62.—GOVERNOR OF BURGER GAS ENGINE.

The secondary or cam shaft is on the opposite side of the cylinder from the governor, and controls the exhaust valve and the igniter in the usual manner. Inspection of Fig. 61 will show that the exhaust-valve chamber is provided with a removable cap or bonnet opposite the valve to facilitate during each charging stroke of the piston. This valve is of the multiported piston type, and is shown clearly in Fig. 61. The two right-hand rows of ports control the air admission to the mixing chamber and the third row controls the gas admission. The main admission valve is mounted at right angles to the governing valve, and opens directly into the cylinder. It is opened by atmospheric pressure. The governor operates to vary the length of time the regulating valve ports are open to the mixing the removal of the valve, the valve seat being integral with the valve chamber housing.

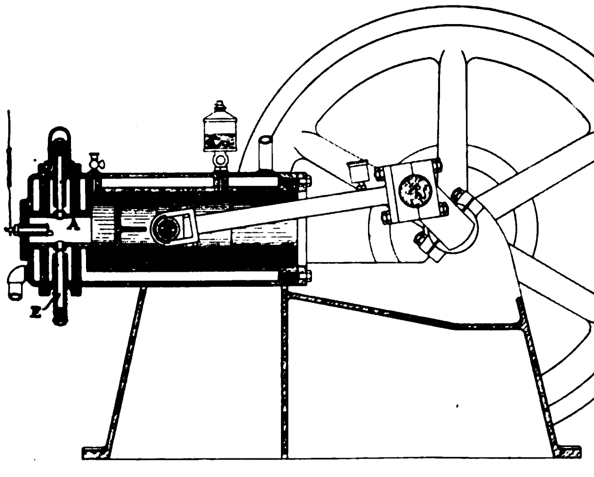

FIG. 64.—COOK GAS ENGINE.

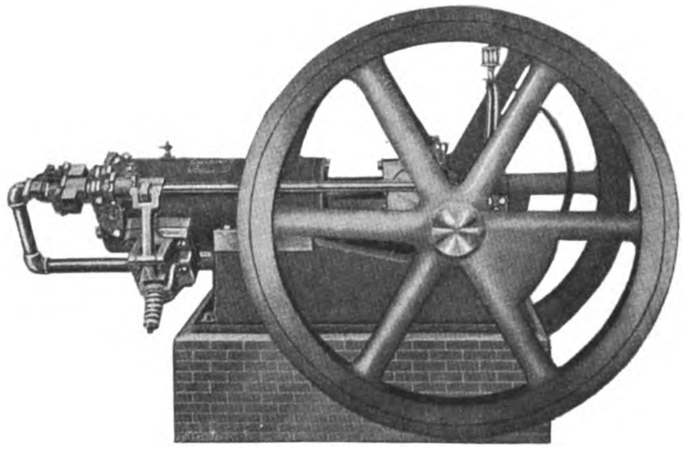

FIG. 65.—MIAMI GAS ENGINE.

The Burger engine is also built on the "hit-and-miss" plan. The gas valve has a hollow stem, and is mounted on the stem of the main admission, or air, valve. The hit-and-miss regulation button on the end of the main valve stem normally engages a pick-blade pivoted on the end of the gas valve stem so that the two valves are opened in unison; excessive speed causes the governor, which is of the centrifugal variety, but mounted on the main shaft, like the Charter governor, to swing the pick-blade out of alignment with the button on the air-valve stem, allowing the air valve to open and leave the gas valve closed. A somewhat similar arrangement is employed in the Burger gasoline engine.

Fig. 63 shows the arrangement for gasoline. The fuel is delivered to the fuel valve past a small regulating valve, shown in the upper part of the engraving. The fuel valve is opened by a collar on the stem of the admission valve, this collar being pushed forward by the button on the admission-valve stem engaging with the pick-blade pivoted on the rear end of the collar. The pick-blade reciprocates between two studs set in a slide controlled by the governor; excessive speed causes the governor to raise this slide (as the parts are shown in the engraving) and pull the pick-blade out of reach of the button. The builders do not recommend hit-and-miss control where close regulation is required.

The engine of the Cook Manufacturing Company, Albion, Mich., is illustrated in section by Fig. 64. This is a "hit-and-miss" engine operating on the usual four-stroke cycle. The admission and exhaust valves are practically alike, and are mounted in removable cages, as indicated in the engraving. The admission valve is opened by atmospheric pressure and the exhaust valve by a rocker-arm at right angles with the cylinder bore and pivoted beneath the cylinder. The end of the rocker-arm next to the secondary shaft (which is parallel with the cylinder and bed) is depressed by a cam on the shaft, and when the speed rises above normal the governor swings a finger over a projection on the end of the rocker-arm which catches the arm in the "open" position and holds the exhaust valve open during the charging stroke. The cylinder being kept open to the atmosphere, there is no difference of pressure to open the admission valve, and the charge is omitted. The governor is of the simple "fly-ball" variety, located above the exhaust-valve cam and gear-driven from the secondary shaft.

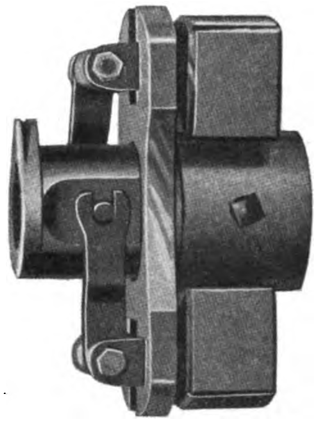

FIG. 66.—MIAMI GAS ENGINE GOVERNOR.

This engine has the unusual feature of a cylinder head integral with the cylinder. There is a relatively small circular opening in the back end of the cylinder, which is closed by the flange of the igniter plug; the remainder of the rear wall is integral with the cylinder barrel.

Fig. 65 illustrates the Miami gas engine, built by The Middletown Machine Company, Middletown, Ohio. As in the case of the Witte engine, the governor is mounted directly on the secondary shaft and its spindle carries the cam which opens the fuel valve, as shown by Fig. 66, which gives a view of the governor alone. The air and exhaust valves are opened by means of the usual cams on the secondary shaft, and each is mounted in a cage which is detachable from the cylinder. Fig. 67 shows the air valve and its cage. It will be noticed that a bell-crank lever is interposed between the valve-stem and the cam, the latter (not shown) acting against the roller carried by the bell-crank. The object of this arrangement is to obviate side strains on the valve stem and consequent unsymmetrical wear of the guide plates, which would allow the valve to seat improperly and tend to produce back-firing. The exhaust-valve bonnet and rocker-arm are shown in Fig. 65 very clearly. The rectangular governor weights also show plainly just beyond the end of the cylinder. The igniter cam appears a little to the left of the exhaust-valve cam; ignition is electric.

It will be noticed by reference to Fig. 65 that the weight for counterbalancing the crank and reciprocating parts is cast in the fly-wheel, between two spokes and near the center. It is stated that the center of gravity of this weight is the same distance from the center of the crank-shaft as that of the cranks, and that more nearly perfect balancing is thereby obtained. This engine is also adapted to operate on gasoline or distillate.

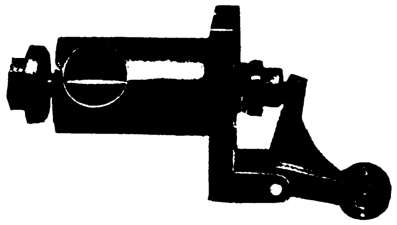

FIG. 67.—AIR VALVE, MIAMI ENGINE.

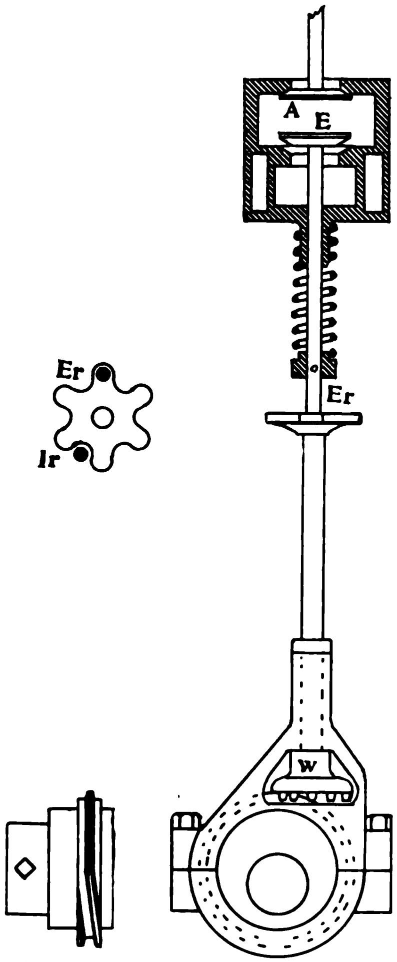

FIG. 69.—MEAD EXHAUST VALVE AND IGNITER GEAR.

The engine shown by Fig. 68 differs from every other one described in this article in that the charge is ignited by a Bunsen tube. Electric ignition is provided by the builders when desired, but their own preference is for the incandescent tube method. The short secondary shaft parallel with the crank shaft is used, and this merely actuates the exhaust valve; the admission valve is opened by atmospheric pressure so long as the speed is normal, and the fuel is delivered from the supply pipe directly to the admission valve chamber without the intervention of a fuel valve. The proportion of fuel to air is regulated by means of a hand valve, as is customary in all gas engines. The admission and exhaust valves are set in opposite ends of a single chamber, and the exhaust-valve stem is pressed back by a slide, which is reciprocated by an eccentric on the secondary shaft. There are no cams, rocker-arms or other moving parts besides those just enumerated, and the governor, which is of the pendulum type similar to that described in connection with the Springfield engine. The action of the governor is different from that of the Springfield engine, however, in that it swings a latch in front of the exhaust-valve stem when the speed rises, this latch holding the exhaust valve open and preventing the difference between the pressure in the cylinder and that of the atmosphere which normally operates the admission valve during the charging or "suction" stroke. This engine is built by the Utica Gas Engine Works, Utica, N. Y.

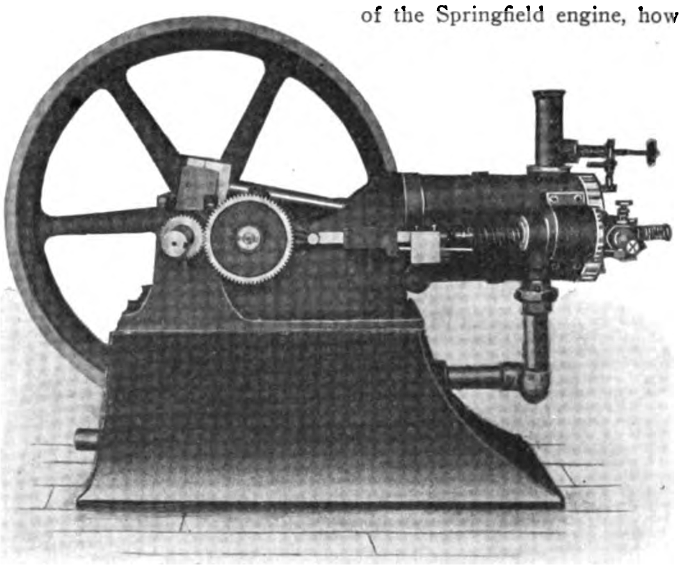

FIG. 68.—UTICA GAS ENGINE.

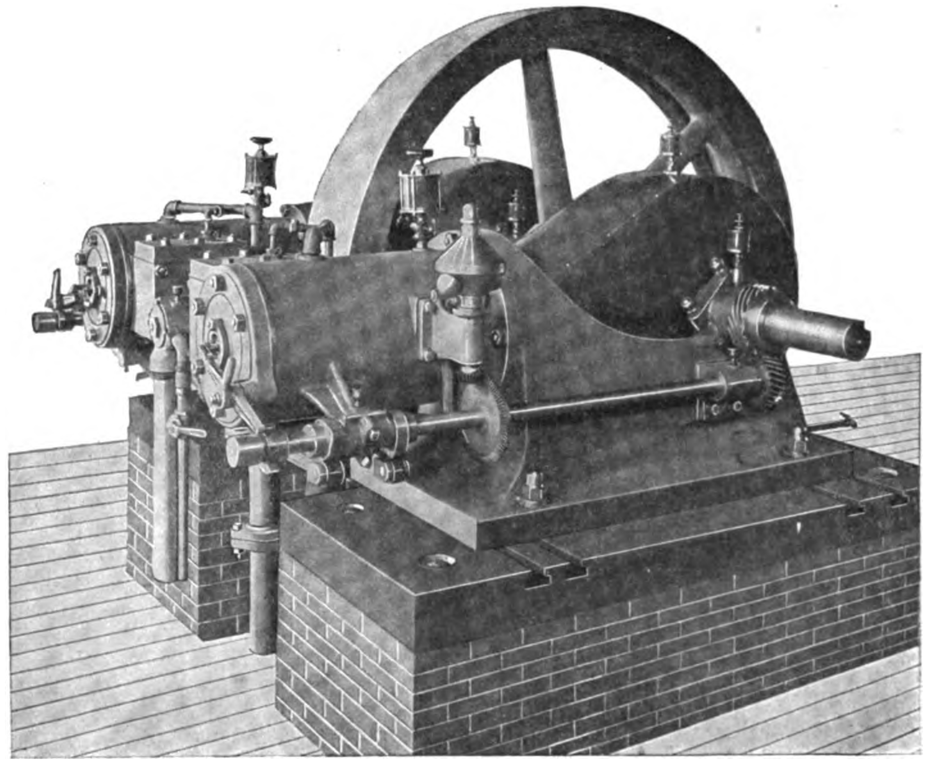

FIG. 70.—RUGER TWIN GAS ENGINE.

Fig. 69 illustrates a very ingenious method employed by the Mead Gas Engine Company, Providence, R. I., for operating the exhaust valve and igniter of an engine working on the four-stroke cycle, without using a secondary shaft. An eccentric on the crank-shaft reciprocates an eccentric rod in the usual manner, but the rod is twisted through one-twelfth of a revolution about its axis at each revolution of the crank-shaft by means of a crown wheel, *w*, mounted on the end of the eccentric rod and engaging with a partly spiral thread or web around the hub of the eccentric. This web is shown by the detail sketch at the left of the eccentric. The other end of the eccentric rod carries a star wheel which rotates with the rod, so that one of its teeth impinges against the end of the exhaust valve stem at the end of the working stroke of the piston but misses it at all other strokes. The star wheel similarly engages with the igniter rod at the proper time, and is rotated out of alignment with it when ignition is not required. The exhaust-valve stem or rod is indicated by *Er* and the igniter rod by *Ir* in the sketch.

Fig. 70 illustrates a twin gas engine for electrical service, built by the Ruger Manufacturing Company, Buffalo, N. Y. This machine is of the throttling type and works on the four-stroke cycle. The valves of the engine are, of course, of the poppet type, and are set vertically. Both valves are operated positively from the secondary shaft and the igniter, which is of the usual butt-contact type, is, of course, operated by a cam on the same shaft. It is stated that the valves are cushioned so that they close noiselessly. The mixture of gas and air is proportioned in the usual way, by means of a hand valve, and the governor controls the quantity of mixture admitted to the cylinder during each charging stroke. In the case of twin-cylinder engines, such as the one illustrated here, one throttling valve controlled by the governor regulates the quantity of mixture admitted to both cylinders, although each cylinder has an independent mixing valve, and independent exhaust valves of course are used. The admission and exhaust valve cams for the near cylinder are shown one on each side of the journal bracket of the secondary shaft in the engraving. The governor, as the engraving clearly shows, is of the familiar fly-ball type. In a recent test of a 20-h.p. twin-cylinder engine speeded at 252 r.p.m. under full load, the speed of the engine with three-quarter load was 255 r.p.m., with half load 257 r.p.m., and no load 259 r.p.m.

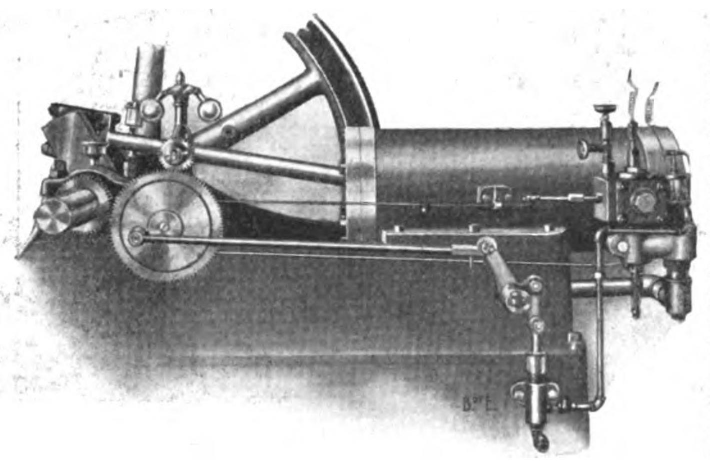

FIG. 71.—WHITE GASOLINE ENGINE.

Oil Engines.

Most of the gas engines described in the foregoing part of this article are adaptable to work with gasoline as fuel, and some of them may be worked on distillate, as mentioned in the course of the descriptions. There is, however, a distinct class of internal combustion engines designed especially to work with oil as fuel, and although the number of such engines is relatively very small, it has been deemed preferable to separate the descriptions of them from those of the gas engines proper.

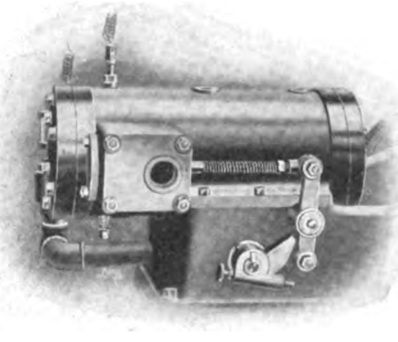

FIG. 72.—WHITE EXHAUST MECHANISM.

The White engine, the constructional features of which are illustrated by Figs. 71, 72 and 73, is built by The Globe Iron Works Company, Minneapolis, Minn., for operation with gasoline as fuel. It is made with both "hit-and-miss" and throttling regulation, according to the character of the service to be performed. The builders have the frankness to say that the throttling regulation is less economical when running with loads below one-half the normal or thereabouts, but the "hit-and-miss" regulation does not give as nearly uniform rotation as the other method, and is no more economical with loads considerably above half-load than the throttling method of regulation, while the wear and tear on the engine is probably a little greater than when throttling is employed. For electric light service, the throttling engine is furnished, naturally.

This engine has the short secondary shaft and plain spur gears described in connection with several of the gas engines. The pitman shown extending back from a crank-pin on the secondary gear in Fig. 71 oscillates a rock-shaft which passes transversely through the engine base and carries on its other end a cam for operating the exhaust valve. The bell-crank at the end of the rock-shaft, visible in Fig. 71, actuates the pump by which gasoline is delivered to the sight-feed reservoir shown in Fig. 73. When the rock-shaft draws the plunger of the pump up, the cam on the other end opens the exhaust valve. This cam and its relation to the exhaust-valve rocker-arm are shown by Fig. 72. A point claimed for this latter arrangement is that the exhaust valve can be so adjusted for starting the engine that there is no "hard" point to overcome in turning the flywheel over by hand, and consequently no danger of the attendant being thrown down by having to exert excessive strength at one moment and having the strain released unexpectedly the next. This, it is stated, makes auxiliary starting apparatus unnecessary, even for large sizes of engine.

Fig. 73 shows the mixer and the arrangement of the igniter points within the admission port. The admission valve is opened by atmospheric pressure. The movable igniter electrode is reciprocated by a cam on the secondary shaft, and is unusual in character; it is merely a black machine-steel pin, and is pushed into rubbing contact with the point of the stationary electrode, which is a similar pin. The rate at which the gasoline is fed to the cylinder is determined by the adjustment of the needle valve in the center of the sight-feed cup, Fig. 73, except for the intervention of the governor, which regulates the engine speed by varying the quantity of oil taken into the cylinder at each charge. The oil passes down from the sight-feed cup to the vaporizer, which is heated by the exhaust gases, and thence it is drawn into the cylinder along with the inrush of air when the piston "sucks" the admission valve open. In the "hit-and-miss" White engine, the governor operates to hold the exhaust valve open during the charging stroke, so that the pressure on opposite sides of the admission valve is equalized and the valve remains closed. It is quite conceivable that these engines could be operated equally well with gas for fuel by omitting the pump and sight-feed, and delivering gas to the admission-valve cage, unless the compression might not be suitable for efficient performance.

An oil engine built to use plain kerosene, crude petroleum, or the so-called "fuel" oil is shown by Fig. 74. This is the Hornsby-Akroyd engine, built in this country by the De La Vergne Refrigerating Machine Company, New York. It is radically different

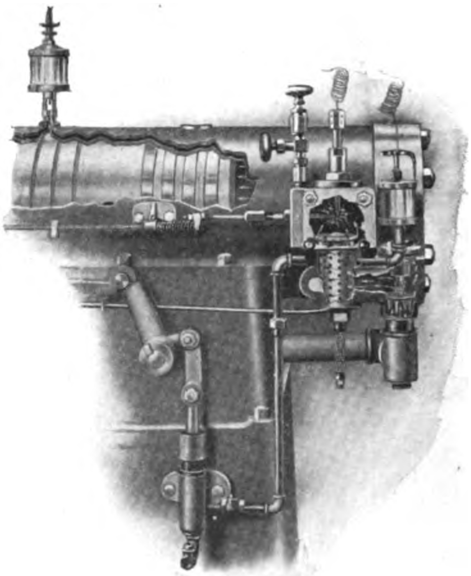

FIG. 73.—MIXER AND IGNITER ARRANGEMENT.

in several respects from any gas or gasoline engine. Back of the cylinder and opening into it through a contracted neck is a vaporizing and combustion chamber, into which oil is injected by a pump during the charging stroke; at the same time an air valve is opened by the same cam which actuates the pump plunger, and air is drawn into the cylinder (not the vaporizing chamber). On the return stroke of the piston the air is forced into the vaporizing chamber, where the charge of oil has been vaporized, and the mixed oil vapor and air are compressed to the temperature required to ignite the mixture. The explosions keep the vaporizing chamber at the proper temperature for vaporizing the oil when it is injected by the pump. After the working stroke of the piston is finished, the exhaust valve is opened by a cam and rocker-arm, as in the case of many of the gas engines described. The rocker-arms which open the air and exhaust valves are close together, as shown in Fig. 74. The governor regulates the speed of the engine by controlling the quantity of oil delivered by the pump.

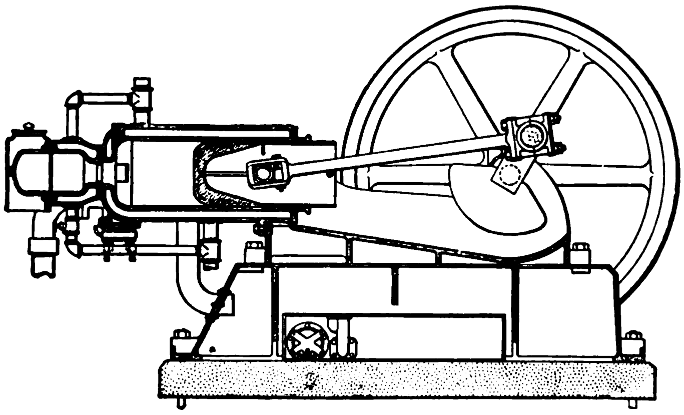

FIG. 75.—SECTIONAL VIEW OF HORNSBY-AKROYD OIL ENGINE.

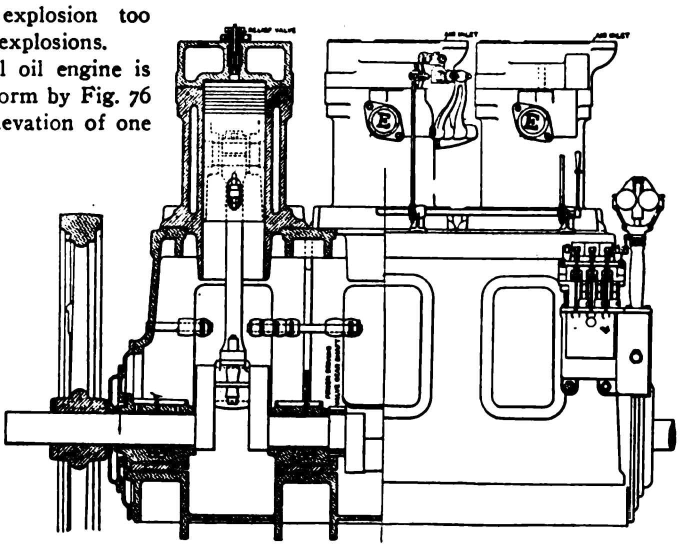

FIG. 76.—SEMI-SECTIONAL VIEW OF DIESEL OIL ENGINE.

Fig. 75 shows the arrangement of the cylinder and vaporizing chamber; the rear half of the latter is housed by a hood to protect it from drafts of air and keep up its temperature, while the front half is water-jacketed, like the cylinder. This engraving shows the contracted opening between the vaporizer and the cylinder. It has been stated by some authorities that the size of this opening has a very important bearing upon the operation of the engine, too small or too large an opening making an engine entirely inoperative by reason of either choking or localizing the explosion too much or causing premature explosions.

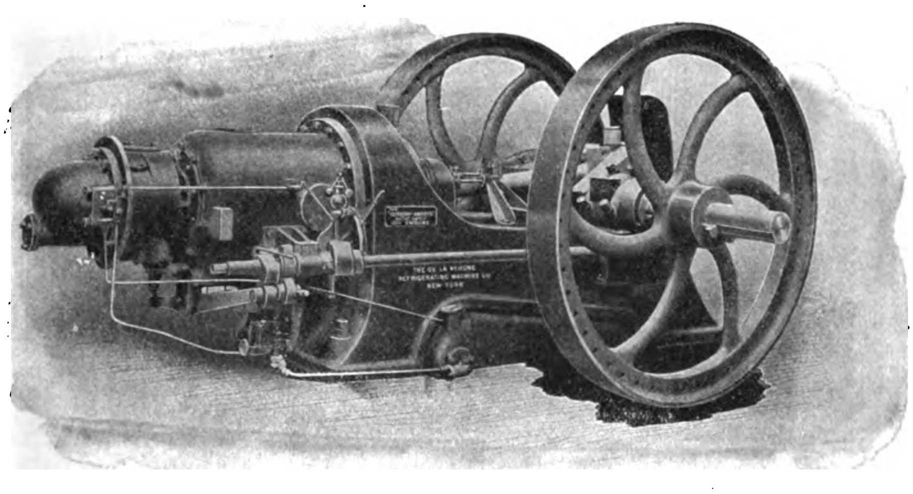

FIG. 74.—HORNSBY-AKROYD OIL ENGINE.

The now celebrated Diesel oil engine is represented in two-cylinder form by Fig. 76 and Fig. 77, is a sectional elevation of one cylinder. As indicated in the latter engraving, the secondary shaft is located within the crank housing and parallel to the crank-shaft, from which it is driven through an intermediate gear, as in the case of the Marinette gas engine. The secondary shaft opens the fuel valve and the exhaust valve at the proper moments by the usual cam and reach-rod arrangement and the valve which admits air opens automatically under atmospheric pressure. The arrangement of the valves is shown by Fig. 78. The fuel valve is of the needle type, and is surrounded by brass washers which break the oil up into fine particles; two pipes are shown leading into the fuel valve cage; one of these delivers oil and the other compressed air by means of which the oil is literally blown into the cylinder. The action of the engine, which works on the usual four-stroke cycle is as follows:

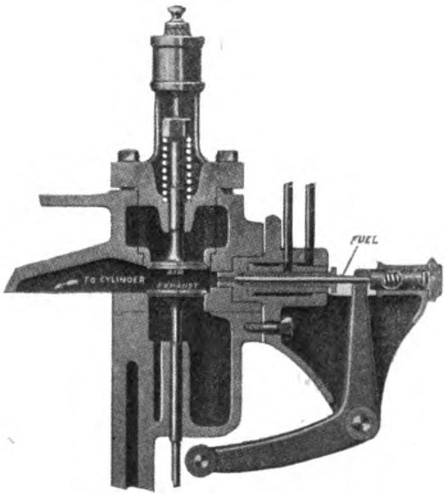

FIG. 78.—ADMISSION VALVE, DIESEL ENGINE.

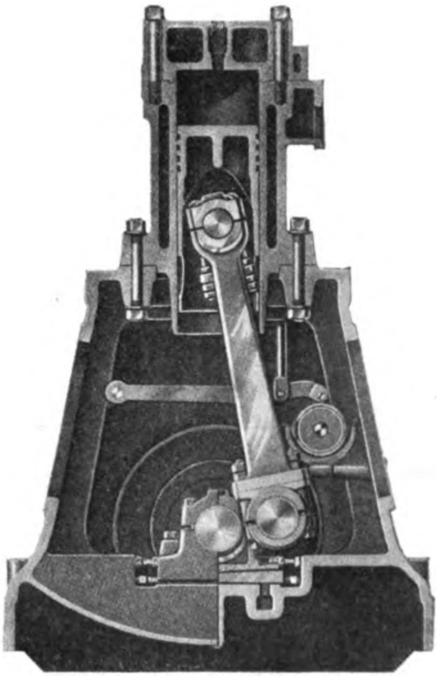

FIG. 77.—SECTIONAL VIEW, DIESEL ENGINE.

During the charging stroke of the piston, air is drawn into the cylinder through the automatic valve marked "air" in Fig. 78, but no oil is drawn in. On the return stroke the piston compresses its charge of air to something like 500 pounds pressure per square inch, producing a temperature of about 1000 Fahrenheit. At the end of the compression stroke, the fuel valve is opened and the oil forced into the cylinder by compressed air, the latter being obviously required on account of the pressure existing within the cylinder at that moment.

The oil enters in the form of fine spray, and is instantly ignited by the high temperature of the air, mentioned above. The working stroke follows, of course, and then the exhaust stroke. Oil is admitted to the cylinder during about one-tenth of the working stroke of the piston, and is ignited as fast as admitted; after the supply is cut off the burning gases act expansively, of course.

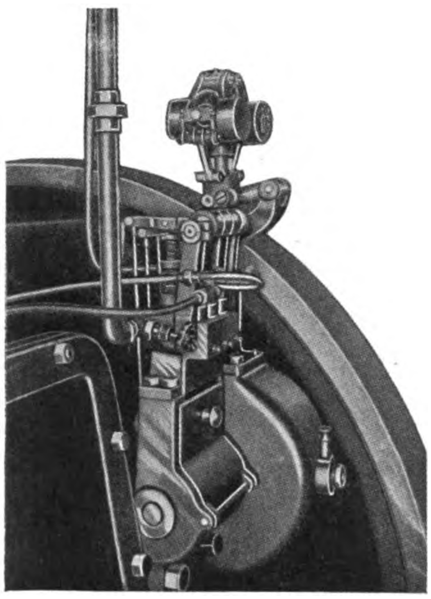

FIG. 79.—PUMP AND GOVERNOR, DIESEL ENGINE.

Speed regulation is effected by varying the quantity of oil sent to the fuel valve for injection into the cylinder. The oil for each cylinder is pumped to the fuel valve by a small oil pump, and the governor controls a by-pass around the pump; Fig. 79 shows the pumps for a three-cylinder engine, together with the governor and the three by-pass valve-rods adjusted by the governor.

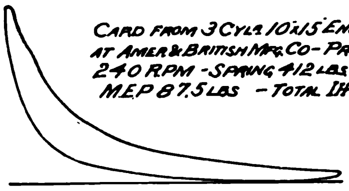

FIG. 80.—INDICATOR CARD FROM DIESEL OIL ENGINE.

In addition to the distinctive features of extremely high compression and the ignition of the fuel by the temperature due to compression alone, the Diesel engine has the unique characteristic of operating without any explosion or increase of cylinder pressure above the pressure of compression. The oil is burned as it enters the cylinder, and since it enters in very fine particles (spray) the burning does not take the nature of an explosion, but occurs gradually and continues until the combustible gases are burned, the expansion during this combustion being the impelling force. This is clearly shown by the indicator diagram reproduced in Fig. 80, which was taken from an engine developing 103 horse-power. The manufacture of the Diesel engine is controlled in this country by The American Diesel Engine Company, New York.

Igniting Generators.

The widely used method of igniting the charge of a gas engine which consists of connecting a sparking coil and a battery to the electrodes of the igniter proper is too well-known to require any discussion. In addition to this, there are several magneto generators built for use in the place of the battery and spark coil. Two of the most recent and most ingenious of these are described here. One is built by The Auto-Igniter Company, and the other by the Goodson Electric Ignition Company, both of New York. Fig. 81 shows the "Auto-igniter," which is a dynamo of the inductor type. The revolving element is a disc of soft iron, which has an oblong opening cut near the rim and carries a piece of non-magnetic metal set into this hole; this is indicated in Fig. 81 by the dark spot near the bottom edge of the disc. The permanent field magnet is provided with two polar projections of soft iron, on one of which is mounted a single coil, the only winding on the machine. The disc rotates between the faces of the two polar projections and the face of the opposite magnet pole, and the non-magnetic piece of metal set in the disc is of such shape and size as to lap the edges of both polar projections when it is in alignment with them and to conform to the outline of a pole when its edge is opposite the edge of the pole with the latter covered. It is obvious that while the iron part of the disc is between the poles the magnetic circuit is nearly closed, and the flux is maximum; when the inserted metal passes the poles, the reluctance of the magnetic circuit is suddenly increased and the flux weakened, producing an e.m.f. in the coil; when the iron part of the disc again enters the air gap, another e.m.f. is induced, so that there is a double impulse or two impulses one immediately following the other. The absence of collector rings and brushes is a particularly advantageous feature in a machine of this small size and operated under the conditions of neglect that are inevitable in this case. Fig. 82 shows one of these igniters attached to an engine; the disc is mounted directly on the engine shaft and the magnet held by braces from the bed frame.

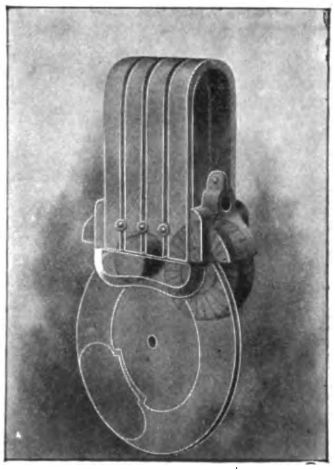

FIG. 81.—AUTO-IGNITER.

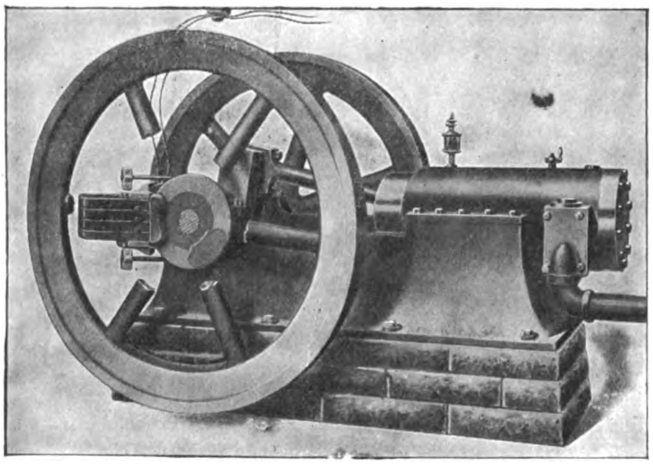

FIG. 82.—AUTO-IGNITER IN POSITION.

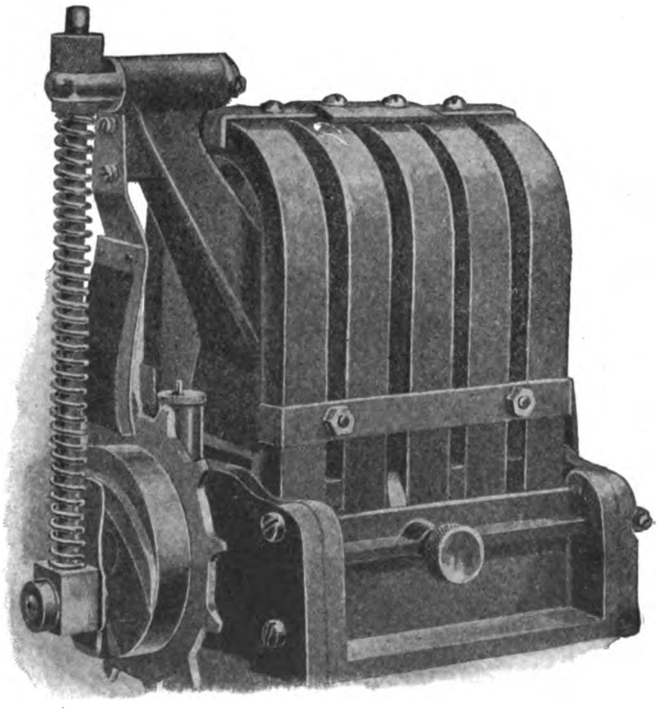

FIG. 83.—THE GOODSON GENERATOR.

The Goodson apparatus comprises a complete system of igniting generator and igniter plug and involves the probably unique feature of having the igniter electrode oscillated by an electromagnet. Fig.

83 shows the generator complete. The armature shaft is driven by the sprocket wheel shown in the engraving, a chain being used to belt this wheel to a mate on the secondary shaft (if a two-stroke-cycle engine). The sprocket is mounted loosely on the shaft, however, and rotates the latter through half a revolution by means of a lug engaging a similar lug on the crank disc outside of the sprocket. This crank disc is keyed to the shaft, and when the sprocket wheel has carried it around to a point where the crank-pin is just past the upper center, the helical spring runs the crank disc through the other half revolution with a snap, far in advance of the motion of the lug on the sprocket wheel. The igniting e.m.f. is induced by this sudden motion, and it is evident that since the spring carries the armature through the second half revolution without regard to the movement of the sprocket wheel, the e.m.f. is always the same, no matter what the speed of the sprocket wheel may be. Therefore, the ignition of the charge is as reliable when starting up as when running at full speed.

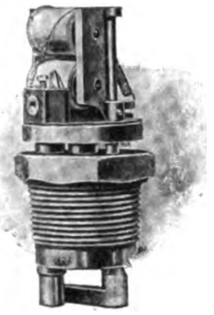

FIG. 84.—GOODSON SPARK PLUG.

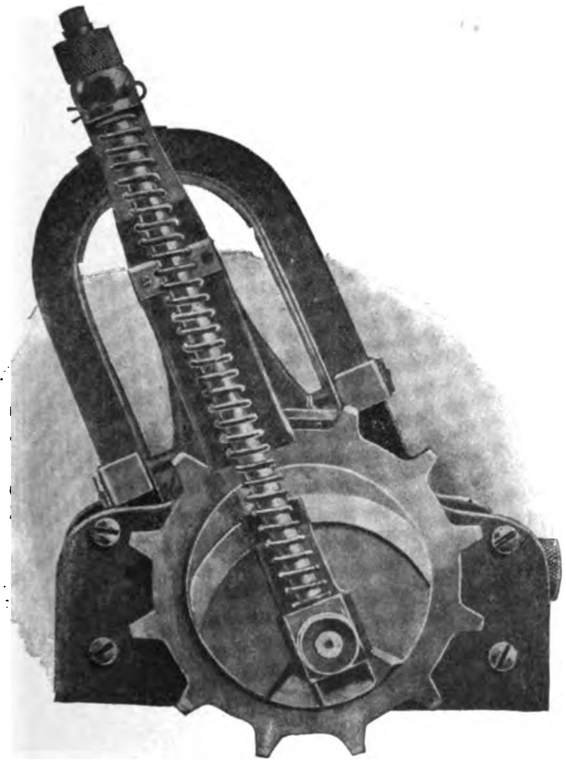

FIG. 85.—GENERATOR TILTED FOR LATE IGNITION.

The Goodson spark plug is shown by Fig. 84. It carries on its head a small electromagnet, the armature of which is mounted on the spindle of the movable electrode. When the magneto generator sends its sharp impulse of e.m.f. to the plug, the magnet is energized and separates the electrode contacts. The armature is adjusted so that it will not respond to the feeble e.m.f. produced by the generator during the first half revolution, through which it is driven by the sprocket wheel.

The field magnet of the generator is mounted on pivots co-axial with its armature shaft so that it may be tilted one way or the other, and the time of ignition thereby adjusted; Fig. 85 shows the magnet tilted in the direction to produce late ignition, the direction of shaft rotation being counter-clockwise. This view also shows the ingenious brake used to bring the shaft to rest at the end of its quick motion and avoid hammering by the lugs on the sprocket and the crank disc. The crescent-shaped surface is raised above the face of the disc, and a flat spring mounted on the head of the spring-supporting rod rubs against this crescent surface when the crank-pin is at the "rest" position, but does not touch it during the second half revolution when the armature shaft is under the control of the helical spring. This ignition system has been adopted by The Fairbanks Company for use on its gas engines, as noted in the description of that company's product.

Abstracts from Foreign Contemporaries

Gas Producer for Bituminous Coal.—Considerable attention is being paid to the problem of producing gas from bituminous coals, free from objectionable tarry vapors which give so much trouble when such gas is used in gas engines. Fig. 1, taken from the London *Mechanical Engineer,* shows how Crossley Brothers, the well-known gas engine builders, propose to attain this end. In gas producers as usually constructed the fuel is generally fed into the top of the producer, arranged with the object of keeping a reserve of fuel and a constant working fuel depth. In this apparatus the fuel is fed into a closed retort and the resultant volatile gases and vapors are then passed into the lower portion of the fuel bed of the gas producer together, along with steam and air or other gases. Any tarry vapors present in the mixed gases and vapors are broken up during their passage through the heated fuel, leaving the upper portion of the producer as permanent gases and enriching the other gases produced. The engraving shows an arrangement in which the fuel is distilled in the retorts *A* by means of the sensible heat of the gases and the radiant heat of the fuel in the producer, the caked residue being afterward fed into the producer and consumed there. The retorts are arranged with hollow spiral castings *B,* which close the bottom end. Screw tackle is arranged so that the casting *B* may be rotated independently of the screw. When charging a retort the valve face of the casting *B* is tightened in its place, and fuel admitted into the retort is projected downward into the spaces between the spirals by turning the capstan *C*. When discharging a retort the casting *B* is first lowered a distance by means of the tackle and the capstan is then turned in the same direction as when charging. The coked fuel in the retort *A* is then projected downwards and broken up by the spirals. The volatile gases given off from the green coal in the retorts *A* are conducted by way of the pipes *E* and *F* to the lower portion of the fuel bed of the producer. When a charge has been completely distilled in a retort the gas outlet therefrom is shut off temporarily by means of the dampers *G*. The coke or residue is broken up into suitable sections by the spiral *D* and is dropped out of the retort into the producer. A fresh charge is fed into the retort through the door which is then secured, and the damper *G* again opened. The fuel after passing through the retorts will not cake a second time, and is thus very suitable for use in the producer, and the gas produced is more uniform than that obtained in the usual manner.

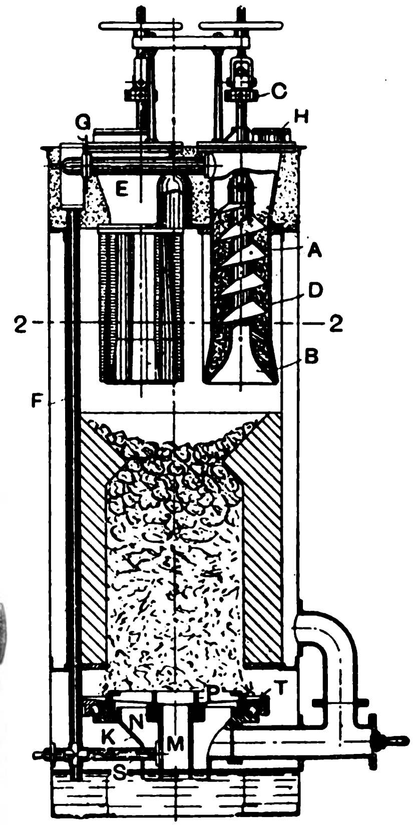

FIG. I.—CROSSLEY GAS PRODUCER.

Regenerator for Gas Producers.—The adaptation of the principle of Green's well-known economizer or feed-water heater to the regenerative heating of the air and vapor supplied by gas producers forms the subject of a patent granted to A. Wilson, a description of which appears in a recent number of the London *Mechanical Engineer.* The gas issuing at a high temperature from the producer is caused to pass among tubes through which the air, or mixture of air and vapor, to be heated passes. The sensible heat of the hot gases is thus transmitted to the mixture in the tubes, the hot gases entering and passing through a chamber at as near a point as convenient to where the gases leave the fuel. The tubes in this chamber are arranged, preferably at right angles to the direction of the current of the hot gases, and fitted if desired with a mechanical scraper or other cleaning appliances to remove any deposit of tar, soot or dust. The air or other mixture after passing through the interior of one stack of tubes and becoming heated, enters the water chamber and there encounters a water shower and absorbs a certain amount of water vapor which causes the generation of steam. The vaporized air or mixture of air and steam is then sent through a second stack of pipes before its introduction to the producer. In this way the evaporation of water is effected by the hot gases issuing from the producer in a vessel which can be readily cleaned and examined. The gases from the producer flow through the stack of regenerator tubes in a direction opposite to the direction of flow of the mixture in the interior of the tubes, which may obviously be arranged in several groups and modified to suit circumstances much in the same way as a Green's economizer.

Self-Contained Self-Regulating Gas Plant.—Fig. 2 herewith, taken from the London *Mechanical Engineer,* represents Dunlop's self-contained self-regulating gas plant, which is intended to produce from bituminous coal a gas suitable for use in a gas engine cylinder without the necessity of any attention further than that of filling the generator completely with fuel and turning on the water supply. A gas generator of this kind must of necessity contain within itself the means of regulating the quality of the gas produced, and when bituminous fuel is used it must insure against the formation of clinker, and at the same time the arrangement must be such that no tarry vapors or other combustible hydro-carbons are contained in the gas that enters the engine cylinder.

The manner in which these results are secured in the generator is illustrated as follows: The gas generator consists of a metal shell with an inner cylindrical shell lined with firebrick. At the lower end is a rocking grate with a poking finger. The shells are so arranged that free communication is established at all times between the top and bottom of the generator. Placed centrally in the generator is a water-jacketed collecting pipe, through which the gases produced are drawn off to be cooled and washed for use in the gas engine cylinder. The fuel is supplied by two hoppers at the top, and the water supply to the collecting pipe jacket is regulated by a cock, and sealed by a syphon pipe. The collecting pipe jacket is in free communication with the top of the generator, the upper end of the collecting pipe being closed by a lid, through which the condition of the fire may be observed, or through which the fire may be started by a piece of cotton waste soaked in petroleum. From the collecting pipe the gases pass to a tubular heat interchanger, shown at the side of the generator, the gases passing downwards, inside the tubes, which are in two lengths telescoping each other. The water overflowing from the collecting pipe jacket passes by a syphon seal to the top of the heat interchanger, and, flowing over the upper ends of the tubes, descends in a film inside the tubes along with the gases. At the same time a regulated quantity of steam is mixed with the gases as they leave the collecting pipe.

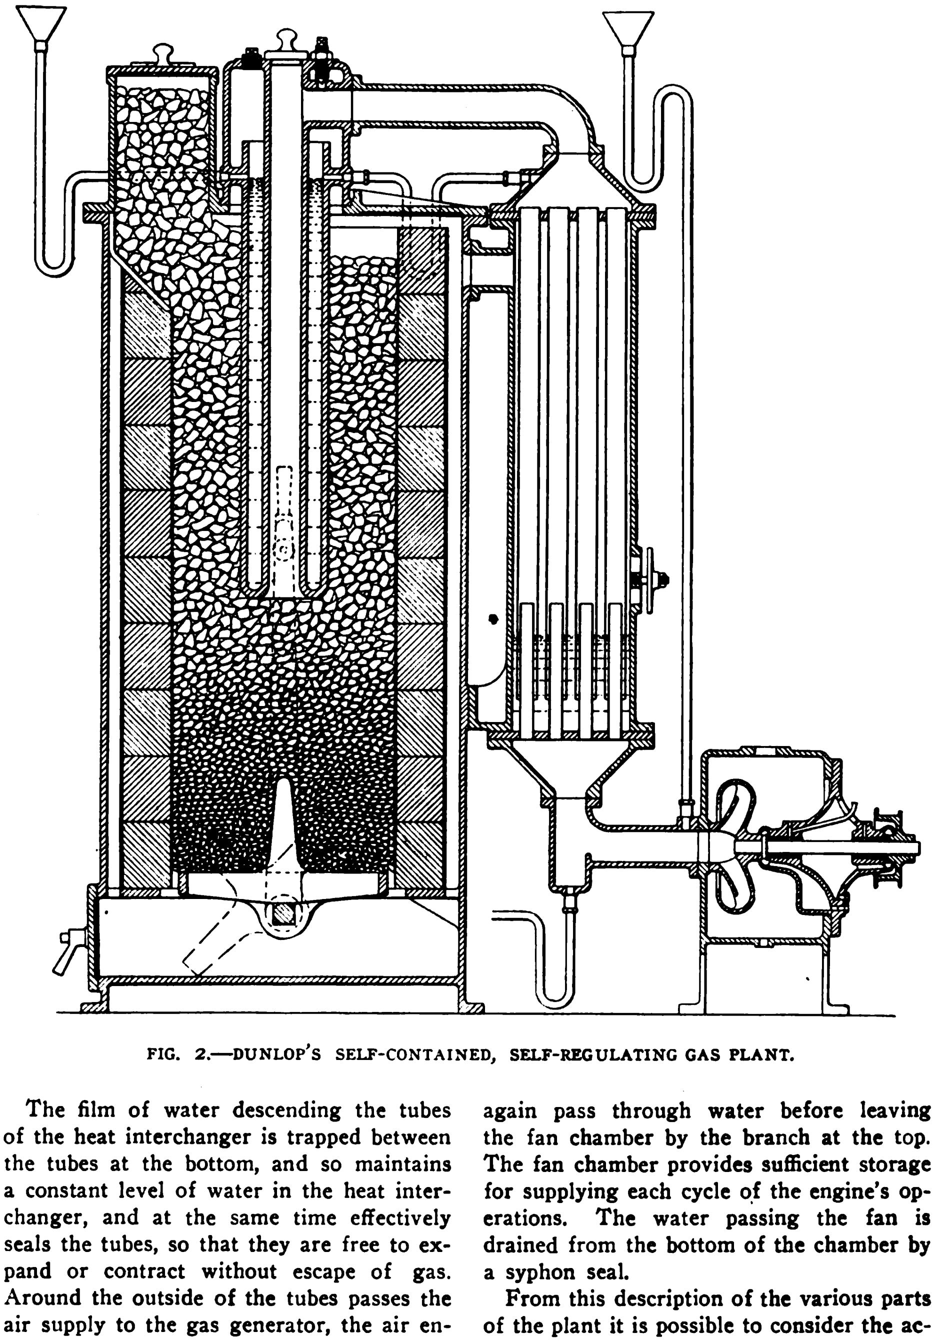

FIG. 2.—DUNLOP'S SELF-CONTAINED, SELF-REGULATING GAS PLANT.

The film of water descending the tubes of the heat interchanger is trapped between the tubes at the bottom, and so maintains a constant level of water in the heat interchanger, and at the same time effectively seals the tubes, so that they are free to expand or contract without escape of gas. Around the outside of the tubes passes the air supply to the gas generator, the air entering the adjustable opening close to the surface of the water, and passing into the lining of the generator near the top.

The surplus water from the bottom of the heat interchanger passes away through a syphon seal, and a fresh supply of cold water enters along with the gases into a centrifugal cooler and washer. This cooler and washer consists of an exhaust fan driven by the engine at a moderate speed sufficient to relieve the engine of the work of drawing the gases through the generator, etc. The construction is specially designed for the purpose of condensing the steam mixed with the gases, and for removing any tarry vapors or other condensible hydro-carbons that may have passed over with the gases. For these purposes the periphery of the fan is surrounded by a U-shaped ring, which maintains a water seal around the periphery, and through which all the gases must pass on their way to the engine. The water overflowing this seal is spread out in a sheet around the ring, so that after passing the seal the gases must again pass through water before leaving the fan chamber by the branch at the top. The fan chamber provides sufficient storage for supplying each cycle of the engine's operations. The water passing the fan is drained from the bottom of the chamber by a syphon seal.

From this description of the various parts of the plant it is possible to consider the actions that take place.

Assuming the plant in operation, air enters the heat interchanger at a rate determined by the speed of the washer fan and the requirements of the engine as adjusted for by the plate locked on the side of the heat interchanger. As it enters this air mixes with steam rising from the water in the bottom of the heat interchanger, and passing upward around the tubes is heated by the gases passing inside the tubes. When it enters the generator this mixture of air and steam mingles with a further quantity of steam overflowing from the top of the generator. This second quantity of steam is what is left of the steam generated in the jacket of the collecting pipe after supplying the amounts that pass direct downwards through the fuel, and that pass away with the gases at the top of the pipe. The mixture of air and steam passes direct to the closed ashpit, being heated up by contact with the inner shell, so that it is in a fit state to maintain a rapid rate of combustion when it passes through the grate. The amount of steam, however, is such that the formation of clinker will be prevented. In passing upward to the collecting pipe the air in this mixture first promotes combustion of the fuel, and later forms with the carbon of the incandescent fuel a mixture of carbon monoxide and nitrogen. The steam is dissociated, the hydrogen passing to the collecting pipe uncombined, while the oxygen combines with carbon to form carbon monoxide. While this action is taking place the steam in the top of the generator is driving the gases distilled from the fuel around the collecting pipe downwards through the incandescent zone, the tarry vapors and condensible hydro-carbons in these gases being there split up into fixed gases and passed to the collecting pipe.

Automatic Motor Starters.—The *Elektrotechnische Rundschau* contains a description of two automatic starters designed for either starting or stopping motors from a distance. The starters are manufactured by the German Lahmeyer Company, and are applicable for direct and alternating-current motors. Both for stopping and starting the lever of the rheostat is actuated by the motor in question, but the speed of the movement of this lever is, of course, different for turning on and switching off the current. In Fig. 3 *A* denotes the starting resistance. As soon as the motor begins to rotate, the lever *h*, by means of an intermediate crank, *k*, is set into a rocking motion. It carries two pawls, *Z*, Z_1, which are pressed by springs against the toothed disc *S*, fastened on the spindle of the starting lever. The meshing of either pawl is effected by means of a rod, *a*, and an electromagnet, *e*. So long as no current flows through the electromagnet *e*, the pawl *Z* is kept away from the toothed disc by means of a pin *s*. This is the position of the mechanism when at rest. If now the motor circuit is closed, no matter where, it is obvious, as seen from the diagram, that the electromagnet *e* is energized and attracts its armature. The pin *s* is lowered, and the upper pawl *Z* comes into contact with the toothed segment. Since the resistance on the first stop is so dimensioned that the motor receives sufficient current to start, the rocking lever *h* gradually cuts out the resistance, this lasting according to the length of the toothed periphery. Although the lever *h* continues to rock to and fro, the starting lever remains on the last stop. If the motor is to be stopped, the switch is opened, the armature of the electromagnet being thereby released. The upper pawl is drawn away from the segment *S* by the pin *s*, and the lower pawl Z_1 now comes into contact with the teeth of the disc, rapidly bringing the starting lever back to its original position. In virtue of the momentum of the motor armature, the lever *h* will continue to rock for some time, without, however, causing any further movement of the disc *S*. Another arrangement is shown in Fig. 4, the chief difference between it and the former device being the adoption of a clutch instead of a pawl and ratchet-wheel. A worm-wheel, *R*, is attached to the lever of the starting box (shown in the sketch arranged for three-phase work) and is driven by a worm, *W*, in a clockwise or counter-clockwise direction, according as which of the two wheels *S* and S_1, rotating in opposite directions, is coupled to the shaft carrying the worm *W*. Both wheels are driven by the motor, but with different speeds; the one for starting—*i.e.*, S_1—turns slowly as compared with the other one, *S*, which is employed for switching off the motor. On completing the motor circuit, the energized electromagnet *M*, in attracting its armature against the pull of a spring *F*, couples the worm *W* to S_1. The disc *R* begins to rotate, and resistances are cut out until the pin s_1, striking the lever, causes S_1 to become disengaged. On opening the circuit, the armature of *M* is released, and the tension of the spring *F* is sufficient to cause the left-hand clutch to engage, connecting thereby the worm *W* to the quickly rotating pulley *S*. The disc *R* is rotated until the pin *s* disengages the clutch.

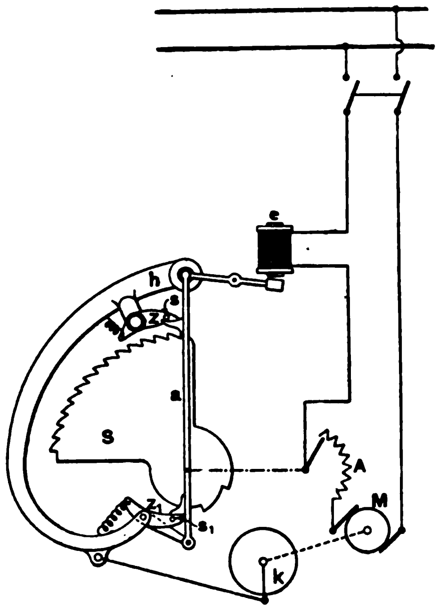

FIG. 3.—AUTOMATIC MOTOR STARTER.

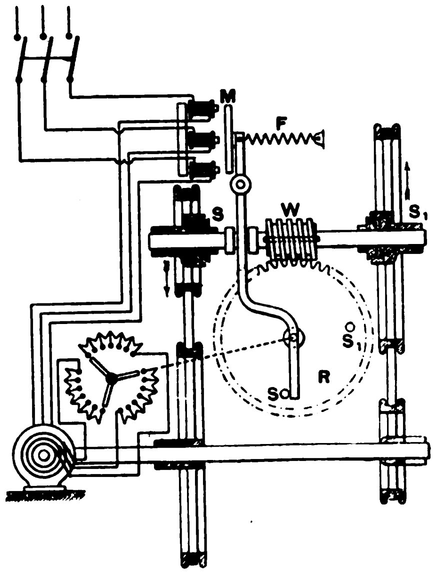

FIG. 4.—AUTOMATIC MOTOR STARTER.

A New Detector of Hertzian Waves.—W. Schloemilch describes, in a recent issue of the *Elektrotechnische Zeitschrift*, a new detector for Hertzian waves, which is based on electrolytic principles. Although still to some extent in the experimental stage, its essential points may be gathered from this description. If a cell, consisting of platinum or gold electrodes immersed in dilute acid, be connected to a source of electricity, the e.m.f. of which slightly exceeds the back e.m.f. of the electrolytic cell, a small and constant current will traverse the latter, producing at its electrodes a feeble generation of gases. On electric waves impinging upon this cell an increase of the decomposing current is observed. In order to increase the effect of the phenomenon, the surface of the positive electrode is made as small as possible, and it may be mentioned in this connection that the Gesellschaft für Drahtlose Telegraphie, the maker of the detector, employs electrodes only 0.001 mm. in diameter, and of a length of about 0.01 mm. The negative electrode, on the other hand, has seemingly no material bearing upon the phenomenon, and may consequently be used in any practical form or size. So far, the exact nature of the phenomenon remains unexplained, and it is not settled whether the cell acts as a capacity or as a resistance. The gas bubbles are more easily detached under the influence of the impinging waves, and with strong impulses this is marked to such a degree that the Morse signals sent may, it is stated, be interpreted directly by observing these fluctuations. If, however, the small electrode be changed over, so as to form the negative plate of the cell, the effect produced by the impinging waves is nearly nil, and it may be concluded, there-

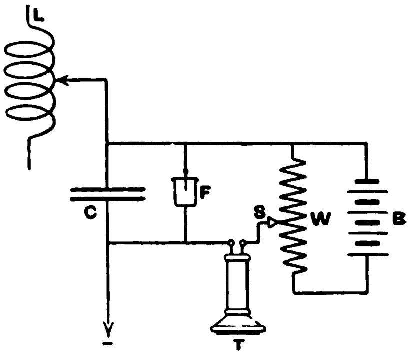

FIG. 5.—DIAGRAM OF CONNECTIONS FOR HERTZIAN WAVE DETECTOR.

fore, that the effect depends on the nature of the gas produced at the small electrode. It is necessary to adjust separately for each cell the applied e.m.f., because the sensitiveness of this wave detecting device is greatest at a certain rate of gas production, and diminishes both for a greater or smaller generation of gas bubbles. In special cases the auxiliary battery may be dispensed with by making the cell itself a primary battery, which can be done by choosing electrodes of suitable metals. In this form, however, the sensitiveness is less than in the former case. One of the diagrams of connection, which may be followed with good results, is shown in the illustration. In this engraving *L* represents the air wire; *E*, earth; *T*, telephone; *W*, resistance; *C*, capacity; *F*, electrolytic detector; *S*, moving contact, and *B*, a battery.

Steam Trap for High Pressures.—In the London *Engineer* is described the steam trap illustrated by Fig. 6 herewith and devised by Holden & Brook, who claim that it embodies in the one apparatus all the advantages which experience in trap work has suggested. For instance, it is stated that while the action of the trap is perfectly quiet its discharge, which is distinct and intermittent, has been greatly increased in quantity, making the trap free from dribble, and that owing to the peculiar construction of the valve it, together with its seat, is protected against cutting. Regarding the action of the trap, a straight piece of brass tube *A* when filled with condensed water contracts. The yoke piece *J* is then pressed against the ends of the rods *R* and *R'* by the action of the studs *J'*, which are fixed to *C*, the latter being screwed to and forming one piece of the tube *A*. As a result of this, both *R* and *R'* are forced against the upper and lower portions of the mechanism, shown at the left-hand of the engraving. *R'* comes against a rigid portion which will not give; the consequence is that since the rod is hard up against *J*, as is also the rod *R*, the expansion of *R'* is practically added to the expansion of *R*, making the left-hand end of the latter travel just twice as far to the left as it would have done had it been alone. The movement is sufficient to depress the lever *D* and to open the valve *E*, thus allowing the water to escape. It is stated that owing to its special construction and to the steam pressure being against it the valve does not open gradually in accordance with the motion of the lever, but hangs back and opens wide and suddenly, so that any foreign particles are readily blown out, and as it closes in the same manner the discharge is quite positive and the objectionable dribbling avoided. Another feature claimed is that the traps contain no delicate parts which cannot be repaired or replaced by an ordinary mechanic. When steam re-enters the tube *A*, after the expulsion of the water, the tube re-expands and by releasing the pressure on the rods *R* and *R'* permits the lever *D* to rise and the valve *E* to reseat itself. To blow through by hand the extension to the lever, *T*, is depressed. This lever returns to the closed position on release by the action of the spring *D'*. The cap *L* can be removed without interfering with anything else and the valve and seat examined or withdrawn. *M* is an adjusting screw provided with a locknut for regulating the discharge.

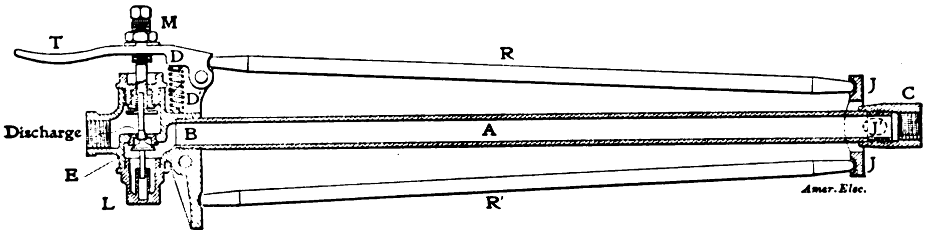

FIG. 6.—HOLDEN & BROOK STEAM TRAP FOR HIGH PRESSURES.

Vaporizers for Oil Engines.—In internal combustion engines of the compression type, and more particularly those in which the fuel consists of hydro-carbon oils, in which a heated explosion chamber or vaporizer is in open communication with the working cylinder through a contracted passage, part of the air from the cylinder is forced by the engine piston during the compression stroke through the contracted passage into the vaporizer, where after mixing with the vaporized hydro-carbons and forming an explosive mixture it is ignited, and the piston is driven out on the power or working stroke of the engine. The ignition may be due partly to the heat of the vaporizer and partly to the heat imparted by compression, or it may be due to external or other causes. Engines of this type usually require to work with a great percentage of explosions on possible working strokes at all loads, from no load to heavy load, in order to retain the vaporizer at the requisite heat, and the gear which operates the fuel inlet is usually arranged in such a manner that at no load or on a light load only a small quantity of oil enters the vaporizer for the working strokes, and on a heavy load a greater quantity of oil for the working strokes.

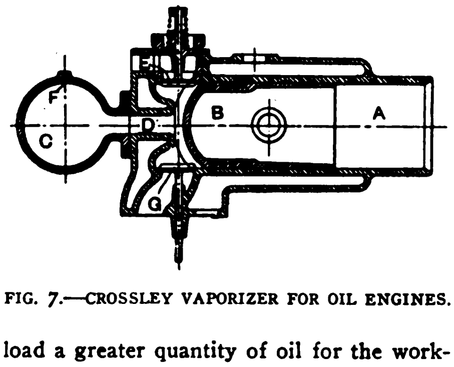

FIG. 7.—CROSSLEY VAPORIZER FOR OIL ENGINES.

The accompanying sketch, for which we are indebted to the London *Mechanical Engineer*, illustrates an invention of Crossley Brothers, which consists of means whereby this form of vaporizer may be retained at a sufficient temperature even without it being necessary to alter the quantity of fuel for the working strokes at different loads. These means consist of providing the engine with a governor which prevents the exhaust valve being opened when the speed of the engine exceeds the normal, and therefore prevents the burnt charge escaping, and also prevents the admission of new charges of either oil to the vaporizer or air to the cylinder. The burnt charge, being retained in this way, is compressed and expanded from time to time, until the speed of the engine is reduced to the normal, when the action of the governor permits this burnt charge to escape and allows the admission of a new charge of oil to the vaporizer and air to the cylinder, the two being afterwards compressed, mixed, and ignited as before. During the governing period, when the burnt charge is being compressed and expanded in the cylinder and vaporizer, it remains at a comparatively high temperature, and serves to prevent such rapid cooling of the vaporizer as might otherwise take place. Fig. 7 illustrates the cylinder of an engine provided with a vaporizer of the type described. In this figure the cylinder, which is water jacketed, is shown at *A*, the piston at *B*, the vaporizer at *C*, the contracted passage between the cylinder and vaporizer at *D*, the air-admission valve at *E* the hydro-carbon inlet at *F*, and the exhaust valve at *G*. The governor is not shown.

Regulating Fuel Supply to Oil Engines.—The arrangement shown in the accompanying engraving has been designed for the purpose of utilizing the suction of the main piston of an oil engine for introducing the liquid hydro-carbon into the vaporizer, thus obviating the necessity for using any special means for the purpose.

Fig. 8 is an end elevation of the cylinder and vaporizer of an internal-combustion engine provided with the arrangement, the latter being partly in section, and a vertical section drawn to a larger scale of the regulator suction box, is shown to the left. *A*

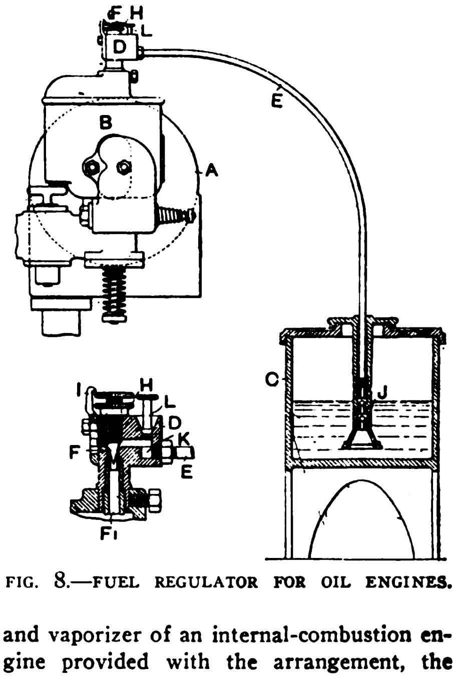

FIG. 8.—FUEL REGULATOR FOR OIL ENGINES.

is the cylinder of the engine and *B* the vaporizer. *C* is the tank containing the supply of hydro-carbon, and *D* the regulator suction box connected with the vaporizer *B*, *E* being the pipe connecting the tank and box together. *F* is the needle valve in the box *D*, by which the quantity of oil to be drawn into the vaporizer through the passage *F*, by the suction of the engine piston can be regulated by adjusting the position of the point of the valve relatively with its seating. *H* is a nut for locking the valve *F* when adjusted. *I* is a pointer arranged in connection with the head of the stem of the valve *F*, the head being provided with a graduated upper surface. *J* is a double ball valve at the end of the suction pipe *E* within the tank *C* for insuring that the pipe *E* shall always be full of oil; and *K* is a recess in the box *D*, which is located below the level of the mouth of the passage F_1, controlled by the valve *F*, so that the oil from the upper part of the pipe *E* shall not drain past the valve *F* into the vaporizer, the recess *K* forming a small reservoir into which the pipe *E* opens. *L* is a screw plug in the box *D*, which plug, when the screw *G* is upon its seat, is removed, so that the pipe *E* can be filled up with oil before starting the engine. By the arrangement described it will be seen that during the out stroke of the piston of the engine oil will be drawn thereby from the tank *C* through the pipe *E* past the valve *F* into the vaporizer *B*, the valve *F* being regulated according to the quantity of oil required for each explosive charge. We are indebted to the *Mechanical Engineer* of London for the foregoing data.

Notes on the German High-Speed Railway Trials.—The *Elektrotechnischer Anzeiger* publishes an interesting article on the recent high-speed railway trials between Marienfelde and Zossen. As is known, these trials have been carried out by the "Studiengesellschaft für Elektrische Schnellbahnen." Preliminary trials and laboratory tests with regard to air pressures at high velocities showed that a parabolic form offered the least resistance, this being about 90 kg. per square metre at a speed of 200 km. per hour. To reduce this item further, Siemens & Halske gave the top of the car a tapered form, so as to appear like a hood. Very little alteration appears to have been made in general design of either of the cars since two years ago. The Siemens & Halske car affords seating capacity for 48 passengers, and is 22 metres (72 feet) long and 2.56 metres (8 feet 4 inches) wide. On the other hand, the car of the Allgemeine Elektricitäts Gesellschaft has a length of 21 metres (69 feet) and a width of 2.8 metres (9 feet 2 inches), and provides room for 40 passengers. Both are built as corridor cars. The bogies are mounted on springs, both spiral and flat springs being used. At the beginning of the tests a wheel base of 1.9 metres (6 feet 3 inches) was employed, the wheels being 1.2 metres (4 feet) in diameter; afterwards these dimensions were increased. Brakes—operated on the Westinghouse system and also by hand—act on every wheel, and an electric brake, actuated by current from a storage battery, is also provided. It is stated that if the brakes are applied when the car is traveling at 200 km. (124 miles) an hour, it travels a distance of 1.5 km. (nearly a mile) before stopping. The cables were placed underneath the floor and on the roof of the car. In the Siemens & Halske car all control operations are done by pneumatic means, the driver having, consequently, only light work to do. Mechanical means were employed by the Allgemeine Elektricitäts Gesellschaft for transmitting these operations to the various apparatus distributed at different parts of the car. For this purpose a main shaft runs along the ceiling of the car. Owing to the construction of the bogies, and also to the high speed of the cars, gearing between the motors and axles was neither possible nor desirable, and the 250-h.p. motors—two for each bogie—are mounted directly on the axle, and in the case of the Siemens & Halske car without the intervention of springs. The Siemens & Halske motor weighs 4 tons, and its rotor is fed with three-phase current at a potential of from 1150 to 1850 volts, the voltage of the stator varying between 500 and 1000. Arrangements are provided to connect the transformer at will, either in star or delta fashion. The Allgemeine Elektricitäts Gesellschaft motor is lighter, weighing only 3.2 tons. Its conductors consist of copper bars, the voltage of the rotor and stator being 325 and 435 volts, respectively. A play of 30 mm. (1.18 inches) between the hollow axle of the motor and the car axle has been allowed by this firm, and a mechanical connection between the two is provided by means of a spring coupling. Siemens & Halske adopted metallic resistances —built up of metal strips—which were well cooled by being placed on the outside the car. Liquid resistances with forced circulation were employed by the Allgemeine Elektricitäts Gesellschaft. They possess the great advantage of gradually increasing and decreasing the working current. The transformers are mounted horizontally beneath the floor and efficient cooling by air presents no difficulties. In the Allgemeine Elektricitäts Gesellschaft's car, the air for cooling was collected from the roof and conducted through pipes to the transformers. A vertical iron pipe is mounted in the car and through it all the cables are conveyed from the roof to underneath the floor. Instead of mounting the three collector bows on one vertical hollow steel post as Siemens & Halske do the Allgemeine Elektricitäts Gesellschaft employs for each bow a separate pole. Of the total weight of about 93 tons, 16.3 tons are in motors, 12.3 tons in transformers and 5.1 tons in resistances. In the course of the trials, however, it became evident that the total weight might be reduced by several tons. Siemens & Halske constructed the overhead equipment. At a distance of 7.4 feet from the center of the track is the line of wooden posts. These are spaced 38 yards apart and carry horizontal iron brackets to which the overhead wires are attached by means of double insulators. A small horizontal play is thus secured to the wires, and this is said to ensure a good contact between bow and wire. A distance of 39 inches separates the wires, which are vertically mounted one above the other. Every kilometre (0.62 mile) the overhead wires are anchored to resist horizontal stresses. At these points section switches are inserted in the line. If a high-tension wire should break, the line conductors are automatically short-circuited. This is performed by a loop of copper wire, which normally encircles a metal rod connected through the track rails to the common point of the three-phase system. When any one wire breaks, the loop is drawn together and comes into contact with the rod. As feeders, both cable (with a copper section of 70 square mm.) and bare copper conductors (section 50 square mm.) were employed. Suitable switches are interposed between the feeders and the line wires. Electric energy is generated at the power station situated at Oberspree by a 2500-h.p. three-phase alternator, delivering current at 6000 volts. Two transformers, connected in parallel, raise the pressure to 14,000 volts. After many preliminary tests and calculations, the actual speed trials were commenced on the line Marienfelde-Zossen, 23 km. (14 miles) in length in 1901. Since the maximum gradients are but 1 : 200, and the smallest curves have a radius of not less than 2000 meters (6550 feet), this line is particularly suited for high-speed tests. The results of these trials and other particulars have been reported from time to time in our columns.

Steam Engine, Turbine, and Gas Engine Compared.—W. A. Chamen, in the course of his inaugural address as chairman of the Glasgow Local Section of the Institution of Electrical Engineers, referred to the increased employment of steam turbines. So successful, he said, had the larger sizes of steam turbine proved that there was a likelihood of his adopting this type of plant before long for the Corporation of Glasgow in connection with its general electricity supply. Referring to gas engines, he said that the capital cost of a gas engine, dynamo, and producer plant at the present time seemed to be considerably more than the cost of steam engines, dynamos and boilers, and was far greater than that of steam turbo-generators and boilers. This was no doubt partly owing to the comparatively low speed of gas engines, and to the fact that in large sizes it did not seem possible to construct vertical engines. The turbine operated by gas pressure was, he thought, little more than a dream. The difficulty appeared to be that the necessary cooling was so expensive as to rob the machine of any efficiency which might otherwise be expected. Saving of fuel was useless if it tended to increase the standing charges. Referring to the question of superheating, he said this had not been successful hitherto, owing probably to the difficulties of keeping the amount of superheat of the steam within the necessary limits and of finding a lubricant for the internal parts of the engine capable of standing high temperature.

SOME RECENT ELECTRICAL PATENTS

Insulator.—The progress of high-tension power transmission and the tendency toward higher and higher potentials for such lines has resulted in many notable improvements in insulator construction. One of the latest forms of insulators for this class of service is that shown by Fig. 1 herewith and devised by Fred M. Locke. This insulator is of the now well-known sectional or multiple-petticoat type, but it differs from the others of that class in the provision of air spaces between the successive sections of the insulator, these sections resting on each other merely at the edges, as shown at *f* and *g* in the drawing. The sections are fused together at the points of contact. Patent No. 745,284.

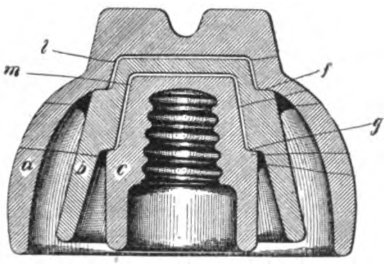

FIG. 1.—HIGH-TENSION INSULATOR.

Induction Motor.—Figs. 2 and 3 herewith illustrate the rotor of an induction motor which has been patented by Donald M. Bliss. The object of the invention is to reduce the starting current required by the motor and the inventor accomplishes this by providing two independent systems of inductors on the rotor, one of these, *b*, having relatively high resistance and the other, *c*, relatively low resistance. The high-resistance inductors are permanently close-circuited, and at starting up these are the effective ones, the low-resistance system being open circuited. As the speed increases, the balls, *h*, are thrown outward by centrifugal force, and their action against the beveled face of the collar, presses that inward against the opposition of the helical spring, f_3, and close-circuits the low-resistance inductors by means of flexible contacts carried by the collar. With the low-resistance system of inductors thus connected up, the presence of the high resistance set has practically no influence upon the operation of the machine. Patent No. 745,772.

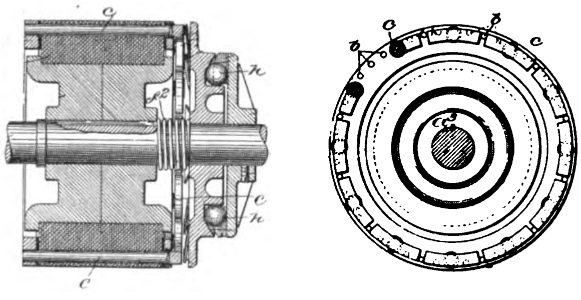

FIG. 2.—INDUCTION MOTOR.—FIG. 3.

NOTES.

Index of the Technical Press—One of the most convenient of the several European publications having for their object the recording of the titles, authors' names and general character of articles appearing in the technical press is the *Index of the Technical Press*, published monthly at Brussels, Belgium, which is just starting on the second year of its existence. Unlike most of the publications of this class, the *Index* restricts its references to the technical articles to a mere statement as to the character of the article, and does not give anything like an abstract or a digest of it, hence its name. The list of periodicals covered by the *Index* is of rather appalling length, and gives a very fair idea of the magnitude of the undertaking.

The Electric Club Journal.—The Electric Club, of Pittsburg, an organization of young engineers connected with the Westinghouse interests, has decided to issue an illustrated monthly magazine which will be known as *The Electric Club Journal.* The first number will appear next month. The chief object in issuing the journal will be to put in a permanent form the engineering papers and technical discussions which form part of the regular work of the club, and many of which are written by members of the engineering staff of the Westinghouse Company. The page of the new magazine will be 6 ins. by 9 ins., and there will be probably 48 pages in each issue. Mr. Frank D. Newbury is the editor and Mr. John H. Smith, business manager.

American Society of Mechanical Engineers.—The annual meeting of this society was held in New York December 1 to 5, inclusive. The address of the president, Mr. James M. Dodge, on the subject of "The Money Value of Technical Training," is worthy of preservation and frequent perusal by all beginners or intending beginners in any branch of technical work. Among the several extremely interesting papers read at the various sessions was one by Mr. C. H. Morgan, of Worcester, Mass., in which the author described very meagerly a proposed gas engine of the walking-beam type to operate on the two-stroke cycle. The description would probably have been of much value if it had been more lucidly presented and not mixed up with remarks concerning a totally different type of gas engine. Mr. Frank B. Perry, Boston, Mass., read a paper on the method of determining rates and prices for electric power, in which he criticised the step rate system, one of the points of criticism being the inconsistency of the method which makes it possible for a consumer's bill to be less for a meter read just beyond the point where the rate changes than it is for a meter reading just below that point. Mr. Perry's argument, however, was not very practical, and the value of his deductions was considerably impaired by his apparent unfamiliarity with the ruling rates for electric power. Other papers were read as follows: "Tests of a Compound Engine Using Superheated Steam," by D. S. Jacobus; "The Pressure Temperature Curve of Sulphur Dioxide Vapor," by Edward F. Miller; "Construction and Efficiency of a Fleming Four-Valve Engine Direct Connected to a 400-kw. Generator," by Benjamin T. Allen; "Slide Rules for the Machine Shop," by C. G. Barth; "What are the New Machine Tools to Be?" by Professor John E. Sweet; "Improvements in the Valve Motion of Duplex Air Compressors," by Sterling H. Bunnell.

Test of the First Turbine for the Interborough Power House.—An interesting series of tests was begun at the Westinghouse Machine Company's works, on December 21, of the first 1250-kw. turbine-generator set for the Interborough Rapid Transit power house. The first two tests, which were completed on December 21, consisted of running under full load with 27 inches vacuum and under the same load with 28 inches vacuum. The generator is a three-phase machine, operating at 11,000 volts, and was loaded by means of a three-compartment water rheostat supplied through transformers at 500 volts potential in order to avoid the difficulties of handling the generated pressure. All measuring instruments were in duplicate and readings were taken every five minutes during the test. The full-load tests were made with 66 amperes in each phase, and after making the usual corrections the results of the first two tests mentioned showed a steam consumption of 20.1 pounds per kilowatt-hour (15 pounds per electrical horse-power-hour) with 27 inches of vacuum, and 19.4 pounds per kilowatt-hour (14½ pounds per electrical horse-power-hour) with 28-inch vacuum. At the finish of the two economy tests, the efficacy of the governor and automatic safety stop was demonstrated. The load was thrown on and off instantaneously several times and the change of speed was barely perceptible. The governor lever was held down so as to leave the turbine uncontrolled and allow it to run away; the safety stop had previously been set for 10 per cent excess over normal speed, and when the turbine attained this the safety stop operated and shut off the supply of steam instantly.

The series of tests is in progress as we go to press, and we regret that time limitations make it impossible to obtain the results from the complete series for publication in this number.

Developments in Gas Motors and Power Gas Generators.—After describing the arrangement and working of suction gas plants, H. Neumann, in a paper recently read before the Association of German Engineers, discussed the problem of cost. For a 60-h.p. plant, the operation by lighting gas, producer gas and electromotors, respectively, were compared both for full and half loads. For outputs as high as 150, 300 and 1000 horse-power steam engines were next compared with producer gas plants, also for half and full loads. It was pointed out that producer gas plants are by no means limited to anthracite, operation by coke being in many cases more advantageous. Cheap anthracite dross may also be employed, though the generator should be made of special form where this fuel is used, and the steam-air mixture introduced under pressure. In an experimental plant of 60 horse-power installed in the workshops of the Gasmotorenfabrik Deutz, 3.6 cubic meters of gas of 1300 heat units per cubic meter were produced from a kilogram of moist anthracite dross (the maximum size of grains being 8 mm. and the percentage of water 10 per cent). As a modern gas motor uses 2000 heat units per horse-power-hour, the consumption of coal will be 0.45 kilograms per horse-power-hour. (Our correspondent evidently refers to metric horse-power and kilogram-calories.) As brown coal plays a specially important part in Rhenania and Saxony, the above firm exhibited a generator gas plant for brown coal at the Duesseldorf exhibition, where with brown coal having a heating value of 2400 heat units, the generator produced from one kilogram of carbon 1.5 cubic meters of gas having a value of 1200 heat units, the consumption of carbon per horse-power-hour thus being 1.12 kilograms. These satisfactory results are due not only to the progress made in the field of generator construction, but as well to the improvements made in gas engines. By a convenient modification of the combustion chamber the builders are able to increase the compression without the danger of premature ignition.

Interstate Independent Telephone Association.—The third general meeting of this association was held at Chicago on December 8, 9 and 10. About 500 delegates and visitors were present, and there was a very good showing of exhibits. Among the papers that were read was an extremely interesting one by Professor J. C. Kelsey, of Purdue University, on the subject of "The Standardization of Telephone Apparatus," and another by W. C. Polk, of Kansas City, on "The Standardization of Telephone Construction." Professor Kelsey in his paper urged that a committee be appointed by the Interstate Association for the purpose of making tests with a view of standardizing apparatus and material for all the independent companies, the committee to be composed of representative telephone engineers. Mr. Polk in his paper suggested a national organization board composed of experienced practical engineers and construction superintendents, this board to furnish advice for investors and operating owners. Mr. H. D. Critchfield, one of the Independent pioneers and now representing the Illinois Telephone Company which put in the Chicago automatic exchange, gave an interesting talk on the subject of the Illinois Telephone Company's progress and plans. The automatic apparatus used by this company is that formerly known as the Strowger ssytem. Mr. Critchfield stated that 21 miles of tunnel had been completed in the Loop district for telephone cables, freight purposes and other public utilities, and that the company proposed ultimately to complete 92 miles of tunnel. He stated that toll line connections would be ready for service into Chicago next fall. The officers for the ensuing year were as follows: H. A. Barnhart, of Rochester, Ind., president; E. H. Moulton, of Minneapolis, Minn., vice-president; E. M. Coleman, Louisville, Ky., secretary; A. B. Conklin, of Aurora, Ill., treasurer. The new executive board consists of O. Rex, North Manchester, Ind.; C. E. Hull, Salem, Ill.; J. S. Bellamy, Knoxville, Iowa; Richard Valentine, Janesville, Wis; W. G. Jones, Columbus, Ohio; H. G. Conger, Hannibal, Mo.; W. Matthews, Maysville, Ky.; C. E. Wells, Kansas; J. G. Splane, Pittsburg, Pa. The association adjourned without day.

A New Rapid Type-Printing Telegraph.—A novel kind of rapid type-printing telegraph is being developed, and has just been brought out in Germany by the Siemens & Halske Company. The apparatus belongs to the class of the so-called automatic telegraphs (Pollak-Virag system) in which the telegram is prepared by a typewriting device piercing for each letter to be telegraphed a given hole or set of holes in a continuous paper ribbon. The latter on being drawn through the rotating telegraphic transmitter will automatically send corresponding current impulses into the circuit. In the Siemens apparatus, two holes are pierced in the paper ribbon for each letter, the letter being also printed in plain type form immediately above, so that the perforated ribbon contains the telegram in distinct readable form. In order to insure the accurate printing of 2000 letters per minute without any delicate mechanical apparatus, the electric spark is employed. A disc in which the various letters are cut out as in a pattern is rotated at a speed of 2000 turns per minute through a spark-gap and a continuous ribbon of photographic paper. Whenever a spark passes in the gap, a silhouette of the letter at that instant in front of the latter is projected on the paper ribbon. It is evident that the spark must be produced with an accuracy as high as one 40,000th part of a second in order to have the proper letter appear at the proper place. The paper ribbon next passes beneath some sponges impregnated with developing and fixing liquids, the photographic process requiring only 9 seconds, and the ribbon is delivered printed. The problem of causing the spark to be produced with accuracy at an instant in accord with the current impulse transmitted from the sending apparatus was solved by utilizing to a high extent the property of electric condensers of being susceptible of charging and discharging in very short intervals. The receiver, apart from the photographic device, comprises a shaft driven by an electric motor on which, in addition to the above-mentioned type disc, some brushes are mounted sliding over contact discs, together with five relays of special design, the tongues of which follow the rapid impulses of the transmitted current. A special and rather ingenious device causes the receiving apparatus to perform in a given time precisely the same number of revolutions as the transmitter.

The Berlin Teletyping Exchange.—A novel exchange, of the class of the ordinary telephone exchange, was recently opened at Berlin. The instruments are printing telegraph machines of a peculiar form, known as "teletypers." The keyboard of the teletyper is similar to that of an ordinary shift-key typewriter, comprising superposed rows of seven keys each. Of these, 26 are transmitting keys, one serves as beginning or letter key, and the other, bearing the inscription "Zahl," is the shift key, the type-wheel having two rows of characters on it. The apparatus may be used either as a sender or as receiver without any special preparation or switching being necessary, both instruments being automatically and simultaneously operated by the keys of either of them. As soon as the "beginning" key of either machine is pressed downwards the circuit of the transmitting apparatus is completed, resulting in a switching roller being set rotating, sending alternating electric currents into the printing circuit and through the line relays connected to the apparatus; the latter control, both in the transmitting and receiving apparatus, local currents which by means of magnets produce the rotation of the type-wheels from the position of rest. When a letter key is pressed downwards, a peg on the other end of its lever strikes against the rotating switching roller brush, stopping the latter and thereby the type-wheels of the machines. At the same time the type levers of both machines are attracted, causing the letter corresponding to the depressed key to be printed. As long as the key is pressed downwards, the type-wheels are held in the position to which they were rotated, so that transmission can be effected at any desired speed. After a telegram is transmitted, both the transmitter and receiver are switched out automatically at a certain position of the type-wheel, stopping the apparatus. Twelve cells of storage battery serve as working battery. The line e.m.f. is about 12 volts, which is obviously so low as to exclude any possibility of an inductive influence by the printing telegraph circuits on neighboring telephone circuits. The central station or exchange just opened is fitted with a switchboard having indicators, etc., for 100 subscribers. As soon as a subscriber presses down the calling key of his teletyper, the switchboard operator is advised by the indicator of the subscriber in question dropping and an alarm being rung, when he will put himself in communication with the caller, ask for the desired connection, and connect both subscribers, almost exactly as in telephone exchange operation.

ESTABLISHED 1889.

American Electrician

A Journal of Practical Electrical and Steam Engineering.
WITH WHICH IS INCORPORATED
Electrical Industries.

CECIL P. POOLE, Editor.

Published on the first of each month by the
McGraw Publishing Company,
114-118 Liberty Street, New York.
Telephone Call, - - - 7606 Cortlandt.
Branch Offices:
Philadelphia: 929 Chestnut Street.
Chicago: Monadnock Block.
Cleveland: Cuyahoga Building.
London: Hastings House, Norfolk Street, Strand.

The New Year.

To all of our readers we extend once more our wishes for a happy and prosperous year. Unfortunate developments in some industrial lines have had a retarding influence upon almost every branch of industry during the past year, but we believe firmly in the "never say die" disposition which incites men to smile in the face of misfortune and refrain from croaking. If we are not very much mistaken, most of the electrical fraternity are of that optimistic class and will join us in toasting the New Year and expecting from it the full measure of prosperity.

◆

The Internal Combustion Engine.

The article relating to American gas and oil engines which appears in this number, while it does not include every engine built in this country, is an excellent presentation of the status of gas engine design; there are many builders of gas and oil engines ranging from 5 to 100 horse-power, only two are actually building gas engines of 500 horse-power, and there are just two oil engines of high power designed with regard to electric service. It is a significant fact, however, that several American manufacturing establishments have acquired rights to build gas engines of foreign design, and while this does not appear to be especially complimentary to the engineering talent of this country it at least indicates a commendably enterprising spirit. Referring again to the gas engine article, even the most casual reader will doubtless note that of the engines described, only three work on the two-stroke cycle, and one of these is a toy so far as real engineering is concerned; another is built in the respectable sizes of 100 to 200-h.p. units, while the third compares favorably with large Corliss engines in magnitude of output. The reason for this is very clear. The production of a two-stroke-cycle gas engine capable of a performance equal to that obtainable with the four-stroke cycle is an engineering problem involving prodigious difficulties. Some highly capable specialists have decided that the two-stroke cycle is a sort of sirenical impracticability; others, that an economical two-stroke-cycle engine is merely a matter of high-grade engineering but that the game is not worth the candle commercially. On the other hand, there are engineers of international repute, such as Borsig and the Körtings, who have adopted the two-stroke cycle and are building very large engines of this class.

* * *

A complete self-contained engine working on the seductive two-stroke cycle is evidently impractical in large sizes. Hence it is that the Körting and Oechelhauser machines are accompanied by external pumps for controlling the air and gas. This, however, does not involve a great amount of complication, especially as the pumps are practically parts of the general construction. In both engines a liberal charge of air is sent into the cylinder to clear out the burned gases just before the explosive charge is admitted. We confess inability to conceive that these operations with elastic media can be so exactly controlled as to prevent one or two of three objectionable results, *viz.*: loss of some of the fresh charge through the exhaust ports, retention of a considerable quantity of burned gases, and uneconomical mixture of the incoming explosive charge with the scavenging air left in the cylinder. Since the engines in question are actually doing commercial work of importance, however, it is fair to assume that the disadvantages mentioned have been reduced to commercially negligible proportions. If it were practicable to compress the explosive mixture to 150 lbs. or thereabouts in a separate reservoir and deliver it to the engine cylinder ready for ignition, the two-stroke-cycle engine would at once be placed on the same plane with the steam engine as to the available number of impulses per revolution. Also "if" a reliable and uncomplicated method of doing this is ever devised, the four-stroke cycle will take its place in the same class with the simple D-valve for steam engines and the open-arc lamp.

* * *

In the matter of gas-engine speed regulation, no conspicuous advances appear to have been made during the past five years. The rather uneconomical method of regulation by throttling the explosive mixture is practically the only resort of the gas-engine designer when steady angular motion is essential, as in driving dynamos. The case is different with oil engines, since it seems to make no difference in the completeness of combustion how much air there is so long as there is the minimum proportion of oxygen required by the oil. Moreover, the character of the fuel renders it very easy to vary accurately the quantity admitted and to deliver it against high cylinder pressures. Gas, on the other hand, is not so easily managed, and requires for complete combustion a definite proportion of air; above and below the correct proportion the efficiency of combustion falls off rapidly. The proper proportion of air to gas is widely different, of course, for different gas analyses. Speed regulation by varying the quantity of gas admitted, while working with constant compression, is therefore economical within a very limited range only. Throttling the complete explosive mixture is more economical, and but for the fundamental fact that the efficiency of a gas engine diminishes with a decrease in compression, it would be the ideal means of speed control. Variable expansion on a parallel with that obtained in a steam engine cylinder is not feasible with the prevailing type of gas engine, since there is no sustained pressure in a gas engine cylinder corresponding to the admission line on a steam engine diagram; it is all compression and expansion lengthwise of the diagram.

What Occurs in Telephone Wires.

We are in receipt from a regular reader of a clipping and the very direct query "Is this intended seriously?" The clipping is from the *New York Times* and contains an editorial discussion of "Telephone Phenomena," which we had already read with much interest. Among other things the *Times* writer says "The little disc in the transmitter undoubtedly vibrates. Why the corresponding disc in the receiver should repeat these vibrations if the mass of metal connecting them is inert, those who think that vibrations are not set up in the conductor may be left to explain." The *Times* had previously stated that the human voice caused the 565 tons of telephone wire between Boston and Omaha to "vibrate in unison throughout its several parts," and the present discourse is in reply to a correspondent who contradicted the original statement. We are unable to answer positively our correspondent's inquiry as to the intended seriousness of the *Times'* statements, but inasmuch as journals of its standing do not indulge in hoaxing in their editorial columns, and furthermore since the editorial which last appeared enters into a labored quibble about molecular vibrations to sustain the original assertion as to the Omaha line, it is only reasonable to ascribe sincerity to the writer or writers of both. The effort of the *Times* writer to wriggle out of the uncomfortable position created by the first statement is somewhat amusing but more pathetic. His reference to "those who think that vibrations are not set up in the wire" is an excellent specimen of hedging; it is an easy step from the vibration of a mass of metal as a whole to "vibrations set up within" it, and another short transition thence to molecular disturbances.

It is not necessary to assure any first-year student that a telephone wire is not vibrated in the slightest degree by the voice currents which traverse it. That the *Times* writer knows this quite as well as anyone else is shown by his struggle to identify molecular disturbances with vibrations of the wire as a unit in order to bolster up his original statement. This latter is evidently of the class of quasi-scientific utterances to which many sciolistic speakers and writers resort when they wish to be a little sensational. The reference to the "mass of metal which connects" the transmitter and receiver discs is inaccurate; no such condition exists in an ordinary commercial telephone circuit. But that is not material, since the writer evidently knows that the vibrations of a transmitter are not literally transmitted through the line conductor to the receiver disc; it is only one of the many slovenly expressions employed by the average daily newspaper writer in discussing technical subjects. What actually happens within the mass of a telephone or other electric transmission wire no one knows positively, not even the scientific *Times* man. But assuming the molecular theory to be correct, his contention that the phraseology of the assertion concerning the Omaha line is as accurate as the limitations of language will permit is obviously a desperate excuse, and the claim that that assertion is equivalent to a statement of what occurs according to the molecular theory, or is justified by that theory, is irrational, not to say absurd.

Unnecessary Complications.

A well-known physicist once expressed the opinion that no result should be accomplished by electrical means if it could be brought about any other way. This evidently is an extreme view if taken literally, and it was probably intended to be considered more as an admonition against the unnecessary use of electricity than to discourage one from using it at all. It is, of course, true of electricity, as it is of every other means to an end, that it should not be employed for any purpose if the desired results can be obtained more economically otherwise; when costs are even, however, results should be accomplished by the most direct method always. In this connection "costs" include expenditure of personal vigor and mental effort, and drafts upon similar assets other than money and time. One of the prime requisites to success in engineering is directness—directness of thought, directness of personal effort, directness of mechanical means. Roundabout methods are always wasteful and frequently disastrous in all classes of work except politics—but perhaps politics should not be classified as work.

It is not infrequent that one finds an elaborate aggregation of apparatus used where a much simpler arrangement would produce at least as good and possibly better results. Engine valve-gears and electric motor controllers are fruitful subjects of such elaboration. Among the chief features that caused the instant success of a well-known engine governor are its simplicity and directness of action. Many of the gas engines described in this issue embody those same characteristics. On the other hand, one finds other pieces of apparatus refined and elaborated to such a degree that the interest on the cost of the "improvements" is two or three times as great as any possible gain in economy, even if the apparatus were operated twenty-four hours a day continuously and were not more liable to failure than a simpler design. Quite as frequently, too, complex methods or whole systems are advocated or employed where much simpler and more reliable media serve as well or better. For example, wireless telegraph apparatus has been proposed recently for automatic fire alarm service. If there ever was a case where "any other method" is preferable this surely is one. If anyone should sit up nights for a month ferreting out a list of applications for which wireless telegraphy is wholly unfit this would lead the list. Many actual instances could be cited of the application of means unsuited to the end in electrical engineering and allied branches. The burden of these remarks, however, is not to hold up to criticism anyone's practice, but to urge directness and consistency in engineering methods and designs.

The Hurry Craze.

Mankind was ever inconsistent. We see hordes of unhappy people jammed on the platforms of express trains on the elevated roads, most of whom could just as well ride on a slower "local" train arriving some six, eight or perhaps ten minutes later. Mr. Jones stands in the lobby of an office building talking with a friend for fifteen or twenty minutes, and growls with rage when the elevator gate shuts just too late for him to get that car and forces him to wait thirty or forty seconds for another; or works himself into an ill temper over the snail's pace of the elevator system which takes two minutes to take him up to the top of the building. It is the same way in every phase of city life involving power transit; men grasp frantically at any device to save a few minutes or seconds of time, and demand all sorts of speed characteristics in local transit systems which, when analyzed, do not amount to the value of a dozen handkerchiefs a year to any one person who utilizes his time sanely. Where is it all to stop?

DESIGN FOR A GASOLINE MOTOR.

BY J. C. BROCKSMITH, M. E.

The engine shown in the accompanying drawings is of the high-speed enclosed crank-case type which has become quite conventional in automobile work, but which can also be used for stationary purposes and on account of its high speed is suitable for direct connection to an electric generator for battery charging or lighting.

Provided very close and accurate work has been done in fitting up the parts and under the most favorable conditions of mixture, spark, etc., this motor should develop 5 horse-power at 1000 r.p.m. Its normal speed for continuous operation, however, is 900 r.p.m., and it is suitable for driving a light automobile weighing complete not more than 500 pounds. The motor alone will weigh approximately 125 pounds completed.

Fig. 1 is a sectional view of the complete motor which shows all the working parts in their proper relation. It is obvious, of course, that the machine operates on the Otto or four-cycle plan, having a mechanically operated exhaust valve and automatic inlet valve. The cylinder is water jacketed and the cylinder, head, valve chamber and jacket are all cast in one piece, which obviates the use of packed joints. The cranks are of the disc type, and act as the flywheels of the engine. They are not as heavy as would ordinarily be adopted on a stationary engine having the cylinder dimensions of the engine shown, but in view of lightness and high speed some departures along this line are permissible.

Ignition is by means of the jump spark, the spark plug being screwed into the valve chamber directly below the inlet valve, where it will always be surrounded by fresh mixture during the ignition period. The primary contact maker is located on the extended shaft of the secondary gear, and makes a momentary contact with the spark coil once in every two revolutions of the crank shaft. The period at which the ignition takes place may be adjusted by rotating the ignitor plate through a certain angle around the cam.

The lubrication of the piston, crank and wrist pins, and main bearings is accomplished by the "splash" system. The crank case, being oil tight, is partially filled with oil or a mixture of oil and water which is distributed over the working parts by the rotation of the crank discs. This method of lubrication is open to some objections, but it is about the only simple method which can be applied on a small enclosed motor that must operate for considerable periods without attention.

Fig. 1 also shows the location of the various connections for water, gas and exhaust. Screwed connections are shown, but flanged connections could be substituted without any radical changes in the design.

Fig. 2 is a front elevation of the complete motor which shows the overall dimensions, and is useful in laying down the design of any outfit which includes the motor as part of the driving mechanism. The crank case is provided with two removable plugs, one at the bottom for draining off the waste oil, and one at the top for renewing the supply. There are two ways of keeping a supply of clean oil in the crank case, one being to use a sight feed lubricator which maintains a small but constant supply, and another way is to put into the crank case at intervals a measure of oil which must be determined by experiment and which will last for about two hours running. Fig. 2 also makes clearer the location and operation of the ignition or trembler plate.

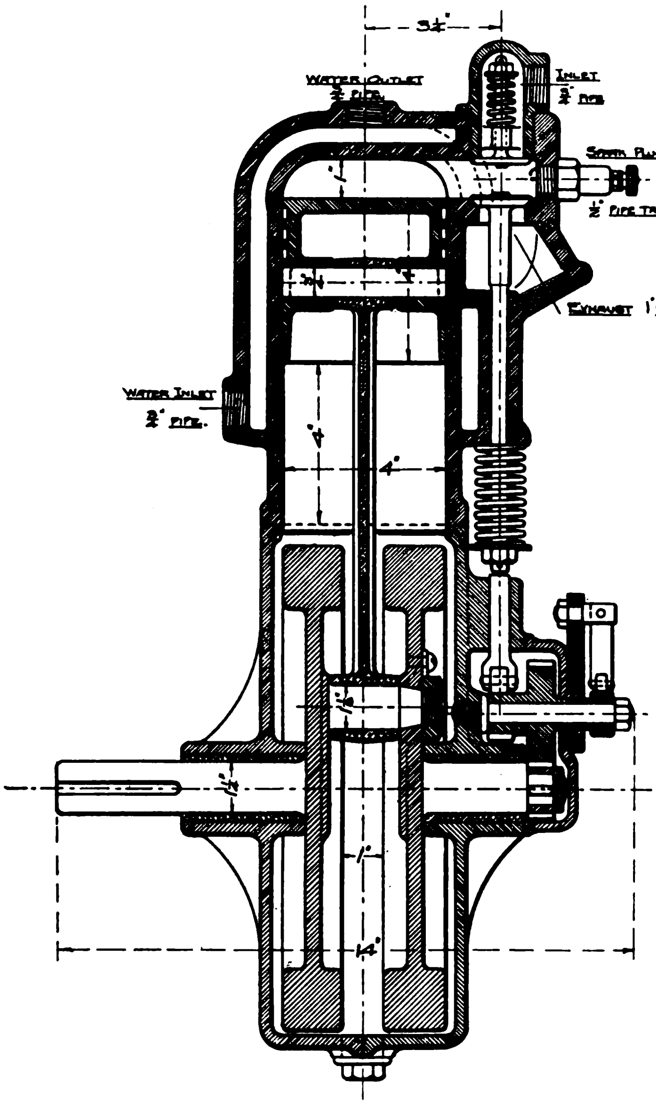

FIG. 1.—SECTION OF COMPLETE MOTOR.

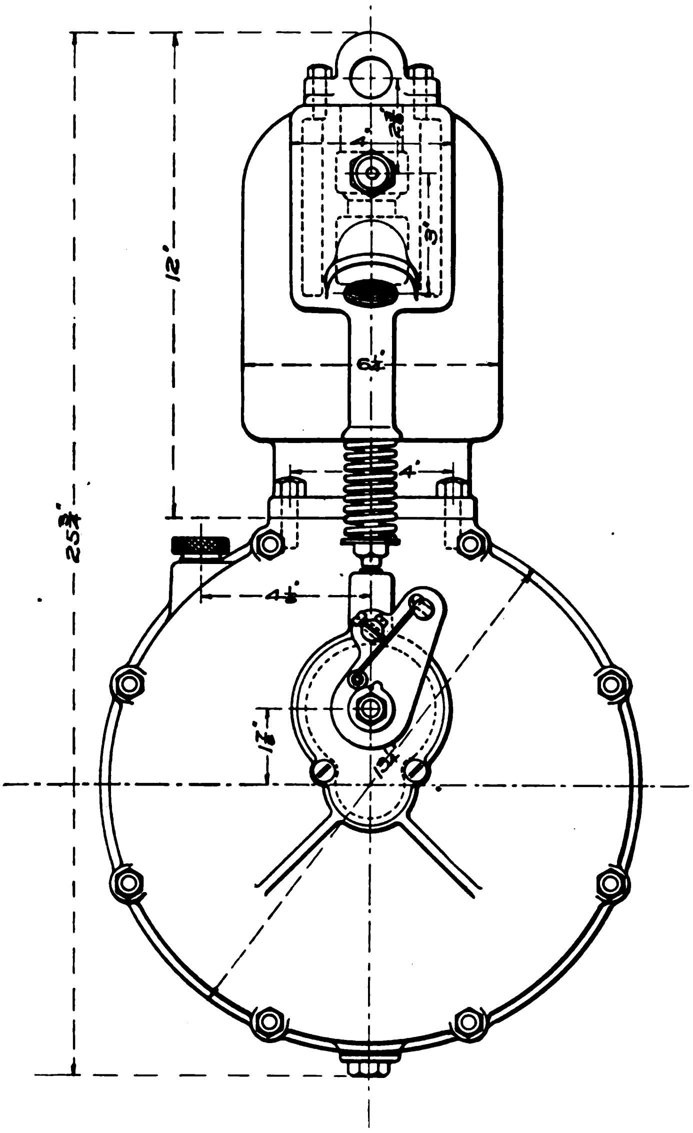

FIG. 2.—ELEVATION OF MOTOR.

Fig. 3 is a plan view of the engine and brings out the shape of the extension on the cylinder casting in which the valves are located. It also shows the lugs extending across the crank case through which are passed ⅜ in. by 5¾ in. studs with a nut at each end to draw the two halves of the crank case together. Some general dimensions are given on this view not shown in other views.

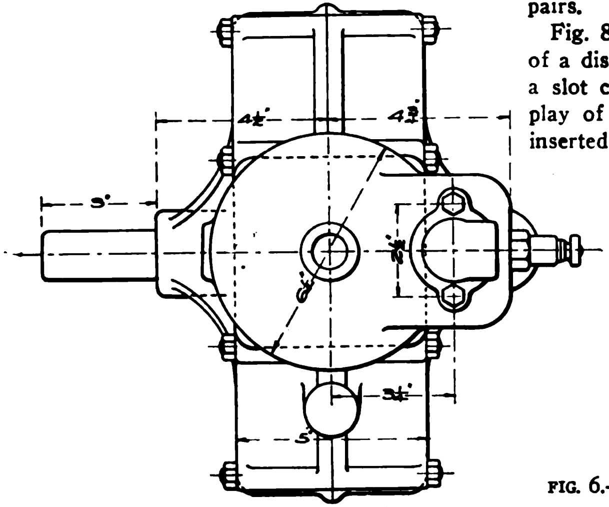

FIG. 3.—PLAN VIEW OF MOTOR.

Fig. 4 is a vertical section through cylinder, water jacket and valve chamber, and shows all the important dimensions of these parts. The cylinder should be cast in good close-grained gray iron; the bore is 4 ins., and should be finished as smooth as possible and of uniform diameter throughout.

The valve chamber should be bored 1½ ins. where the inlet valve casing enters it, and the seat of the exhaust valve should be finished to an angle of 45 degs., and the hole for the valve stem drilled exactly concentric with this facing. The end of the cylinder should be faced and a tongue turned to fit the counter-bore in the crank case.

Fig. 5 is an elevation of the cylinder with the valve chamber in section and shows some dimensions of the latter not given in other views.

Fig. 6 is a horizontal section of the cylinder taken through the center line of the spark plug opening. This view brings out the shape of the water space, which does not completely encircle the valve chamber, but is stopped off to allow openings to be tapped for the reception of the spark plug and exhaust pipe.

Fig. 7 is a section of the cylinder taken below the water jacket and shows the flange and the layout of holes thereon for bolting the cylinder to the crank case. For this purpose four ½-in. by 1¼-in. hexagon cap screws may be used, or four ½-in. studs may be screwed permanently into the crank case and the cylinder held on by means of ½-in. hexagon nuts threaded on these studs.

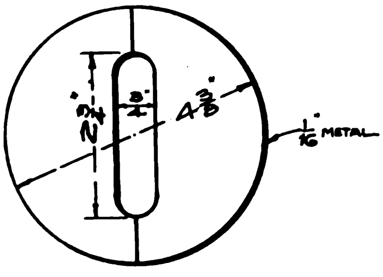

FIG. 8.—SPLASH PLATE.

This latter is the better method to use if it is thought likely that the cylinder will be frequently removed for inspection or repairs.

Fig. 8 is the splash plate which consists of a disc of sheet brass 1-16 in. thick, with a slot cut out in the center to allow free play of the connecting rod. This plate is inserted in the counter-bore of the crank case and acts as a diaphragm between the cylinder and crank case to prevent an excessive amount of oil from being thrown into the cylinder, which would foul the spark plug and thus prevent proper ignition. The size of the slot may be varied somewhat until the proper amount of lubrication is obtained.

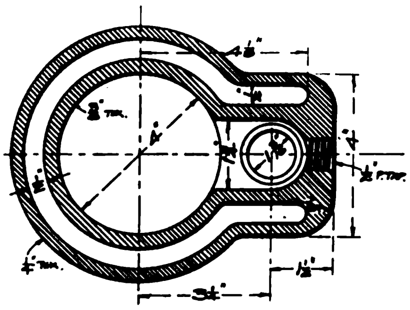

FIG. 6.—SECTION OF CYLINDER THROUGH VALVE CHAMBER.

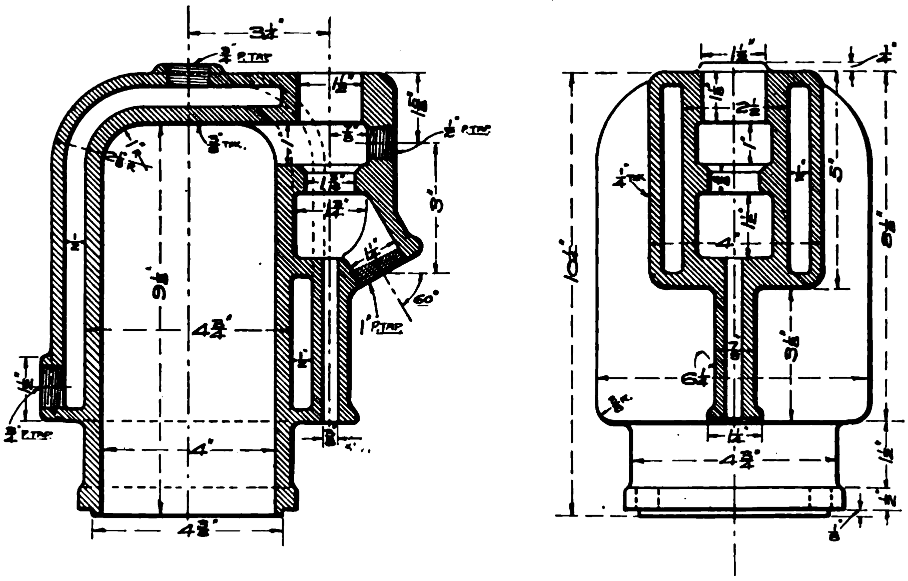

FIG. 4.—SECTION AND ELEVATION OF CYLINDER.—FIG. 5.

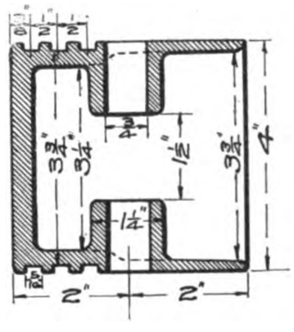

FIG. 9.—DETAIL OF PISTON.

Fig. 9 is a detail of the piston; this also is of cast iron and is provided with three grooves, ½ in. between centers, for receiving packing rings of cast iron 5-16 in. wide. These rings should be turned up about 1-64 in. larger than the bore of the cylinder, and about ⅛ in. thick. They are then cut through with a diagonal saw cut, taking out about 1-32 in., and are fitted to the bore of the cylinder so that the ends stand the merest trifle apart. When they warm up during running they will expand somewhat and become tight.

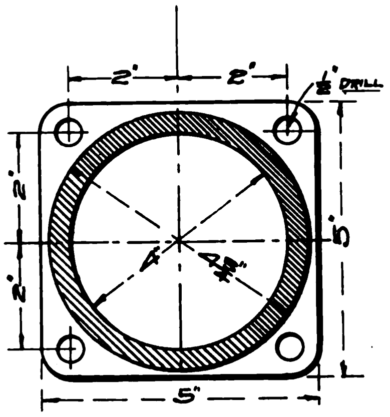

FIG. 7.—SECTION OF CYLINDER BELOW WATER-JACKET.

The body of the piston itself should be turned an exact running fit for the bore of the cylinder. The grooves should be carefully turned to a nice fit for the rings, and the rings can then be snapped into place. A ¾-in. hole must be bored for the wrist pin.

The fitting of the piston and its rings to the cylinder forms the most delicate part of the work on a gasoline motor and upon the accuracy of this work the efficiency and developed power depend to a large extent. The motor will, of course, run hard when

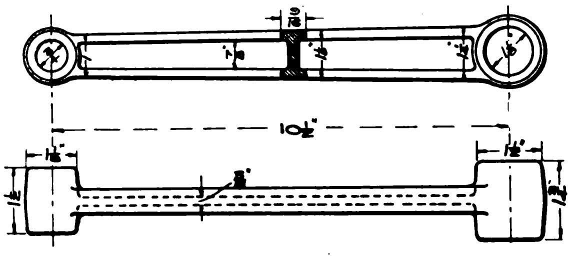

FIG. 10.—CONNECTING ROD.

first assembled, and should be driven by outside power at a moderate speed for a couple of days with a liberal supply of oil to limber up the bearings and piston.

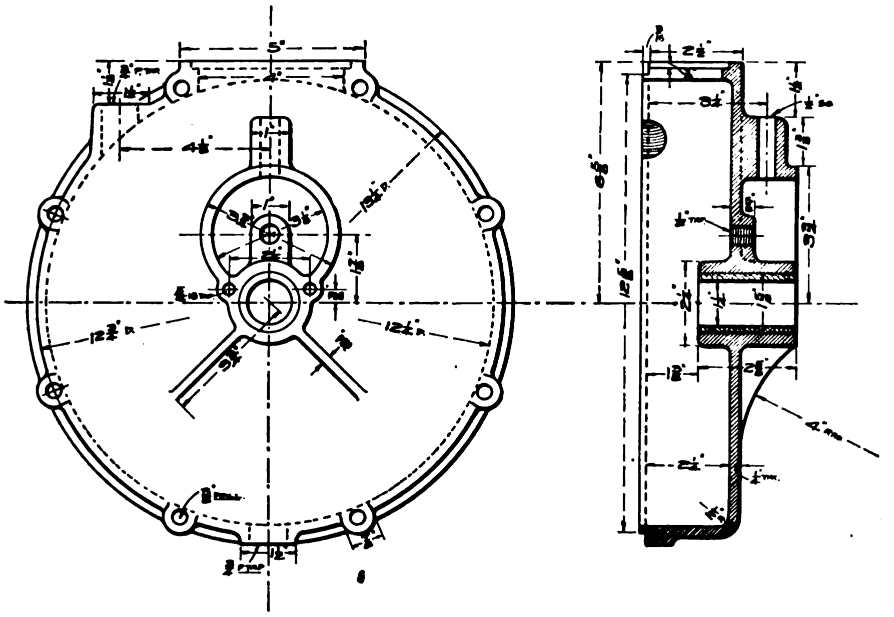

FIG. 11.—CRANK CASE.

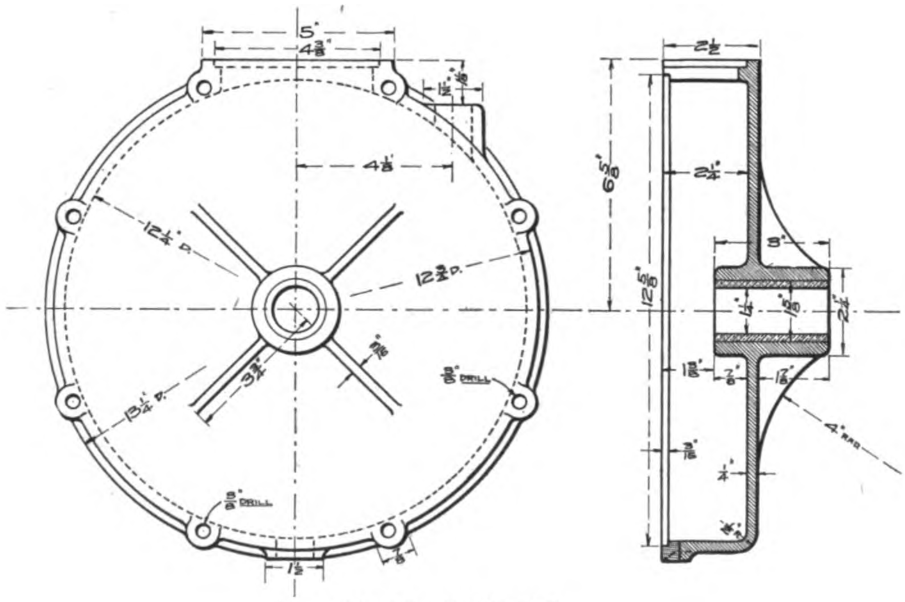

FIG. 12.—CRANK CASE.

Fig. 10 is a detail of the connecting rod which is intended to be made of a phosphor bronze casting. The only work necessary on this is the boring of the ends of the rod.

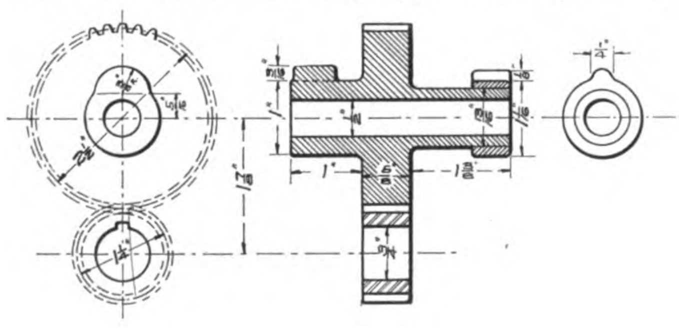

FIG. 15.—VALVE GEARS AND CAMS.

Fig. 11 shows a front view of the crank case on the valve gear side of the engine, and also a section of the same. This case is intended to be cast from aluminum-zinc alloy, containing 25 per cent to 30 per cent of zinc. Eight lugs, equally spaced around the outer periphery, are drilled for ⅜-in. studs to bolt the two halves of the crank case together. The bosses for the crank shaft bearings are provided with phosphor bronze bushing 3-16 in. thick and ribs are used to stiffen the case. The exhaust valve cam and gear are enclosed in a small box, cast integral with the crank case; the upper portion of this box serves as a guide for the exhaust valve opener; the hole is ½ in. square.

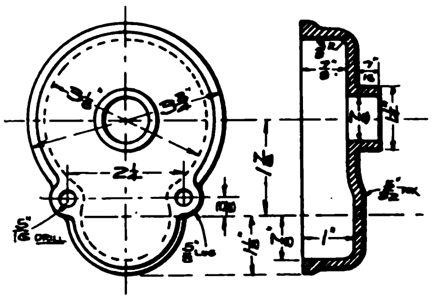

FIG. 13.—GEAR CASE.

Fig. 12 shows the other half of the crank case. This is similar to the one just described, and is cast of the same material. It does not, of course, have the gear case. One pattern can be made to answer for both halves, as they are so nearly alike that by making a couple of small changes, castings which are mates can be obtained. After bolting the two halves together they must be faced and counter-bored at the top to take the cylinder and the holes for the oil plugs must be drilled and tapped. It will be noted that where the halves come together they are matched with tongue and groove; this joint should be turned a good fit, as otherwise the oil will leak out.

Fig. 13 shows the small gear case cover which is fastened to the crank case by means of two 5-16-in. by 1¾-in. machine screws. This is cast of the same material as the crank cases, and it serves to encase the two to one reducing gears for the valve motion. It is intended that this be packed with some heavy grease to minimize noise and wear of the gears and cam.

Fig. 14 gives the dimensions of the crank discs. A departure has been made in the construction of these discs, in that there is only one screwed joint inside the crank case instead of four, as is the usual practice, with a consequent reduction in liability of the parts working loose and causing trouble. The crank discs would best be made of cast steel, but if for any reason this cannot be obtained cast iron could be used. It is not necessary to turn the discs all over; this involves a considerable amount of work, and only those parts which are to be a working fit actually need to be turned.

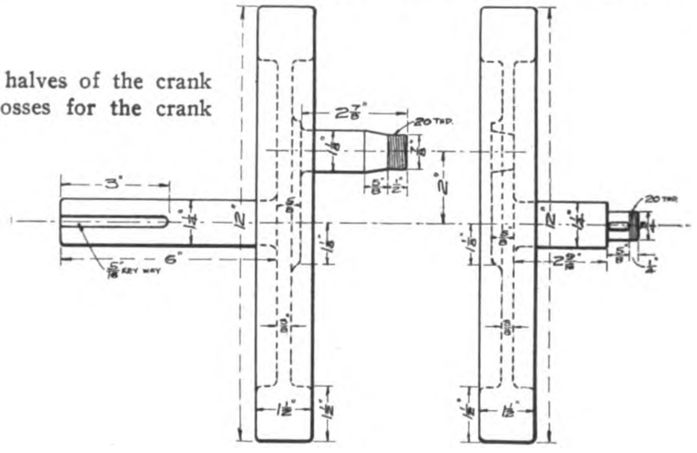

FIG. 14.—CRANK DISKS.

The cranks are not counter-balanced, but balance weights can be added if desired and screwed to the web of the discs. The exact size of these wights can best be determined by experiment. It should not be expected by the builder that the engine can be made to run entirely without vibration, no matter what arrangement of balance weight is used. There will always be a considerable amount of vibration in a light motor of this type due to the unbalanced explosion pressures in the cylinder, which cannot be eliminated.

Fig. 15 gives the dimensions of the gears for operating the exhaust valve; these are 12 pitch, with ⅝-in. face, and have 15 and 30 teeth, respectively. The large gear can be made of cast iron, but the small gear is to be of machine steel. The exhaust cam may be cast in one piece with the gear, or it can be made of tool steel and hardened. The ignitor cam is, of course, made separate, so it can be set in its proper relation to the exhaust cam. The engine can be set to run in either direction, according to the relative position of these cams.

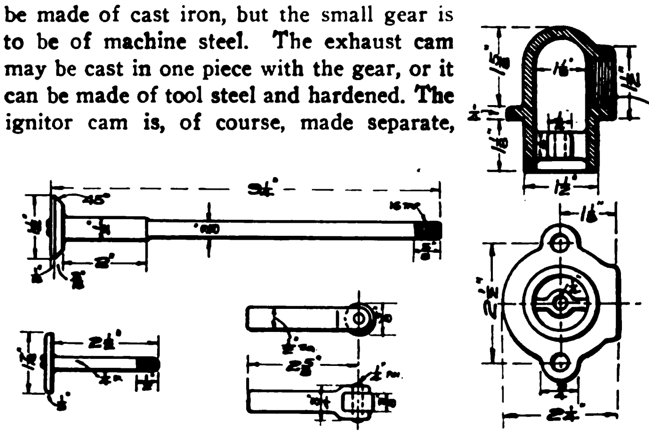

FIG. 16.—DETAILS OF VALVE CASING AND VALVES.

Figs. 16 and 17 show the details of the inlet and exhaust valves, the exhaust valve lifter, and the inlet valve casing. The valves should be turned from steel drop forgings, and should then be fitted and ground into their seats. The exhaust is finished to a 45-deg. angle, while the inlet valve has a flat seat, which makes it less likely to stick. The exhaust valve lifter consists of a square shank having a steel roller inserted in one end.

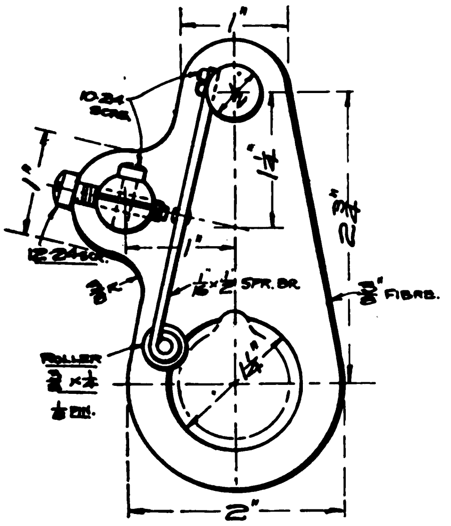

FIG. 17.—CONTACT MAKER.

The inlet valve casing is of cast iron, and is to be finished 1½ in. in diameter, where it fits into the cylinder casing; also the end is faced off to form the seat of the inlet valve. The exhaust valve spring should be quite stiff and strong, a No. 10 Bessemer steel wire coil, 1¼ inches outside diameter, will be about right. The inlet valve spring, on the other hand, should be quite light, and the motion of the valve must be limited, by means of a sleeve slipped over the valve stem, to about ⅛ inch. The lift of the exhaust valve is about 3-16 inch.

Fig. 18 is a detail of the trembler or contact makers, the function of which is to send an impulse of current through the primary of the spark coil, at the time when the spark is required to pass in the cylinder. It consists of a cam working a roller and spring blade, upon which a platinum contact is riveted. The stationary contact consists of a screw having a bit of platinum riveted or brazed into the end. A good deal depends upon the proper adjustment of these contacts.

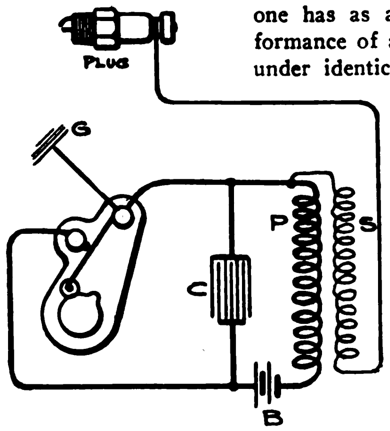

FIG. 18.—DIAGRAM OF CONNECTIONS.

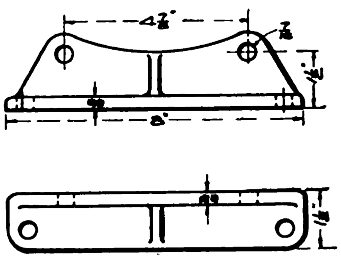

FIG. 19.—BASE.

Fig. 19 is a diagram of connections for the contact maker, battery, spark coil and plug. It will save the builder time and trouble to buy standard apparatus in plug and induction coil for use on his engine. The wiring is quite simple, as one wire is grounded on the frame of the engine, and only two other wires are necessary, one connecting to the spark plug and the other connected to the stationary contact on the trembler. It should be remembered that in this system one other ground will make a short circuit, and consequently particular attention should be given to the matter of insulation. The voltage of the sparking current is very high, and will pierce most ordinary forms of insulation.

Fig. 20 is a detail of the base castings which may be used to support the engine when it is used in stationary work. In this case the two bottom studs of the crank case are made enough longer to pass through the base castings in addition to the crank case. They would also better be made somewhat larger: about 7-16 in. in this case.

To operate the engine on gasoline a carburettor is, of course, required, and here again the amateur will do well to purchase a standard article, as a good carburettor is quite a delicate and complicated piece of apparatus, and the correct proportions of the parts have only been arrived at by long and costly experimenting.

THE CALCULATION OF MAGNET WINDINGS

BY CECIL P. POOLE.

All text-books abound with formulas for the calculation of magnet windings to give a predetermined exciting force, so that there is no lack of information concerning the fundamental principles of this work. When it is considered that in practice the resistance of a given coil may vary as much as 20 per cent. due to temperature difference, and that it is utterly impossible to predetermine what the temperature of a coil will be under operating conditions, unless one has as a guide a record of the performance of a similar coil, or one operated under identical conditions of heat dissipation, it will be evident that the fundamental formulas can serve merely as instructive guides and not as definite means for working out the desired winding.

Just ten years ago the present writer deduced and published the formula

$$d^2 = \frac{K\,At\,L_m}{V}$$

in which

d^2 = Circular mils of the wire to be used.

K = A constant depending upon the temperature of the coil and quality of the wire.

At = The ampere-turns to be obtained.

L_m = The mean length per turn of wire, in inches.

V = The volts at the terminals of the coil.

But for the fact that K may vary between 0.85 and 1.1, according to the temperature of the winding and the quality (specific conductivity at a given temperature) of the wire, the most exact results could be obtained by the use of this formula.

With the best commercial grade of magnet wire, and at a temperature of 135° to 140° Fahrenheit, the constant K becomes unity and may therefore be dropped from the formula. Table I herewith has been calculated on this basis, and will be found of immense convenience when the conditions are as stated. When they are not, the table is worthless. Since the conditions mentioned are entirely practical, the writer has made it a practice to insure that the finished winding of a magnet shall conform to them, in order that the advantages of the table may be realized in all cases. The method of accomplishing this confers inherently the further advantage of enabling one to predetermine with absolute accuracy just what exciting force will be required in the winding of the magnet in order to obtain the desired performance.

This method consists broadly of winding temporary test coils for the magnet of wire much heavier than can possibly be required for the permanent winding, and passing the proper currents through the test winding to obtain the desired magnetic and heating results. The winding is, of course, supplied from some source of current having a considerably higher e.m.f. than is necessary to excite the magnet normally with this winding, and either a water rheostat or submerged rheostat is used to graduate the current. The test coils should be wound to the dimensions that the permanent coils are intended to have, so that the radiating conditions, mean length per turn, etc., will be practically the same in both the test and permanent coils.

Before consideration of the winding is reached, the magnetic circuit to be excited must, of course, have been correctly proportioned, and it is assumed herein that this has been done, with the possible exception of the length of that part of the magnet core that is to be enclosed by the coil; this will depend on the length of coil necessary to provide the proper amount of radiating surface. It may develop, therefore, that after a magnet has been built, it will be necessary to rebuild it in order to get sufficient core length within the coil. This can usually be avoided, however, by making the core length of the first magnet a little longer than comparison with some similar magnet would suggest.

TABLE I.—Relation between Wire Size, Mean Length per Turn, and Ampere-Turns per Volt of Applied E.M.F.

Note:—The figures in lines *A, B* and *C* at the heads of the columns are Wire Numbers, in B. & S. Gauge. Those in the columns *a, b* and *c* are Ampere-Turns per Volt (At ÷ V); the numbers in column *a* correspond to the wire sizes in line *A;* those in column *b* correspond to the wire sizes in line *B*, and those in column *c* to the wires in line *C*.

a	*b*	*c*	*A* 4 *B* 14 *C* 24	5 15 25	6 16 26	7 17 27	8 18 28	9 19 29	10 20 30	11 21 31	12 22 32	13 23 33

The above numbers (in the body of the table) are mean lengths per turn, in inches.

As previously stated, Table I is based on the use of first grade magnet wire at a temperature of about 140° Fahrenheit. The specific resistance of soft copper at that temperature is 12 ohms per mil-foot, and the resistance per foot of standard sizes of wire on this basis is given by Table II for all sizes that are likely to be used in winding magnets. Now, in order to avoid the difficulty of making tests of the quality of the magnet wire available for winding a given magnet, it is necessary to adjust the current passing through the test winding until the resistance per foot of the winding corresponds with the resistance per foot given by Table II, after the winding has been in circuit for five hours. An approximation sufficiently close for all practical purposes can be obtained by adjusting the current to such a value that the resistance per foot of the wire in the test winding is brought to a value just half-way between the resistance at atmospheric temperature, and that given by the table when the winding has been in circuit one hour. The current necessary to accomplish this, or the more accurate result, should be accurately noted; its value is represented throughout this article by the symbol I_h.

Before doing this, however, the exciting current in the test winding should be adjusted to the value that produces the results desired from the magnet, and this value noted accurately; it is represented throughout this article by the symbol I_x. In the case of a magnet for tractive purposes, the current I_x must be such as to cause the magnet to lift its load promptly and firmly every time the switch controlling the supply of current is closed. Having made this test, the test for coil resistance under working conditions should be made as described.

TABLE II.—Resistance of magnet wire at 140° temperature, Fahrenheit.

Wire No.	Resistance per foot.	Wire No.	Resistance per foot.
4	0.0002875	19	0.009316
5	0.0003625	20	0.01176
6	0.0004571	21	0.014814
7	0.00057662	22	0.018691
8	0.0007268	23	0.023575
9	0.0009168	24	0.0297
10	0.001156	25	0.0375
11	0.0014575	26	0.04725
12	0.001838	27	0.05956
13	0.0023175	28	0.0751
14	0.002922	29	0.09471
15	0.003684	30	0.1194
16	0.004646	31	0.1506
17	0.00586	32	0.1899
18	0.007389	33	0.2395

The number of turns of wire in the test coil will, of course, be known, and the product of this number and the current, I_x, is the required exciting force in ampere-turns. The mean length per turn of wire in the permanent winding will be the same as that in the test winding, subject to minor corrections that may prove necessary in rounding out the final results. Tentatively, at least, the mean length, L_m, will be equal to

$$\frac{G_t + g}{2}$$

in which G_t is the girth of the test coil and g the girth of the bobbin or form in which it was wound. Having the ampere-turns required, the mean length per turn of wire and the voltage that will be applied to the terminals of the coil (or each coil, if there are more than one), the size of wire that must be used in the permanent winding is obtainable by the application of Table I. It may happen, of course (and usually will), that none of the mean length values in the table will be found to correspond with that of the test winding; in that event, the nearest table value may be adopted and the mean length per turn of the permanent winding made to conform to this. In many cases it will be found that both the excitation per volt and the mean length per turn of the test winding will differ from all values in the table; in such a case, the nearest mean length value in the table should be adopted which gives the nearest excitation per volt *in excess* of the desired value.

The table is worked out on the assumption that any two wires drawn to B. & S. gauge and differing in size by ten gauge numbers will have cross-sectional areas differing in the ratio of 1 to 10.163 or 10.163 to 1, according to which wire is considered first. This is not strictly true; the ratio of areas is 10.163 to 1 for Nos. 4 and 14, 10.166 to 1 for Nos. 14 and 24, and 10.16 for Nos. 23 and 33. The differences are obviously too small to be of practical importance, however.

As stated in the note at the head of the table, the ampere-turns per volt in column *a* apply to the wire sizes in line *A* across the top of the table; the ampere-turns per volt in column *b* apply to the wire sizes in line *B*, and those in column *c*, to the wires in line *C*. Thus, if a coil wound with No. 8 wire has a mean length of 45.11 inches per turn, its exciting force will be 366 ampere-turns for each volt at its terminals; a coil of the same mean length but wound with No. 18 wire will have 36 (not 36.6, by the way,) ampere-turns per volt, while a coil of No. 28 wire with the same mean length per turn will yield only 3.54 ampere-turns per volt of applied e.m.f. It may be stated that the table is calculated on the basis of the wire sizes in line *B* and the ampere-turns per volt in column *b*, hence the latter values are not numbers from which decimals have been dropped, but are exact.

TABLE III-a.—For Correcting Length of Magnet Coil.

It	Length of test coil: *Lt*.

If the winding is to operate at constant potential, as most magnet windings do, the watts dissipated will be exactly proportional to the current passing, and this will be inversely proportional to the length of the coil parallel with the magnet core if the girth and temperature remain constant. The temperature will be unchanged, of course, the value I_h, of the current necessary to produce the working temperature having been ascertained by trial, as previously described. If the girth of the permanent winding cannot be made identical with that of the test winding, the correction in dimensions will be simple. First, the proper length on the hypothesis of unchanged girth must be determined. As the temperature of the coil is a function of the heat dissipated per unit of effective radiating surface, and the radiating surface is approximately proportional to the length of the coil parallel with the core (assuming the girth fixed), the heat dissipated per unit of surface will be approximately proportional inversely to the square of the coil length. Therefore, if the girth of the permanent winding were identical with that of the test winding, the proper length of the permanent coil would be given by the equation.

$$L_t \times \sqrt{\frac{I_x}{I_h}} = L_c \text{ ....} (1)$$

in which L_t is the length of the test coil and L_c the *calculated* length of the permanent coil on the basis of unchanged girth. Table III (divided into four sections, III-a, III-b, III-c and III-d, for convenience in pasting in a data book) gives the corrected coil length, L_c, corresponding to a considerable practical range of test coil lengths, L_t, and ratios of I_x to I_h. If no correction in the mean length per turn is necessary, this set of tables will, of course, give the proper length, L, of the permanent coil, which in such cases is identical with L_c. If a correction in mean length is necessary and is such as to alter materially the girth of the coil, and therefore the radiating surface per unit of length, after making the correction in mean length, as explained in a preceding paragraph, and ascertaining the calculated length of coil, *Lc*, by means of Table III, the final value for the length (*L*) of the permanent coil may be obtained by means of the formula

$$\frac{L_c \times G_t}{G} = L \ldots\ldots\ldots\ldots(2)$$

G being the girth that the permanent coil will have after correcting the mean length per turn, and G_t the girth of the test coil.

For convenience in making corrections in the mean length per turn and the girth of the finished coil, Table IV (divided into IV-a to IV-f inclusive) has been prepared. This gives the depth of coil that will be obtained with different numbers of layers of the standard sizes of magnet wire, single and double cotton covered.

The table is based on the insulation thicknesses used by the Roebling factory, and while the coil depths are given to the second and third decimal places, it will, of course, be understood that this is not intended as an intimation that coils can be wound in practice to any such degree of accuracy, even if the insulation ran absolutely uniform always, which it does not do. The full figures are given in this, as in Tables I and II, merely in order that one may see what the exact theoretical values are. The table has not been made to include very small sizes of wire, for the reason that any approach to accuracy in calculations based on the insulated diameters of such wires is impossible.

For coils wound around a continuously convex surface, such as that of a bobbin for a round magnet core or one of oval cross-section, the mean length per turn of wire is readily obtained by means of the formula

$$g + \pi d = L_m \ldots\ldots\ldots\ldots(3)$$

in which *g* is the girth of the bobbin or former in which the coil is wound, and *d* is the depth of the winding (in inch measure, or whatever unit of linear measurement may be used; not in layers). The girth of the coil will be obtainable by means of the formula

$$g + 2\pi d = G \ldots\ldots\ldots\ldots(4)$$

The mean length per turn in a coil wound on a bobbin of substantially rectangular

cross-section will be greater than the value given by this formula on account of the bulging of the wire away from the core in the parts of the winding which cover the straight surfaces of the bobbin or former. This is also true, and to a greater extent, of the girth of the finished coil.

◆ ◆ ◆

OPERATION OF STORAGE BATTERIES AND BOOSTERS.

BY W. T. FERNANDEZ.

The use of the cadmium auxiliary electrode and recording charts for keeping an accurate record of individual cell and general battery conditions has been described in the AMERICAN ELECTRICIAN, the daily operation of batteries, end-cell switches and boosters, which determines the satisfactory or unsatisfactory results of cadmium readings and chart records will be considered in this article.

The type of end-cell switch generally used in this country is shown in Fig. 1. It consists of a certain number of taps from the high-numbered cells of the battery to a double set of switch contacts from which a brush contact extends to a distributing bar connected to the cables feeding the switchboard. The brush contacts are movable and travel on worm shafts driven by motors mounted on the switch frame work. Each motor may be controlled from a distance by suitable switches. Automatic cut-out switches are installed with the mechanism which stop the main contacts directly on the contacts of the cells to which they may be run up or down, thus preventing faulty contact with any of the cells.

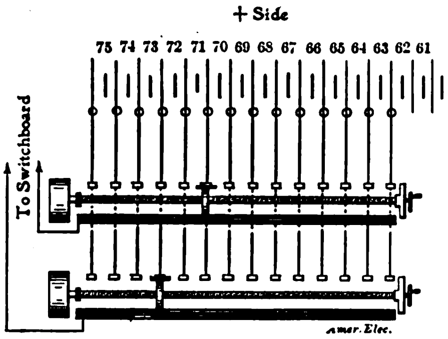

FIG. 1.

As the contact brush travels from one contact to another it must necessarily either open the circuit or short-circuit a cell; this difficulty is overcome by providing a secondary contact of suitable resistance mounted on the same block as the main brush but slightly behind it, so that each cell is close-circuited through that resistance for an instant as the main brush moves forward or backward from cell to cell.

Clutches are provided between the motor and the worm shaft permitting the motor to be disconnected and the worm shaft moved by a hand wheel mounted on its other end, if for any reason the motor fails to operate or become jammed with the brush mid-way between two cell contacts.

The contacts—movable and immovable—must be kept clean and bright with crocus cloth, the moving parts oiled regularly, and if the switches are mounted in a location where the acid fumes reach them, even to a slight extent, the iron parts must be painted with asphaltum paint at least once a year and the copper and brass work rubbed over at frequent intervals with pure sperm or lard oil to prevent corrosion by the acid fumes.

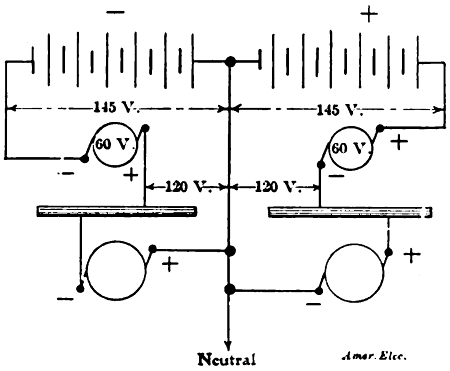

FIG. 2.

The frequent jamming of an end cell switch between two contacts is liable to make the close-circuited cell "slow" in a short time, necessitating a separate charge to that cell. The cause of a switch sticking should always be located at once to prevent possible deterioration of odd end cells throughout the battery. The booster used with a 150-cell three-wire battery usually consists of two 60-volt 36 to 40-kw. direct-current generators direct driven by a motor. They are connected electrically in series with the source of charging current, as shown in Fig. 2.

The source of supply being constant the charging voltage is varied directly by varying the excitation of the booster dynamo field magnets, the available range extending from the voltage of the supply bus-bars to the sum of that voltage plus the e.m.f. of the booster dynamos. With railway and other batteries without a neutral connection, a single machine may be used, as in Fig. 3.

During a charge if for any reason the voltage of the supply bus-bars drops, the charge will, of course, decrease in proportion to the drop, unless the booster fields are more strongly excited to compensate for the drop of the supply bus e.m.f., and if the drop is excessive the battery will discharge through the booster to the supply bus-bars. For example, suppose there are 60 cells on charge on such side of a three-wire system, each cell having an e.m.f. of 2.3 volts, or a total battery e.m.f. of 276 volts. If the e.m.f. of the supply bus-bars is 240 volts and the added e.m.f. of the booster set is 50 volts, the charge is entering the battery under a pressure of 290 volts opposed by 276 volts counter e.m.f. of the battery. Now, suppose the supply bus-bar voltage drops 14 volts; with the booster field rheostats undisturbed there will be no difference of voltage between the battery and booster terminals, and no current flowing in either direction. But if the supply voltage drops any lower under the above conditions, the battery will discharge through the booster to the bus-bars, the rate of discharge depending on the difference in voltage between the battery and booster terminals. A discharge under these conditions may be controlled within certain limits by increasing the dynamo field excitation of the booster, thus raising the booster's terminal voltage to compensate for the drop of the supply voltage. If the discharge cannot be controlled in this manner, the only course left is to cut down the number of cells in circuit as rapidly as possible, regulating the discharge with the booster fields until the field rheostats are at their weakest point, then switching the battery in on the bus-bars, thus cutting out the booster. To attempt to switch the battery directly to the bus-bars with strongly excited fields on the booster would short-circuit the machines and probably burn them out; it is evident, therefore, that the voltage difference between the intake and the output sides of the booster machines should always be as near zero as possible before switching the set in or out between the supply bus-bars and the battery.

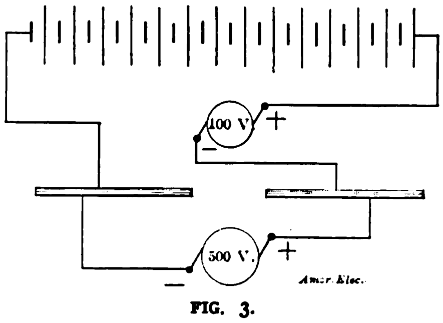

FIG. 3.

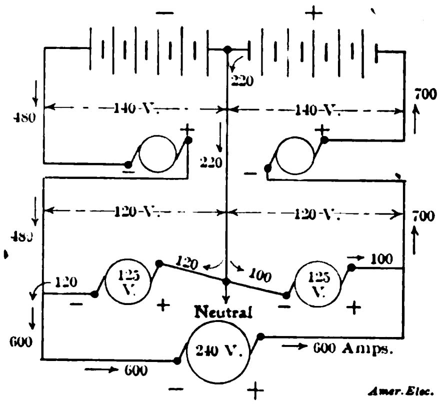

FIG. 4.

Where a battery is connected to a three-wire system but charged from 250-volt generators or rotary converters, an additional piece of apparatus called a compensator is necessary to prevent one side or the other being overcharged or undercharged. The battery discharging on a three-wire system would discharge, on an unbalanced load more out of one side than the other; for example, if the positive side had 3000 and the negative side but 2000 ampere-hours out, when the charge was put back the negative side would be full after 2000 ampere-hours plus about 15 per cent had been charged into it, whereas the positive side would be 1000 ampere-hours short.

With a compensator the rate of charge to one side may be increased so that both sides will reach their maximum e.m.f. at the same time. The apparatus is simple, consisting of two 125-volt machines direct-connected mechanically and connected electrically on the three-wire plan, as shown in Fig. 4. Suppose the negative side has 2000 ampere-hours and the positive side 3000 ampere-hours to go back, and the rate of charge is 600 amperes per side, the field of the negative machine of the compensator set is weakened until that machine receives sufficient current as a motor to drive the positive machine at a high enough speed to furnish the additional current necessary to raise the e.m.f. of the positive side of the battery to its maximum value in the same time required to obtain a similar result on the negative side. The discharge from a three-wire battery may, of course, be balanced with a compensator as well as the charge. Where the unbalance occurs at a definite time and for a definite period, the booster may be used to furnish the additional current required on one side by installing the necessary switches to connect the machines, as shown in Fig. 5.

Where a three-wire battery is in regular operation in conjunction with 250-volt apparatus it is more satisfactory to install a permanent compensator set than to use a booster in that capacity.

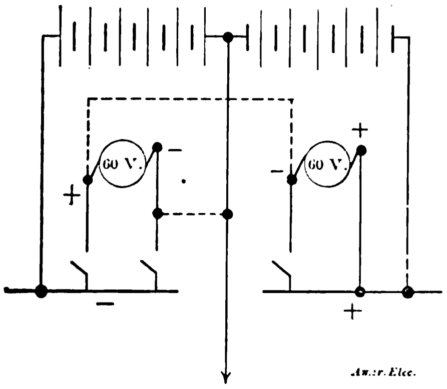

FIG. 5.

A battery without end cells operating on a system which requires the working of all cells or none does not require as much careful attention as one connected to a three-wire system which may require a full or partial discharge of the end cells, in whole or in part, as well as of the main battery.

The requirements of the service may call for a discharge of a certain number of cells at regular periods up to cells 64 to 70, the five cells, 70 to 75, remaining inactive a greater part of the time. As idle cells have a tendency to sulphate under the action of the electrolyte attacking the plates, causing them to harden and decreasing their capacity, it is necessary to discharge the idle cells at regular intervals to keep them in a serviceable condition. When that cannot be done, it is customary to charge them at a normal rate each time the battery is gassed, to work off the sulphate of lead which idleness causes to accumulate on the plates.

The most satisfactory method of keeping account of the battery's capacity where recording charts are not used, is to enter in a book the ampere-hours discharged, add 15 per cent to the total amount discharged and consider the battery full when that number of ampere-hours have been put back into the battery. Where a battery regulates on the bus-bars, which is the usual practice, the book method is not absolutely accurate, but it is a good approximate method of keeping track of the battery's capacity.

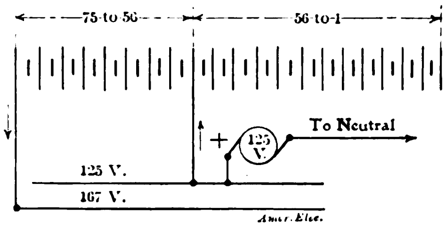

FIG. 6.

In addition to the regular charge put back after each discharge an additional charge, commonly called a gassing charge, is necessary once a week to determine the general condition of the battery and check the book record as to the capacity of the battery. The most satisfactory method of "gassing off" a battery, where end-cell switches are available, is to charge the main battery from the regulating cells downward at the normal rate specified by the manufacturers until the electrolyte boils freely and flows from the center toward both ends of the cells; the electrolyte should change color from limpid to pearl gray and give off numerous bubbles which should explode with a sharp detonation when ignited. Judgment of the correct flow of the electrolyte and proper degree of detonation of the bubbles can be acquired only by experience, but once acquired becomes an excellent guide in keeping track of the cell conditions between the cadmium readings.

Any cell which lags behind its fellows in flowing, detonation of its bubbles or color of its electrolyte should be watched carefully, and if the retrograde action continues, probed, and its specific gravity equalized with that of the other cells. If it remains backward it must be given a separate charge until its action indicates that it has been restored to a healthy condition.

Backward or "slow" cells may be rendered so from several causes: Local short-circuits between the plates, which may be removed by a flat strip of wood moved back and forth between the plates, foreign substances in the electrolyte necessitating refilling the cell, a ground on one cell through a resistance, which will often cause all the cells on that side between the grounded cell and the neutral connection to become "slow" in a period of time depending on the conductivity of the ground and among the end cells, and end cell switches sticking between contacts.

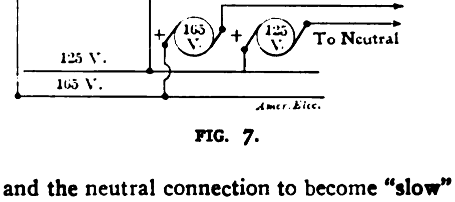

FIG. 7.

After a heavy discharge down to or near the limit of its capacity, a battery should be charged full as soon as possible to prevent the possible reversing of odd cells which may be a trifle "slower" than others connected to them. With the battery practically empty and idle, the higher cells will discharge more or less current into the "slow" cells, frequently reversing them; a prolonged separate charge will usually right a reversed cell.

Buckled plates may be cut out of a cell and straightened by placing them between two flat surfaces and applying pressure to them. The plates should always be well charged, in order to soften them as much as possible, before removal from the cell and charged again when replaced in the cell.

When the main battery has been charged the end-cells from the regulating cell up may be charged direct from the booster by connecting the low side, or side which is connected to the supply bus-bar when charging the main battery, of each booster generator to its respective bus-bar and the high side, or the side which is connected to the battery terminals during main charge may be connected to a spare bus-bar to which is connected the highest end cells. It is necessary, of course, to balance across the two final switches before cutting them in on the bus-bar connected to the high cells.

Cutting out each cell as it is charged, from the highest cell downward, permits a prolonged charge to be put in the cells between the regulating cell and the cell usually used on discharge; the cells mentioned are, as a rule, a little behind the others, and by this method of charging may be kept filled without over-charging the main battery.

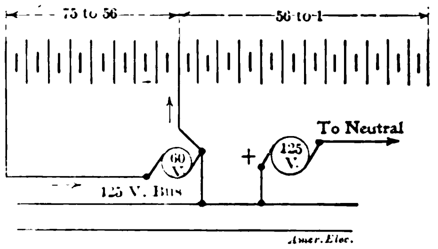

FIG. 8.

The presence of iron in the water supplied to the battery injures the cells; its presence may be detected by adding a few drops of a 10 per cent solution of yellow prussiate of potash to a test tube, two-thirds full, of the electrolyte. If iron is present the solution will turn blue. Where there is any doubt of the freedom from impurities of the water supplied to the cells, distilled water should be used.

A battery equipped with end-cell switches may be used in a number of combinations, and as combination work is more general on three-wire systems than in other work, a series of three-wire battery combinations are shown in Figs. 6, 7 and 8. One side of the battery only is shown; similar connections, of course, are made on the other side of the system. Fig. 6 illustrates a method of boosting through end cells, the e.m.f. of the end cells being added to that of the generator. Care is required that the generator bus-bar does not charge the main battery, as a slow low-rate charge, if persisted in, soon overcharges and injures a well cared-for battery. The extent of boosting is regulated by the number of end cells cut in and an end cell charge put into the cells used when conditions permit.

Fig. 7 illustrates a method of regulating on two bus-bars of different voltages by cutting in one end-cell switch on one busbar with the proper number of cells in circuit and the second end-cell switch on the second bus-bar with the required number of cells to balance with the voltage of the high bus-bar.

Fig. 8 illustrates a method of charging end cells from a booster, at the same time using the main battery for regulation on the bus-bars. The charging current is generated by the booster dynamos and follows a local circuit through the end cells back to the booster generator.

◆◆◆

REDUCING VALVES.

BY R. T. STROHM.

In a large variety of instances it is found desirable to make use of steam at a pressure lower than that at which it is generated. This may occur in a steam plant where the pressure of the steam supplied to the engines must be lower than the boiler pressure; or in paper mills, where it is desired to use low pressure steam in digesters and dryers; or in steam heating systems where a low pressure must be maintained. In many cases, manufacturing plants contain a number of different devices operated by steam, each of which uses, or should use, steam of a certain pressure. The range of pressure thus obtained is often considerable, as, for instance, in a plant where live steam is to be used for heating as well as for operating engines. Manifestly, the engines will not work well with the steam at the pressure of the heating system, and the heating system will not stand high pressure steam. Consequently, there must be some method of reducing the pressure of that portion of the steam which goes into the heating coils. This is accomplished by the use of the regulating or reducing valve.

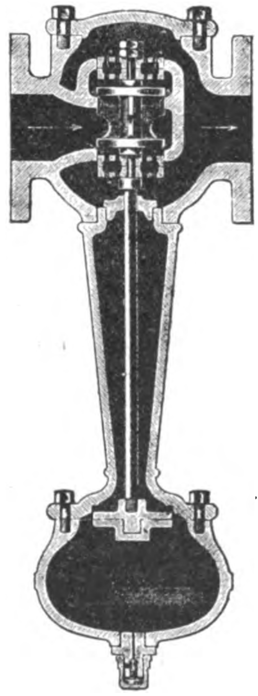

FIG. 1.—DIAPHRAGM TYPE OF REDUCING VALVE.

The action of this valve is, in reality, a simple- wire-drawing of the steam which passes through it, and this wire-drawing effects the desired reduction of pressure, just as in the steam engine any throttling or wire-drawing of the steam during admission causes a drop in pressure between the entering steam and that escaping into the cylinder. The amount of reduction in pressure is, of course, governed by the extent of the wire-drawing. Any desired reduction may be obtained by proper adjustment of the valve. Consequently, in a plant where high-pressure steam is to be used in engines, medium-pressure steam in pumps or auxiliary machinery and low-pressure in heating and drying systems, the reducing valve plays a very important part. Steam may be generated in all the boilers at a pressure equal to that required to operate the engines, and then, by various degrees of throttling by means of reducing valves, the steam necessary to run the auxiliary apparatus may be obtained at the several desired pressures.

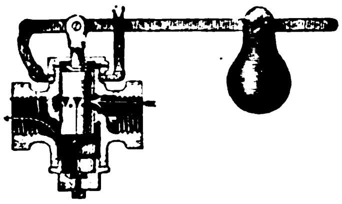

FIG. 2.—SAFETY-VALVE TYPE OF REDUCING VALVE.

A description of the construction and operation of three different types of reducing valves will serve to illustrate the principle of the device. Fig. 1 shows an improved type of steam pressure regulator. As may be seen in the sectional view of the valve, the valve itself consists of two discs fastened to a common stem, the lower end of which is fixed to a diaphragm across the top of the bulb-shaped chamber. The valve thus becomes almost perfectly balanced when under steam pressure. The diaphragm to which the lower end of the stem is connected divides the diaphragm chamber into two compartments, the upper one containing steam at the pressure of the discharge which tends to force the diaphragm downward; the lower one, beneath the diaphragm, is an air chamber into which air is forced by means of a small hand-pump. The pressure of this air obviously tends to force the diaphragm upwards.

Now, it is evident that the discharge pressure depends upon the amount of opening in the main valve. The larger the opening the less the amount of wire-drawing and the greater the pressure on the delivery side. The diaphragm position determines the amount of opening of the valve, and since the position of the diaphragm is determined by the relative pressures on its upper and lower sides, it is evident that by regulating the pressure of the air on the under side, a fixed delivery pressure may be maintained. Increasing the air pressure under the diaphragm increases the discharge pressure and decreasing the air pressure decreases the delivery pressure. This arrangement supports the diaphragm on both sides, distributing the pressure over its entire area, instead of giving pressure on one side only.

In the form of regulating valve shown by Fig. 2, a weight and a lever are used to oppose the action of the delivery pressure and thus determine the valve opening. The weight and lever are external to the valve body, and the pressure at the delivery is changed by altering the position of the weight.

The third type, illustrated by Fig. 3, is of the diaphragm and balanced valve class also, and is controlled and operated by the movement of the diaphragm. This diaphragm is subject not only to the pressure of the steam on the low pressure side of the valve, but also to the action of external springs through the agency of toggle joints. By the adjustment of the spring tension a definite relation between the discharge pressure and the external pressure may be obtained.

The steam from the boiler or other supply enters the reducing valve at *A*, and after passing through the valve, is discharged at *B*. Suppose that steam is turned on for the first time, and that the outlet *B* is connected to an engine. At the moment of admitting steam to the valve, there is no pressure on the discharge side of the valve. The tension in the springs *J*, therefore, will have forced the valve *H* open against the slight resistance of the diaphragm, the amount of opening depending upon the tension of the springs. The steam passing through the valve *H* is throttled, and thereby reduced in pressure. The reduced pressure is immediately transferred, by means of the port *E*, to the chamber *D* beneath the diaphragm and because of its large area the diaphragm is forced upward to some extent, against the resistance of the external springs *J*, and partly closes the valve *H*. This will further reduce the steam pressure at the discharge side of the valve, causing a consequent movement of the diaphragm downward, which opens *H* slightly. A balance is thus quickly established between the force acting upward on the diaphragm, caused by the discharge steam pressure and the force act-

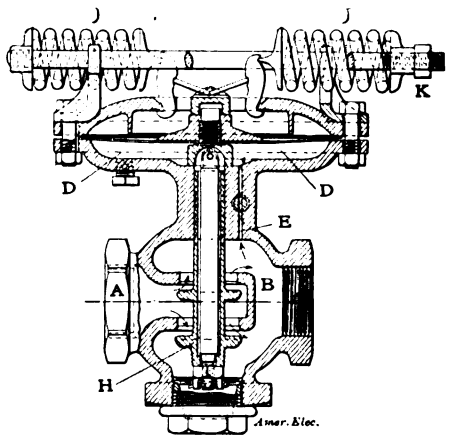

FIG. 3.—DIAPHRAGM AND BALANCED VALVE TYPE OF REDUCING VALVE.

ing downward on the diaphragm, caused by the spring tension. Consequently, if the discharge pressure remains constant the valve will be stationary, but any alteration in the discharge pressure will cause a certain movement of the valve until a new state of equilibrium is restored.

The pressure of the steam on the delivery or discharge side of the valve is regulated by the adjustment of the tension in the springs, which is quickly accomplished by means of the nut *K*. Since the springs act to open the valve *H*, an increase in the tension of the springs means an increased discharge pressure.

The action of the reducing valve is not simply that of lessening the pressure of the steam. The wire-drawing or throttling is accompanied by superheating, in case the steam is dry, or at least in drying it to some extent if it is initially wet. This statement does not mean that the reducing valve superheats the steam above the initial condition of the entering steam. It means that if dry steam is passed through a reducing valve and subjected to throttling action, the discharge steam will be superheated or will possess a temperature higher than the boiling point of water under the pressure on the delivery side of the valve. And i the steam is wet, some of the moisture will be re-evaporated by the wire-drawing.

This point may be made clear by the use of an actual example. Suppose that a pound of steam at an absolute pressure of 100 lbs. is passed through a reducing valve, so that the discharge pressure is 40 lbs. absolute, and for convenience let the steam be initially dry and saturated, and the effects of radiation be neglected. On entering the valve the steam contains 1181.87 heat units. The wire-drawing does not alter the steam weight, so there is one pound of steam both before and after the reduction of pressure. But, one pound of steam at 40 pounds absolute contains but 1163.43 heat units, so that if the steam on the discharge side were saturated steam, it is evident that 18.44 heat units must be accounted for in some manner. The radiation could not have amounted to this much of a loss; the valve and fittings could not absorb it, or they would in time grow intensely hot. The explanation of the disposition of this heat is that the 18.44 heat units remain in the pound of steam at the discharge pressure, and cause it to be superheated, so that its temperature is much higher than 267 degs. Fahr., which is the temperature of saturated steam at 40 lbs. absolute pressure.

The argument has been put forth that dry saturated steam, expanding even under perfect conditions and performing work, will condense somewhat, and that in consequence of this fact there must be condensation in passing through the reducing valve. It is quite true that if saturated steam be allowed to expand in a non-conducting cylinder, and do work, it will condense somewhat. But the steam in expanding in the reducing valve does no external work, and consequently is not called upon to give up any of its store of heat energy to perform external work. The increase in volume which occurs is due to free expansion, or expansion without the performance of external work of any kind, and hence requires no expenditure of heat energy for the overcoming of external resistance.

However, since boilers do not furnish perfectly dry steam, and since radiation losses introduce a certain amount of condensation, there are water globules in the steam that pass through the valve. The wire-drawing of wet steam has an erosive effect upon the valve and its seat, and this erosion is greater as the wire-drawing is greater. Consequently, a good valve should possess working parts of a durable material, and should allow these parts to be replaced at comparatively small cost when too much cut and worn to give good service.

While it is true that the discharge pressure can be varied by adjusting the tension of the diaphragm spring, yet the valve should be designed for a certain definite range of pressure. That is, the same size of valve should not be expected to give all the desired reductions. For if a valve of too great size is used for a considerable reduction, it will be necessary to give it very little lift, and consequently the degree of erosion due to wire-drawing is much increased. Not only does the larger valve cost more, but it is more quickly worn out because of its use to obtain a great reduction. A smaller valve with greater lift, and of less cost, would be better and more economical.

Obviously, to cause wire-drawing, the valve opening will be slight. Hence, to insure satisfactory operation of the reducing valve, it is necessary that all foreign matter be kept out of the valve. In installing new pipe lines on which regulating valves must be used, they should be thoroughly cleaned of all chips, scale, pieces of gasket, and so on, by blowing steam through them before putting in the valves. The additional precaution is frequently taken of placing a strainer of wire gauze on the inlet side of the valve, which effectually arrests any solid matter.

The simpler the construction of the valve, the less liable it will be to become inoperative, and the more readily it can be replaced should it fail to work. A good valve should be so designed that all of its working parts can be quickly and easily examined, which means that all should be quite accessible without the necessity of removing the valve from the pipe line. The location of the springs and toggles outside the valve casing in Fig. 3 removes these springs from the action of the steam and puts many of the working parts in plain view, which is a desirable feature. On the other hand, the complete enclosure of the mechanism within the valve casing, as in Fig. 1, prevents any injury to the working parts such as might occur to the type shown in Fig. 3.

◆◆◆

Coal Storage Under Water.—It has been estimated that at least one-fifth of the power in coal is lost unnecessarily by the method of storage. Coal stored under water, it appears from recent experiments made in England, loses an inappreciable amount of its calorific value compared with that lost by the alternate method of storage with access to air.—*Exchange.*

INDICATOR DIAGRAMS.

BY CHAS. L. HUBBARD.

In a previous article the use of the diagram for detecting the action of the engine valves was discussed. Another use is in the determination of losses in the cylinder due to leaky valves and cylinder condensation. The amount of these losses may be found by weighing the water fed to the boiler, or by condensing the exhaust steam for a given length of time, and then substracting from this the amount shown as doing useful work by the indicator diagram. The difference between the water consumption shown by the actual weighing of the feed water and by computation from the card will give the losses due to leakage and condensation.

The diagram shows by direct measurement the pressure and volume at any point in the stroke of the piston. The weight per cubic foot for any given pressure may be taken directly from a steam table. The method, then, of finding the weight of steam for any point in the stroke is to find the volume in cubic feet, including the clearance and piston displacement up to the given point, which must be taken at cut-off or later, and to multiply this by the weight per cubic foot corresponding to the pressure at the given point measured on the diagram. This will give the weight of steam in the cylinder.

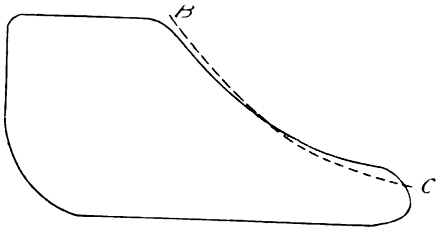

FIG. 1.

As this weight includes the steam used for compression, it must be corrected as follows to obtain the weight used per stroke: Take some point on the compression curve and measure its absolute pressure. Then compute the weight of steam to this point and subtract this weight from the weight of steam to the point taken in the expansion curve already computed; the result will be the weight of steam used per stroke.

The best point on the expansion curve to use for this purpose is that just before release. This is true for two reasons: First, the maximum amount of leakage has taken place, and, second. a certain part of the steam which is condensed during admission and the first part of the stroke is re-evaporated into steam and does useful work toward the latter part of the stroke. This is shown in Fig. 1, in which the solid line represents the actual expansion curve, and the broken line *B—C*, the theoretical expansion curve. The actual curve falls below the theoretical curve during the first part of the stroke, showing condensation and drop in pressure, and rises above it during the latter part of the stroke, showing re-evaporation and rise in pressure above that shown by the theoretical line.

The actual computation of the steam con-

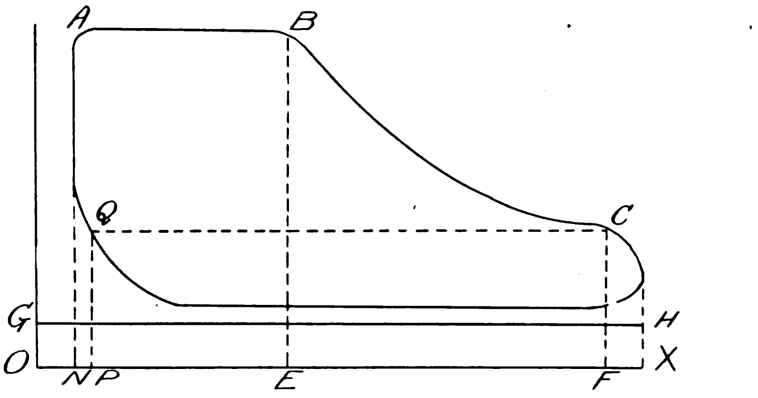

FIG. 2.

sumption from an indicator diagram is best illustrated by working a practical example. Let Fig. 2 represent a diagram taken from a 20-in. by 36-in. engine running at a speed of 80 r.p.m. The card was taken with a 40-pound spring. By measurements the mean ordinate will be found to be 0.91 inch, and the mean effective pressure $= 0.91 \times 40 =$ 36.4 pounds. The indicated horse-power is

$$I.\ H.\ P. = \frac{36.4 \times 3 \times 314 \times 160}{33{,}000} = 166 + .$$

In Fig. 2 *G—H* **is the atmospheric line, and** *O—X* the line of zero pressure so drawn that $O—G = 14.7$ pounds. *O—N* is the clearance volume, which is 8 per cent of the piston displacement. The line *P—Q* is drawn from *O—X* to some point on the compression line. From the point *C* on the expansion line just before release, the line *C—F* is drawn perpendicular to *O—X*. Then measuring from the diagram we have:

$O—X = 3.24$ inches.
$O—F = 3$ inches.
$O—P = 0.375$ inches
$C—F = 0.795$ inches.
$P—Q = 0.795$ inches.

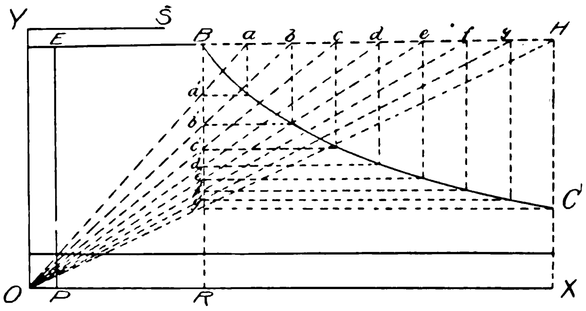

FIG. 3.

The length of stroke is 36 inches, or three feet, and the length of the diagram 3 inches. Then, 1 inch in length on the card corresponds to 1 foot of the stroke. The scale of the spring used is 40, so that one can easily reduce the above dimensions to pounds pressure, and to feet, which gives the following results:

$O—X = 3.24$ feet.
$O—F = 3$ feet.
$O—P = 0.375$ feet.
$C—F = 31.8$ pounds.
$P—Q = 31.8$ pounds.

The area of the piston is 314 square inches, or 2.18 square feet. We can now find the volume of steam at any point of the stroke. When the piston is at *C* the volume is $2.18 \times 3 = 6.54$ cubic feet. When the piston is at *Q*, the volume is $2.18 \times 0.375 = 0.8175$ cubic feet. A steam table shows that the weight of one cubic foot of steam at 31.8 pounds absolute is 0.0777 pound, so that the weight of steam in the cylinder when the piston is at *C* will be $6.54 \times 0.0777 = 0.5081$ pound, and the weight of steam present when the piston is at *Q* will be $0.8175 \times 0.0777 = 0.0635$ lb. The weight of steam in the cylinder at release is 0.5081 pound and the weight kept for compression is 0.0635 pound. The weight exhausted per stroke is therefore $0.5081 - 0.0635 = 0.4446$ pound. This quantity multiplied by the number of strokes per hour will give the weight of steam to be accounted for by the diagram, and this subtracted from the actual weight of feed water used during this time will give the wastes due to condensation and leakage.

There are different methods of constructing the theoretical curve referred to in Fig. 1. One of the simplest is illustrated by Fig. 3. First draw *P—X* equal to the length of the stroke, and *O—P* equal to the clearance, shown as a percentage of the piston displacement. Draw *O—Y* and *P—E* perpendicular to *O—X* and draw *Y—S* parallel to *O—X*, and at a height corresponding to the boiler pressure. The line of initial pressure *E—B* is then drawn parallel to *Y—S* and is usually taken at from 90 per cent to 95 per cent of the boiler pressure if there is no special cause for loss. Then take *E—B* as the portion of the stroke at which steam is admitted. The theoretical expansion line is considered as a hyperbolic curve with *O—X* and *O—Y* as asymptotes. To construct the curve, draw the line *E—B—H* parallel to the atmospheric line, and *X—H* and *R—B* perpendicular to it; then make dots at *a, b, c, d, e, f* and *g* on the line *B—H* and connect them with the point *O*. From the points where the lines *O—a, O—b, O—c*, etc., intersect the line *R—B*, draw lines parallel to *B—H* until they meet perpendiculars from *a, b, c, d, e, f* and *g*. The points of intersection of these lines are points on the hyperbolic curve *B—C*. Enough of these points must be used to determine the curve clearly.

Lessons in Practical Electricity

E.M.F. AND ALTERNATING CURRENT.

It has been explained in a previous Lesson[*] that if a loop of conductive material be mounted on a shaft located midway between two magnet poles, as shown in Fig. 1, and the shaft be rotated, an e.m.f. will be induced in the two sides, *a* and *b*, of the conductor as they sweep past the magnet pole-faces. If the rotation be clockwise, as indicated by the arrows in Figs. 1, 2, 3 and 4, the e.m.f. induced in the loop during its passage from the position of Fig. 1 to the position of Fig. 3 will be in the direction indicated by the arrows on the loop in Fig. 2. When the loop reaches the position shown in Fig. 3 the e.m.f. will have died to zero, and rotation from this position back to the position shown in Fig. 1 will induce an e.m.f. in the opposite direction with relation to the conductor material, as indicated by the arrows on the conductor loop in Fig. 4, which shows the loop midway between the position of Fig. 3 and that of Fig. 1.

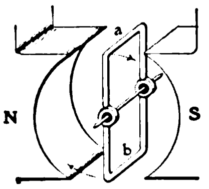

FIG. 1.

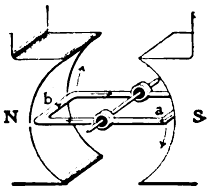

FIG. 2.

It was also explained that this e.m.f., which is in first one direction and then the other within the conductor, varies gradually from zero in the position of Fig. 1 to maximum in the position of Fig. 2; then falls to zero as the loop is brought to the position of Fig. 3; rises to maximum in the opposite direction, in the position of Fig. 4, and again falls to zero as the loop is rotated around to the original position of Fig. 1. This variation in e.m.f. may be made clearer by reference to Fig. 5, where the dots represent one side of the conductor loop, say, the length *b*, in successive positions between that shown by Fig. 1 and that shown in Fig. 3. It will be obvious that with a magnetic field of uniform density, indicated roughly by the horizontal dotted lines, the wire will cut fewer lines passing from position 1 to position **2** than it will in passing from 2 to 3, the number of lines cut in passing from one position to the next increasing as the conductor approaches position 9 opposite the center of

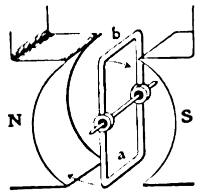

FIG. 3.

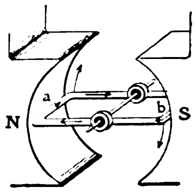

FIG. 4.

---

[*] May, 1902.

the pole-face. After passing this point, the number of lines cut during each increment of motion grows less and less, the decrease step by step being the same that would be observed if the conductor had been stopped at position 9 and returned to position 1. If it be assumed that the magnetic field contains 2,000,000 lines of force and that the actual distribution is absolutely uniform, the number of lines cut in passing from one position to the next will be as stated in Table I herewith. If the conductor loop be revolved at the rate of 62½ revolutions per second, each of the active sides, *a* and *b*, will move from one position to the next (Fig. 5) in 1-2000 of a second, and the rate of cutting the lines of force will be 2000 times the number of lines cut during that movement.

TABLE I.

Between positions.	Lines of force.	Between positions.	Lines of force.
1 and 2	19,210	9 and 10	195,090
2 and 3	56,910	10 and 11	187,590
3 and 4	92,410	11 and 12	172,890
4 and 5	124,360	12 and 13	151,540
5 and 6	151,540	13 and 14	124,360
6 and 7	172,890	14 and 15	92,410
7 and 8	187,590	15 and 16	56,910
8 and 9	195,090	16 and 17	19,210

The e.m.f. generated by cutting lines of force is equal to the number of lines cut per second divided by 100,000,000. Consequently, the succession of e.m.f.'s generated in one wire during the half revolution represented in Fig. 5 will be as given in Table II. If these e.m.f.'s be plotted in the shape of a curve the curve will have the shape shown in Fig. 6, where the horizontal distances represent parts of a second and the vertical distances the e.m.f. generated by the wire in passing from one position to the next. The straight horizontal line is the zero line, and the part of the curve above the line indicates the variation of e.m.f. in one direction, which is usually considered positive, and the part of the curve below the line indicates the variation in the opposite direction, usually considered negative. Such an e.m.f. is termed an alternating e.m.f., and the current which it produces in a circuit is called alternating current, because the polarity of the e.m.f. and current in all parts of the circuit alternates. The e.m.f. curve without the ordinates is reproduced in Fig. 7. This is called a sine curve or wave, and is the basis of all alternating current and e.m.f. diagrams.

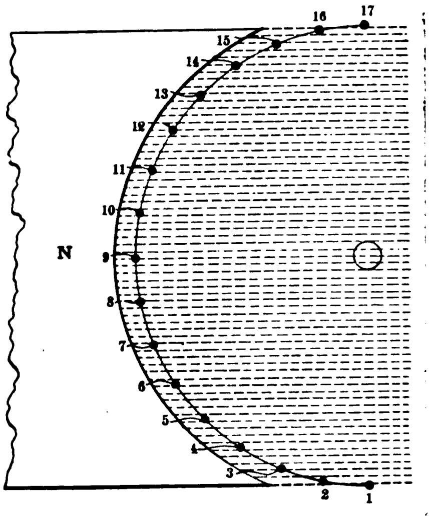

FIG. 5.

If the conductor loop shown in Figs. 1 to 4 inclusive be opened at one end of the shaft and the ends carried to rings against which brushes of conductive material are arranged to rub, as shown in Fig. 8, a closed circuit, *w*, connected to these brushes will carry an alternating current when the loop is revolved between the magnet poles, the strength of the current rising, falling and reversing similarly to that of the e.m.f., as just described. The rotating loop and the collector rings, as they are termed, must, of course, be insulated from the shaft, which would otherwise short-circuit the system. This insulation is represented by the heavy black parts of the diagrams.

TABLE II.

Between positions.	E.M.F.	Between positions.	E.M.F.
1 and 2	0.3842 volts	9 and 10	3.9018 volts
2 and 3	1.1382 volts	10 and 11	3.7518 volts
3 and 4	1.8482 volts	11 and 12	3.4578 volts
4 and 5	2.4872 volts	12 and 13	3.0308 volts
5 and 6	3.0308 volts	13 and 14	2.4872 volts
6 and 7	3.4578 volts	14 and 15	1.8482 volts
7 and 8	3.7518 volts	15 and 16	1.1382 volts
8 and 9	3.9018 volts	16 and 17	0.3842 volts

The armature of a simple alternating-current generator would be wound with a single coil such as that shown in Fig. 8, if the machine had only two poles, but the coil would have a large number of turns. In actual practice alternating-current generators are always multipolar machines, and a machine to generate a simple alternating current usually has as many coils on the armature as there are poles on the field-magnet, the coils being all connected in a single circuit to a single pair of collector rings and arranged on the armature so that at any given moment during the revolution of the armature every coil occupies the same position with relation to the field-magnet poles as that of every other coil. This is necessary in order that the different coils shall not act in opposition to each other.

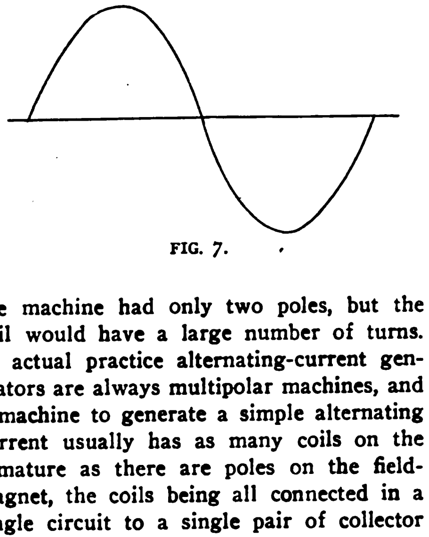

FIG. 7.

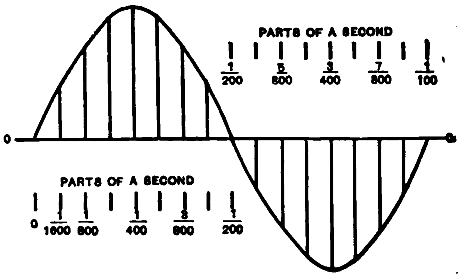

FIG. 6.

The reversals of e.m.f. and current in ordinary alternating-current generators occur as rapidly as 250 or 260 times per second in some cases, the frequency of reversal ranging from this figure down as low as 50 times per second. A reversal occurs, of course, every time the e.m.f. changes from positive to negative and from negative to positive. In Fig. 7, for example, a single reversal is indicated in the center of the diagram, and if the diagram were continued a reversal would be indicated at each of the points where the curve crosses the horizontal line. Two reversals are termed a cycle. It makes no difference whether one considers a cycle to begin when the e.m.f. curve is at the horizontal or zero line, or when it is maximum, or at some other point; a cycle comprises the succession of changes which occur from any one point on the curve to the next point where the curve indicates the same character of e.m.f. or current. For example, in Fig. 9 one may consider that part of the curve between the points *A* and *a* to comprise a cycle, or that part between *B* and *b* to comprise a cycle, or that part lying between *C* and *c* or *D* and *d*. It is customary, however, to consider a cycle as beginning at zero, so that the curve in Fig. 9 represents two complete cycles.

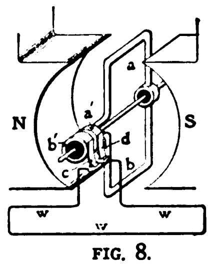

FIG. 8.

The number of cycles per second is termed the frequency of the e.m.f. or current. The standard frequencies are 25, 30, 60 and 125 cycles per second. The frequency of a current or e.m.f. is sometimes referred to in terms of "alternations" per minute; a cycle comprises two alternations, so that a frequency of 25 cycles per second is equivalent to 3000 alternations per minute, and a frequency of 60 cycles per second is equivalent to 7200 alternations per minute.

In alternating-current apparatus and circuits, the e.m.f. available for work is not the maximum e.m.f., but the geometrical average of the e.m.f. values between zero and maximum. On the basis of the sine curve, this average is 0.7071 of the maximum e.m.f. and is termed the effective e.m.f. (in Great Britain it is customary to refer to this value as the "root mean square" value, meaning the square root of the mean squares of the e.m.f. values). In speaking of alternating-current voltages, therefore, the effective e.m.f. is always meant, and it is this e.m.f. which is indicated by measuring instruments. The fluctuations of current are obviously too rapid for the needle of any instrument, however sensitive, to follow, and the instrument therefore indicates the geometrical mean of the fluctuating values.

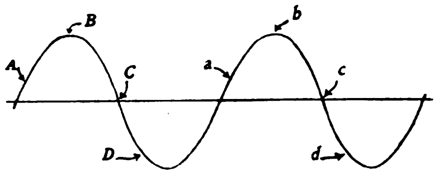

FIG. 9.

Letters on Practical Subjects

The Fire Underwriters' Rules.

To the Editor, American Electrician:

There are some inconsistencies in the requirements of the Fire Underwriters relating to electrical construction as compared with other possible sources of fire, to which I would like to call attention. Every one who has done electrical work under these rules is familiar with the commendable assiduity with which the inspector "camps on the trail" of the wireman, and the wisely rigid rules governing the materials to be used and the method of using them are also familiar to those who are practically concerned with construction work. But did any of your readers ever see any insurance rules demanding that a metallic mat of certain dimensions should surround a wood or coal stove, instead of a rag carpet? Who ever heard of an inspector being on hand to note whether the top of a hot air furnace was within one-half inch or 16 inches of wooden joists above it; or whether the asbestos mat (if one was put in) above the furnace was 1-32 inch or ½ inch thick; or whether the air ducts of this same furnace had a double insulating wall or simply a thin, single metallic wall lying bare against the studding and lathing? Was a carpenter ever required to keep sheathing and rafters clear of a brick flue so that the upper part might settle along with the lower and not leave a good, wide fire leak just under the roof? No; but the electrician's wires, placed *first* and afterwards crossed by a lot of water pipes, have to be moved as soon as the inspector finds the violation of rules, while nothing is said to the plumber and no one considers compensating the wireman for his extra work. We are required (justly) to use insulation on electric wires of sufficient resistance to stand 15 to 90 times the voltage that the wires will ever carry, but where is there a rule requiring that matches be kept in an air-tight non-combustible box having walls of a certain strength? And coming a little nearer home, have the Underwriters ever formulated regulations stipulating that lightning rods must be kept *off* buildings and, in rural districts, erected on poles of certain heights located certain distances from the dwellings or other buildings to be protected?

Now this letter is not written in any spirit of complaint against the restrictions as to electrical work; it is not claimed that since other classes of work are not regulated therefore the electrical work should go scot free. But it *is* my opinion that the efforts of the Fire Underwriters to minimize fire risks should not be concentrated on our class of work to the exclusion of almost everyone else, but that all other branches of construction should be controlled, and the workers in those branches made to face their responsibilities both as to their own work and the relation between that and electrical work. All we ask is fair play.

Testing Defective Armatures.—A Problem in Broken Circuits.

To the Editor, American Electrician:—

Your readers are probably familiar with the rather elaborate methods employed by most manufacturers of electrical machinery for testing out defects in armatures. One of the most widely used is the transformer method, in which a laminated core is employed of such shape that when it is applied to the periphery of the armature core the latter completes its magnetic circuit. This involves considerable paraphernalia, and is seldom a convenient method to use around a repair shop. The accompanying diagram (Fig. 1) represents a modified transformer method that has been used by me under widely varying conditions and always with satisfaction. On an old transformer core (having a closed magnetic circuit) is wound a few turns of coarse wire, *s*, and over this is wound a graduated winding of finer sizes of wire. This latter winding is connected in series with the coarse-wire winding,* and is shown in the drawing extending from the post *p* to the other post indicated by the same letter; taps are led out to a row of intermediate posts, as indicated. The size of wire changes with each section, *a, b, c,* and *d,* and the number of turns also changes, the section *d* having the fewest number of turns and the largest size of wire (except that in the section *s*). From an ordinary alternating-current circuit, leads are brought to a double-pole switch, and on the other side of this switch an incandescent lamp, *L*, is connected permanently in series with a flexible lead terminating at the connecting plugs *e;* this and the plug *f* fit into holes in the posts *p* to *p*. Three flexible leads are carried out from the coarse-wire winding *s*, and terminate at test plugs *T* having insulated handles. Some preliminary testing is necessary for each case in order to find out which pair of plugs, *T*, should be used, and in which pair of posts the plugs *e* and *f* should be inserted. If testing for an open coil in an armature, the outer two of the three *"T"* plugs should be put in firm contact with two adjacent commutator bars where the coil is known to be good, and the plugs *e* and *f* should be put in two posts which will cause the lamps *L* to glow faintly but distinctly. Then by trying each pair of adjacent bars all around the commutator the two to which the open coil is connected will finally be reached and then the lamp will fail to glow because the higher resistance in the secondary circuit will reduce the current flowing in the lamp or primary circuit. In testing for a short-circuited coil, the plugs are adjusted so that when two *T* plugs are on two commutator bars connected to a good coil the lamp will just remain dark; then when the short-circuited bars are reached the lamp lights up. The condition of "just" remaining dark may be determined by working backward from a point where the lamp barely glows to the point where it ceases to show red. A little practice soon enables one to make adjustments quickly for any of the usual tests made in repair shops. A good size of wire for the winding *s* is No. 4 B. & S. gauge, and the primary winding may be graded from No. 14 up to No. 18.

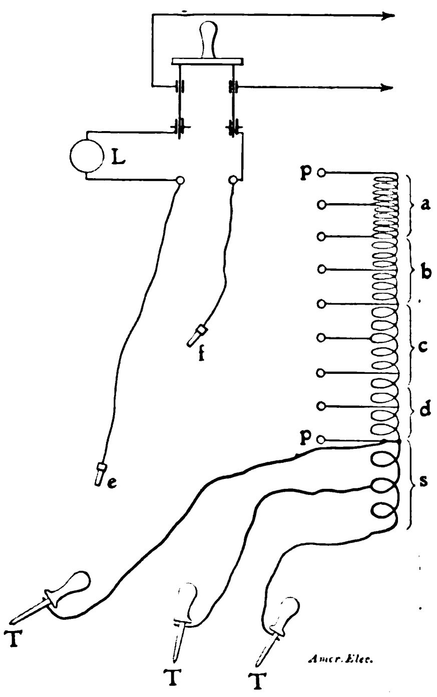

FIG. 1.—MODIFIED TRANSFORMER METHOD FOR TESTING DEFECTIVE ARMATURES.

The other diagram enclosed (Fig. 2) represents a broken two-wire circuit, such as that of a telephone line. The break, *B*, is supposed to have grounded both wires, and the problem is to find out by testing what is the distance of the break from the home end, *A*, of the line. The resistance per foot or mile of the line wire is, of course, known, but nothing else is. Can the break be located roughly under these conditions by a test or series of tests made at the home office at *A*?

Queries and Answers

IMPORTANT.—No attention will be given to any inquiry which does not give the full name and address of the inquirer.

What changes are necessary in order to reverse the direction of rotation of an alternator? G. P. O.

If the machine has a rectifying commutator, transpose the cables leading to the brushes of this commutator. The only other change necessary is to turn all the brushes around so that they trail in the opposite direction.

What is the formula for the indicated horse-power of a gas engine? A. L. H.

The formula is

$$\frac{LEAP}{33{,}000} = H.P.,$$

in which L is the length of stroke in feet, E is the number of explosions or ignitions per minute, A is the piston area in square inches, and P is the mean effective pressure. The value of P cannot be calculated with any approximation to accuracy; it must be taken from an indicator diagram.

Can I cut out a damaged armature coil in a revolving field three-phase alternator, or should the coil be taken entirely out of the slots? (2) Can a damaged field coil be short-circuited or should it be removed in order to continue running? J. A. A.

The damaged coil may be disconnected from the armature circuit and its place bridged over with a piece of wire. The safest plan, however, is to remove the coil entirely, as the e.m.f. induced in it may damage it still further and extend the damage to neighboring coils. (2) The field coil may be simply short-circuited and left on the pole in order to maintain the mechanical balance until a perfect coil is substituted.

If an alternating-current circuit contains self-induction, part of the current flowing in the circuit is referred to as "wattless." If the wattless current be multiplied by the voltage, the result should therefore be wattless watts, which is a contradictory term. What would be the correct term? M. O.

The expression "wattless current" is used merely to save time, the correct expression being "wattless component of the current." Similarly, this value multiplied by the e.m.f. of the circuit would give the wattless component of the apparent power in the circuit. No definite name has been generally adopted to apply to this, some engineers using the term "wattless power," others "idle watts," and still others "useless watts." The last term is obviously more nearly accurate than the others.

Is it good practice to start a rotary converter on the direct-current side and close the switches on the alternating-current side without making sure that the machine is in step with the alternating-current circuit? (2) What effect upon the speed relations of the generator and rotary converter would result from changing the converter connections from three phases to six phases? (3) Why are separate lines run for each rotary converter in a system? R. F. T.

This is almost the worst method that could be practiced. (2) There will be no effect upon the speed relations; the speed of a rotary converter is equal to twice the frequency in complete cycles divided by the number of poles, regardless of the number of phases. (3) When this is done, it is in order to reduce the interference between different converters and to avoid disturbance by the converters of the other circuits of the system.

In connecting a two-phase alternator to a three-wire circuit, does it make any difference which two wires of the different phases are connected to the common-return circuit wire? (2) Will the common-return wire need to be larger than the others, and if so, how much? (3) Does this connection increase the voltage, and if so, can it be reduced to normal by reducing the excitation without changing the speed? L. E. T.

No. (2) The common-return should have one and a half times the cross-sectional area of each of the other wires. (3) The e.m.f. across the two individual phase wires will be 1.4 times the e.m.f. of each phase, but the e.m.f. from each of the individual phase wires to the common-return will be equal to the rated e.m.f. of the machine. There is no necessity to change the e.m.f., but if it is desired to reduce the e.m.f. between the individual phase wires to the rated e.m.f. of the machine this may be done by changing the excitation, but the operation of the alternator will not be satisfactory.

What is the difference between synchronous and induction motors? P. W.

A synchronous motor has its field excited from some direct-current source, while its armature takes current from the alternating-current line. The field of an induction motor is supplied from the alternating-current circuit and its armature is not connected to any source of current, the currents in it being induced by the field; hence its name. Furthermore, a synchronous motor having a certain number of poles and being supplied with current from an alternator having the same number of poles will run at the same speed as the alternator regardless of the voltage or load; hence its name, "synchronous." On the other hand, an induction motor also tending to run in synchronism with the generator which supplies it with current, cannot do so, but lags behind the generator by a small amount, the actual lag, or slip, as it is termed, varying with the load on the motor.

What is the effect of shortening the pitch of a lap armature winding on a multipolar machine? (2) How can the connections of the field windings of a multipolar machine be verified without dismantling the machine when the relation between the two leads of each coil cannot be determined? (3) Is there any loss of current when a circuit otherwise thoroughly insulated is grounded at one point? Is not the result about the same as connecting one side of the line to the ground through a condenser or reactance coil? V. E. H.

If the pitch originally was identical with or smaller than the pole pitch, shortening it will decrease the e.m.f. of a dynamo and increase the speed of a motor. If the original pitch was greater than the pole pitch, shortening it will increase the e.m.f. of a dynamo and decrease the speed of a motor up to the point where the two pitches are equal. If the armature coil pitch is very much smaller than the pole pitch, sparking is likely to result. (2) Test the polarity of the pole faces by means of a compass. (3) There would be no loss if absolute insulation were possible; on a low-voltage circuit the loss would be practically negligible. The condition is very different from that of an alternating-current connected to the ground through a reactance coil or condenser.

Can a cluster of 16-c.p. 110-volt lamps be wired without individual fuses? (2) How many lamps can be connected to a branch circuit protected by a fuse plug marked 10? (3) Can a feeder be supplied from either end of a pair of bus-bars? (4) Adjustment of a field rheostat has no effect on the voltmeter connected to the dynamo; what is the trouble? (5) How can a ground in a field-magnet coil be noticed? A. S.

Yes; provided the current required by the cluster does not exceed 6 amperes; a double-pole fuse-block will be necessary for the complete cluster. (2) About 18 lamps, the figures on the fuse plug indicating its rating in amperes. The lamps will have to be divided into two groups, each protected by an individual fuse block and the division being such that neither of the two groups will require more than 6 amperes. (3) Yes. (4) Either the rheostat is badly short-circuited or the voltmeter is out of order. (5) If there is only one ground the insulation test described in the Lessons Department of the November, 1903, issue of this paper may be used. If there are two grounds, so that a part of the field winding is short-circuited, the short-circuited part will be cold and the remainder of the winding will run hot.

What law does the rise in pressure due to compression in a gas engine cylinder follow? (2) How is the rise in temperature due to compression related to the rise in pressure due to the same cause? (3) What is the usual pressure of compression employed in modern gas engines? (4) Why is expansion not carried nearer to the atmospheric pressure before exhaust? D. L. P.

Representing the total volume of the cylinder and compression space by V, the volume of the compression space alone by v, the absolute pressure at the beginning of the compression stroke by p, and the absolute pressure when compression is completed by P,

$$\left(\frac{V}{v}\right)^x = \frac{P}{p}.$$

The value of the exponent x varies under different conditions, but is usually between 1.3 and 1.4. (2) Representing the initial absolute temperature by t, and the absolute temperature when compression is completed by T, the following formula applies:

$$\left(\frac{V}{v}\right)^{x-1} = \frac{T}{t}.$$

Consequently,

$$\left(\frac{P}{p}\right)^k = \frac{T}{t},$$

in which formula the exponent k is equal to $\frac{x-1}{x}$. (3) This ranges from 75 pounds to 200 pounds, according to the design. (4) Because the expansion curve is so flat during the latter part of the stroke that the cylinder would have to be made impractically long in order to expand down to a terminal pressure anywhere near that of the atmosphere, unless the expansion stroke could be made considerably longer than the compression stroke.

WESTINGHOUSE TURBINES OF LARGE OUTPUT.

The accompanying engraving illustrates the type of turbine which will hereafter be built by the Westinghouse Machine Company for large outputs. The machine illustrated is of 5000 kilowatts normal output. The principle of construction is, of course, the same as that characteristic of the smaller turbines, which have several times been described. The chief difference between the machine here shown and the type of machine hitherto built for large outputs is that the entire working parts of the turbine are contained in a single chamber or housing, whereas heretofore the smaller vane wheels have been encased in a housing separate from that which enclosed the largest ones, the two housings being connected, of course, by piping and a shaft bearing located between them. The saving in space by consolidating the working chambers is considerable. The space occupied by the turbine proper of the 5000-kw. set is 27 ft. 8 ins. from the center of the bearing between the turbine and the generator to the extreme end of the turbine shaft, 13 ft. 3 ins. width of base, and 12 ft. in height up to the top of the hand railing. The over-all length of the complete unit is 47 ft. 4 ins. Fig. 2 gives an interesting comparison of the floor space occupied by two 5000-kw. compound reciprocating engines and generators of the type used in the Manhattan Railway power house and four 5000-kw. turbine generator sets of the new type under discussion. A walk-way of 6 ft. is allowed between the two reciprocating engine outfits, while walk-ways 9 ft. 6 ins. wide are allowed between each two turbine generator sets.

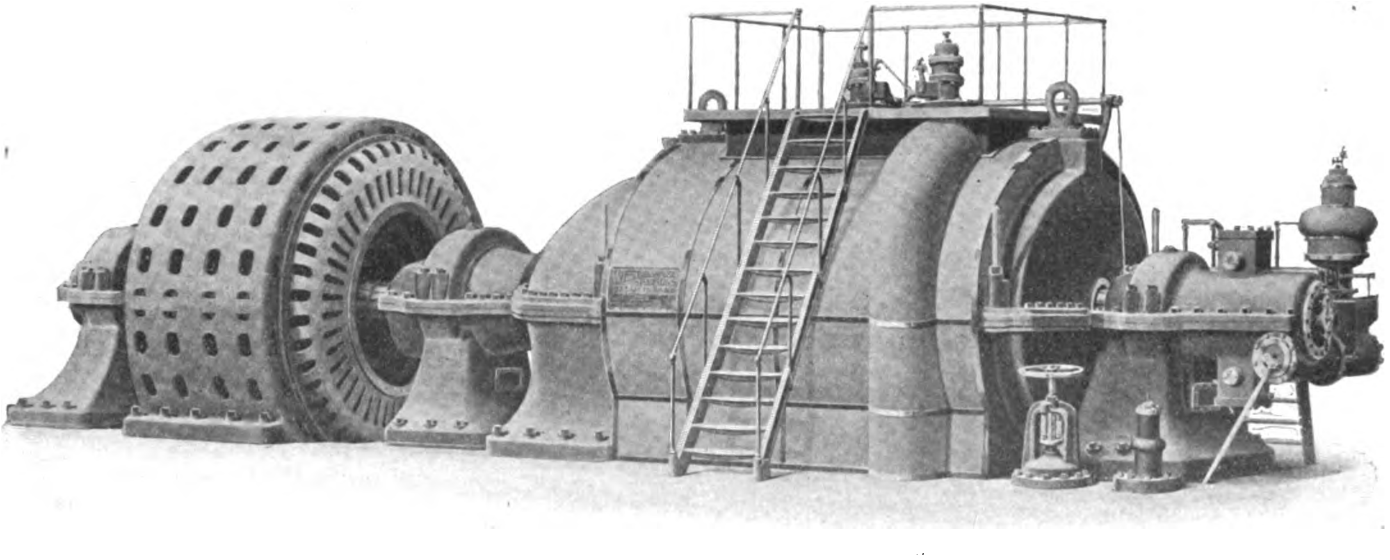

FIG. 1.—WESTINGHOUSE 5000-KW. TURBO-GENERATOR SET.

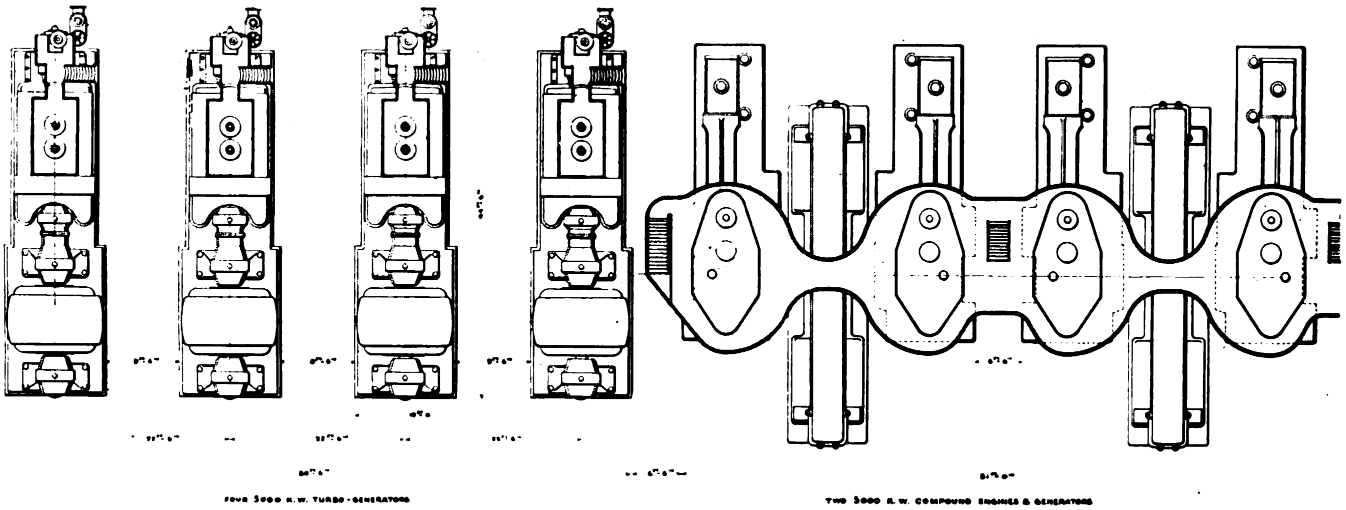

FOUR 5000 K.W. TURBO-GENERATORS
TWO 5000 K.W. COMPOUND ENGINES & GENERATORS
SAME AS IN MANHATTAN POWER HOUSE
FIG. 2.—COMPARATIVE SPACE OCCUPIED BY 5000-KW. TURBO-GENERATORS AND RECIPROCATING ENGINE-DRIVEN SETS OF THE SAME OUTPUT EACH.

The new type of large turbine shows relatively moderate speeds. The 5000-kw. unit will run at 750 r.p.m., the 2000-kw. unit at 1200 to 1500 r.p.m. according to the frequency desired, and the 1000-kw. unit from 1500 to 1800 r.p.m. according to the frequency. There are several interesting details of construction embodied in the new turbine. The bed-plate, for example, is cast in two sections, and the two sections are held together by links shrunk into recesses in the same manner that some types of sectional flywheels are held together. The barrel or housing is similarly cast in two sections, and these are united by shrunk links; the right-hand half, as the unit appears in the engraving, carries the out-board bearing and governor worm casing, and the left-hand section carries the middle journal and has the exhaust outlet cored into it. As in previous types, linear expansion and contraction are provided for by bolting the journal pedestal between the turbine and the generator solidly to the bed-plate and mounting the out-board pedestal in parallel machined ways so that it is free to slide parallel with the shaft. The main body of the housing is heavily lagged with non-conducting material, which in turn is covered by a sheet-steel casing. Leakage of air from the atmosphere into the exhaust spaces of the casing, where the shaft passes through, is prevented by water-sealed frictionless packing glands. No oil is used, so that the condensation from the turbine is pure water.

The vane-wheels and balance pistons of the turbine are mounted on a central steel quill, into the ends of which hollow forged-steel shaft ends are forced by hydraulic pressure; these are screwed in place by arrow-head links shrunk in. High-pressure steam is delivered to all parts of the quill so as to eliminate stresses and consequent distortion due to superheated steam.

On account of the lower speeds at which the large sets are operated, the "floating" or "nested" journal sleeves used in the smaller turbines are not required; the journals are of the ordinary solid self-aligning type similar to that employed in the construction of generators and reciprocating engines. The diameter of the shaft in the journal of a 5000-kw. unit is only 15 ins.

Steam is delivered to the turbine through an automatic quick-closing throttle valve, a hand throttle valve, a separator, and lastly, the main admission valve under the control of the governor. An important feature of the steam distribution consists of an automatic by-pass valve which admits high-pressure steam to the second stage of the turbine when the unit is overloaded. This valve is controlled by the governor in exactly the same way that the main admission valve is controlled, and grades the admission of high-pressure steam to the second stage according to the requirements of the overload. Within the normal load range of the unit, the by-pass valve remains closed. The use of this automatic by-pass valve results in a rise in the economy curve of the engine under heavy overloads. Like the admission valve, it is of the double-beat poppet type, operated by a small steam piston which is controlled by a pilot valve under the control of the governor.

At the extreme end of the out-board pedestal is mounted an auxiliary speed-limit governor of the centrifugal type, which is set to release a small plunger valve when the speed of the turbine reaches a certain rate in excess of the normal, and this plunger valve controls the quick-closing throttle valve already mentioned. The throttle valve is normally held open by means of an overbalanced differential piston, and when a predetermined excessive speed is attained, from any cause whatever, the auxiliary governor operates the small plunger valve so as to remove the excess of pressure on the differential piston and allow it to close the throttle valve instantaneously. The action of this automatic stop was illustrated several times in an interesting manner during a recent test of a smaller turbine generator unit. The stop was set for 10 per cent excess in speed, and the governor lever was held down so as to leave the turbine uncontrolled; the instant the speed reached the 10 per cent limit the auxiliary governor caused the quick-closing throttle to shut off the supply of steam.

FAIRBANKS-MORSE GAS ENGINE AND DYNAMO

Fairbanks, Morse & Co., Chicago, have been carrying on a series of tests and making experiments with a line of gas and oil engines specially designed and constructed for electric light work, and the result has been the bringing out of an engine fitted with a special type of governor acting upon air and gas valves and regulating the supply of mixture admitted to the cylinder. It is stated that this governor is so sensitive that with two-cylinder vertical construction regulation has been secured within one per cent from no load to full load. During these experiments the item of economy has also been carefully considered, of course, and on the above type of engine under full load an economy has been secured of ¼ cent per horse-power-hour with gas costing 50 cents per thousand cubic feet; this is natural gas having about 1000 B. T. U. per cubic foot. The close regulation of the engine permits of direct connection to a dynamo; such an outfit is illustrated herewith. Fairbanks, Morse & Co., also being builders of electrical machinery, have special advantages in the matter of designing and proportioning the generator for direct driving by the engine. The construction of these engines is said to be so simple that they can be handled by anyone of ordinary intelligence, not requiring a specially skilled engineer. The Fairbanks-Morse engines can be operated on gas, gasoline, kerosene, crude oil or distillate.

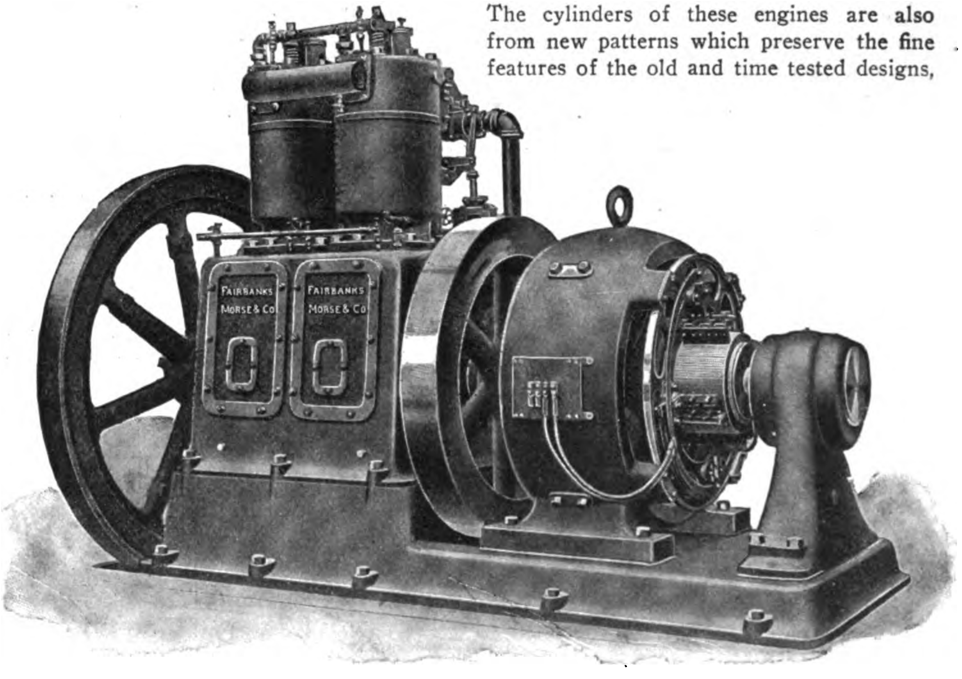

FIG. I.—FAIRBANKS-MORSE DIRECT-CONNECTED GENERATOR SET.

◆

MURRAY "ROLLING MILL TYPE" ENGINES

The Murray Iron Works Company has been developing a new type of engine during the past two years and a number are already in successful operation in as widely separated parts of the country as New York and California, Minnesota and Texas. It terms this new design the "Rolling Mill Type," but it is unnecessary to point out that it is particularly and especially adapted for severe electrical service. The frames of these engines are cast in one piece, and they have lines of beauty and great strength.

The patterns for the right and left-hand styles are entirely separate. Those who know how much is usually sacrificed in the effort to save one set of patterns by making the right do for the left and the left for the right, will appreciate this point. The cylinders of these engines are also from new patterns which preserve the fine features of the old and time tested designs, while adding those required by modern conditions of pressure and speed.

The illustrations herewith show a simple direct connected Corliss engine and a cross-compound unit of the same type.

New Apparatus and Appliances

JUNIOR MIDGET PLUG AND RECEPTACLE.

The accompanying illustration shows a new device brought out by the Marshall-Sanders Company, of Boston, Mass., which they designate the "Junior" midget plug and receptacle. This is similar in many respects to the No. 521 midget plug and receptacle made by the same company, but instead of having a metal lid or hinge to close over the contacts, the connection is made through two insulated holes in the plate. The device can be used in nearly all places where a temporary connection is required with the the exception of floors.

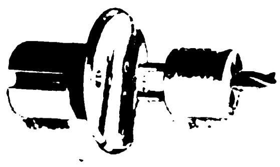

FIG. 1.—MIDGET RECEPTACLE AND PLUG.

THE MORSE THERMO GAUGE.

We illustrate herewith a highly interesting apparatus for gauging the temperature to which steel is heated in the process of hardening or annealing. The principle of the apparatus is shown diagrammatically in Fig. 3. A tube, *T*, contains an incandescent lamp, *L*, having its filament arranged in spiral form, as shown in the end view. At *G* is indicated a source of electric current, at *R* a rheostat and at *A* a voltmeter or ammeter. By means of the rheostat any desired current may be switched on the lamp, giving any desired degree of incandescence, and by noting the current consumption on the ammeter the same degree of incandescence may be obtained at all times.

The instrument is used by simply looking through it at the piece of steel being heated, at the lead bath or into the furnace in which the steel is to be heated, the spiral being, in effect, superposed upon the object looked at. Should the filament be at the higher temperature, it will appear as a bright spiral, while should it be at a lower temperature it will appear as a relatively dark spiral, but, when the two temperatures are the same, the filament will apparently merge into the object looked at and disappear. The temperature at which the best results are obtained in any given case may be fixed for future use by regulating the current to bring the filament to the same temperature which may then be repeated at any future time, or a given temperature in degrees may be obtained by suitable graduations of the ammeter. Fig. 2 shows the instrument as arranged for the direct inspection of tools when heated in a blacksmith's fire. The end of the tube is covered by a hood, to exclude all outside sources of light, the hood having an opening on one side into which the tool is inserted. The accuracy of the indications claimed for the instrument is remarkable. Used in the ordinary way, a variation in temperature of 5° Fahr. either side of that of the filament may be detected, while, by using a magnifying glass, this is reduced to a single degree.

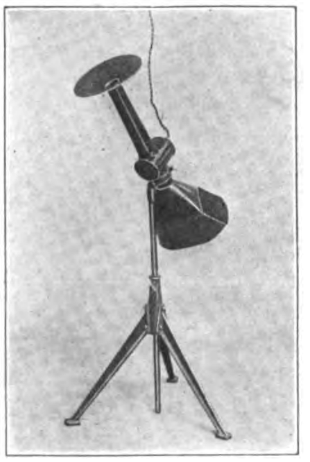

FIG. 2.—MORSE THERMO GAUGE.

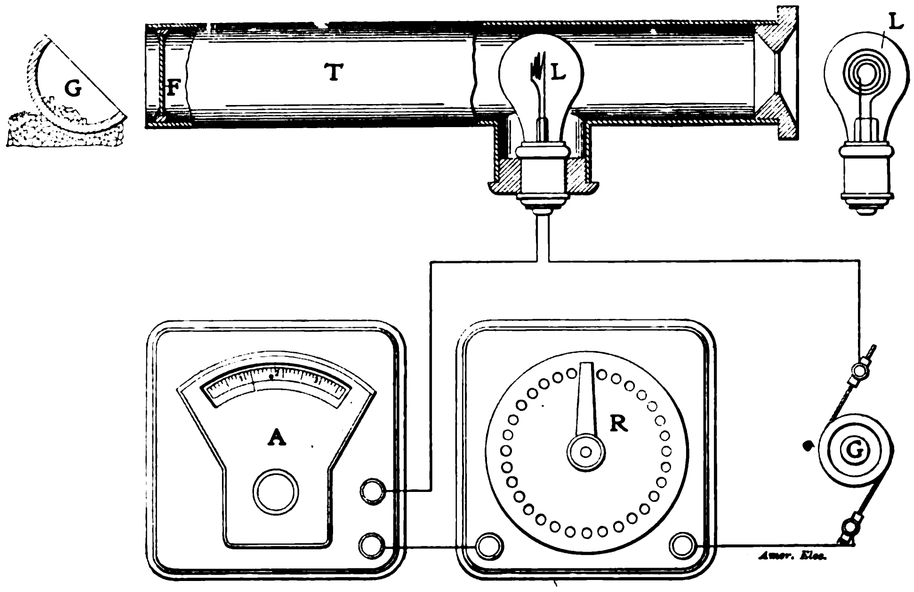

FIG. 3.—MORSE THERMO GAUGE.

Anyone acquainted with the gradual deterioration of the filaments of ordinary incandescent lamps will naturally ask if these filaments do not deteriorate in the same way and thus vitiate the results. This is not found to be the case, for the reason that the temperature at which steel is hardened is much lower than that to which an ordinary incandescent lamp filament is subjected. The latter is a glowing white heat, while the former is a "cherry red" or lower. At these latter temperatures the filaments are not found to deteriorate appreciably, one of them having been in constant use for the past three years. Moreover, the readings of the ammeter are in all cases standardized, in order that different instruments may give the same results. The graduations may be made to indicate the degrees of temperature directly or they may be arbitrary marks for different brands of steel and different classes of work. The instrument is made by the Morse Thermo Gage Company, of Trumansburg, N. Y.

SMALL STEEL FRAME ELECTRIC MOTORS.

The Triumph Electric Company, of Cincinnati, Ohio, has just brought out a new line of small steel frame bipolar machines ranging in size from one-half to five horsepower. The crown and pole pieces are made of soft, close-grained steel, the latter being fitted and bolted to the crown. Cast iron yokes are centered against the sides of the crown and are held in position by bolts. These yokes can easily be rotated so that the machine may be used on a wall or ceiling. The bearings are of the self-oiling gun metal type, and are interchangeable. Fig. 4 herewith shows the frame, armature poles and field coils of a one-half horsepower motor. The armature core is built up of thin sheet steel disks mounted on a hammered steel shaft. These disks are notched and after punching are annealed and varnished before being assembled on the shaft. The field coils are form wound and thoroughly insulated. After being baked they are tested with alternating current before being placed on the poles. The

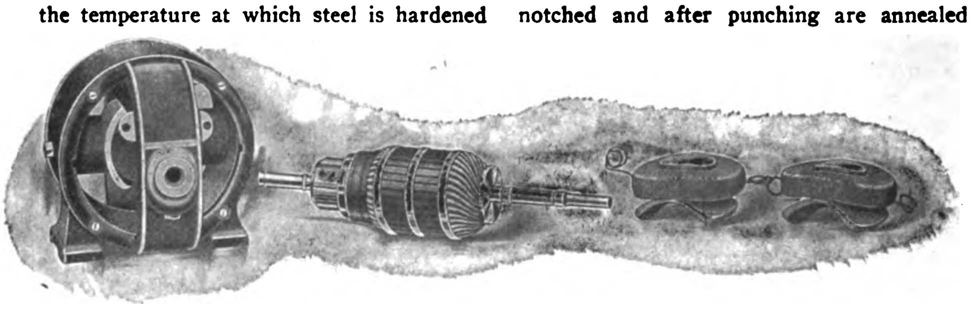

FIG. 4.—TRIUMPH MOTOR FRAME, ARMATURE, POLES AND FIELD COILS.

brush holders are of very simple design. Carbon brushes are used, and these are fastened rigidly at the end of the holder, which is clamped to the stud, and is provided with a simple and ready means for adjustment. As there is no sliding friction of the brush in the holder, the spring has but little weight to move, so that the tension is very light. A quick and sensitive adjustment of the brush is said to be the result whereby sparking and heating and wearing of the commutator are claimed to be eliminated. The efficiencies at full load range from 72 per cent in the half horse-power motor size to 87 per cent in the five horse-power machine. The one-half and three-quarter load efficiencies range correspondingly from 67 per cent and 71 per cent to 83 per cent and 87 per cent.

NEW VOLTAGE REGULATORS.

Recently the General Electric Company has placed on the market two new types of voltage regulators which admirably suit the conditions for which they were designed, They are known as Type TD and Type TA. Type TD regulators (Fig. 5) are designed for use in connection with direct-current generators only, while Type TA (Fig. 6) though primarily designed for use with alternating-current generators, may, if provided with an exciter, be used with direct-current generators as well. These instruments operate on the principle of rapidly opening and closing a shunt circuit across dynamo field rheostat terminals, the rheostat having considerable resistance turned in to give the regulator a good margin to work on. Type TD regulators are arranged to open and close a shunt-circuit across the generator field rheostat; Type TA controls a shunt across the exciter field rheostat.

The direct-current regulator, Type TD, contains a relay and a secondary magnet. The magnet is differentially wound, one of these windings being permanently connected to the work circuit, while the other is opened and closed by contacts which are operated by the relay. As the relay contacts are opened and closed, they simultaneously open and close the secondary magnet contacts by means of the differential winding of the magnet; these contacts open and close the shunt circuit across the generator field rheostat. To prevent injurious sparking at the magnet contacts, condensers are connected in multiple across them. This regulator will maintain constant voltage on one shunt wound generator, or will maintain constant voltage on several compound wound generators operating in parallel, regulating, however, only one at a time. Several generators can be arranged to be controlled by one regulator, by means of a five-point rotary switch, as shown in Fig. 5. The generator which is regulated has a tendency to take the sudden fluctuations of load, but these are equalized between the several generators by means of the compound windings of the machines. With shunt-wound generators it is necessary to have a regulator for each generator to be regulated. These regulators are usually arranged to maintain constant voltage at the bus-bars, but may be connected to pressure wires brought back from the centre of distribution, thus maintaining constant voltage at the centre of distribution.

The Type TA regulator is designed to maintain a steady (but not a constant) exciter voltage, and consists of the same direct-current relay and differential magnet as the Type TD with the addition of an alternating-current control magnet having a potential and an adjustable compensating winding. These two windings work in opposition to each other. This magnet operates the lower main contact. The magnet core and lever are arranged by means of a counterweight to come to a balance at the correct voltage. Should the alternating voltage vary, it would change the position of the lower main contact, which would cause the exciter voltage either to be raised or lowered and restore the normal voltage. Without the use of the compensating winding, the regulator will maintain a constant bus-bar voltage, and by the use of the adjustable compensating winding and current transformer in the circuit to be regulated, the regulator will automatically compensate for line losses. The alternating voltage is automatically kept at its desired value by varying the exciter voltage. Once the regulator is adjusted to maintain constant voltage at the centre of distribution it requires no further adjustment and the station voltage will be automatically increased or decreased with the load to maintain the desired voltage at the centre of distribution. This regulator is independent of temperature and frequency changes.

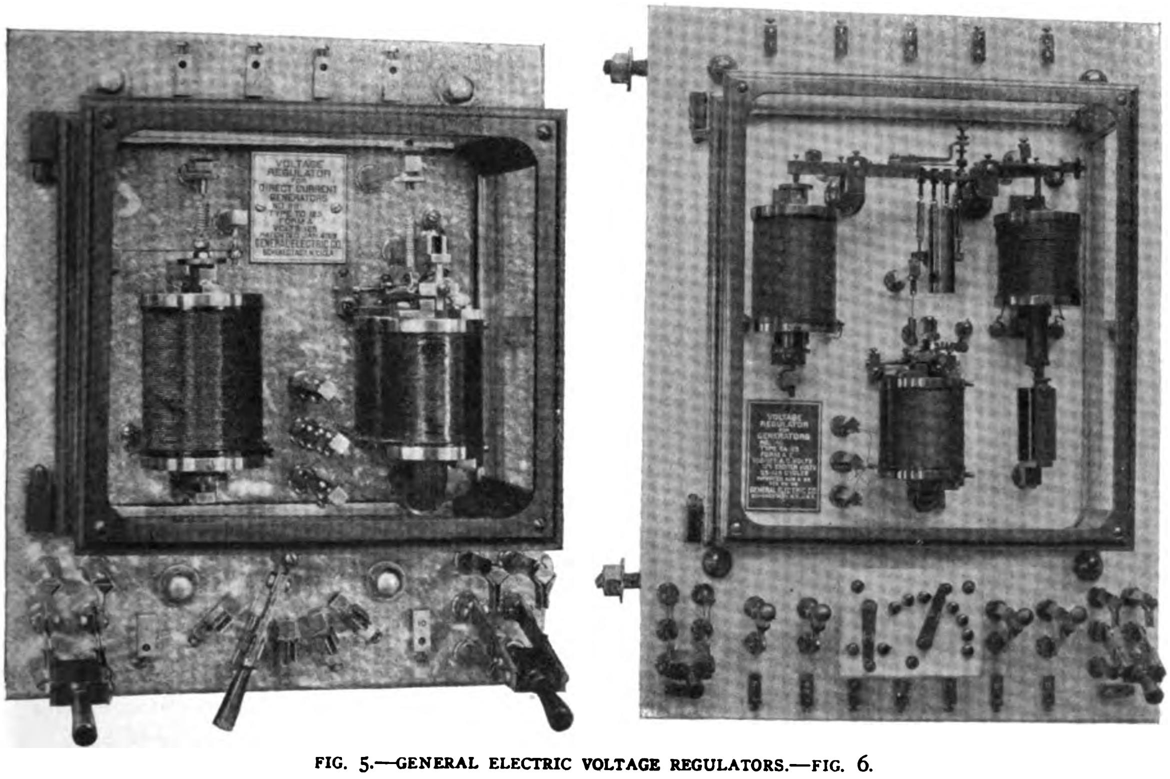

FIG. 5.—GENERAL ELECTRIC VOLTAGE REGULATORS.—FIG. 6.

SMALL STANDARD SWITCHBOARDS.

The W. S. Hill Electric Company, of New Bedford, Mass., has brought out and placed on the market a line of small standard switchboards having capacities of 50, 75, 100 and 200 amperes, designed to control the output of a single generator having an output not exceeding 40 kilowatts. Each board has six circuit switches of various sizes to meet any ordinary requirements, and these are designed to take standard enclosed fuses. The panel is made of black Monson slate and everything possible, it is claimed, has been done to make a board which will conform to the Underwriters' requirements and yet be inexpensive. The boards are equipped with the well-known Weston,

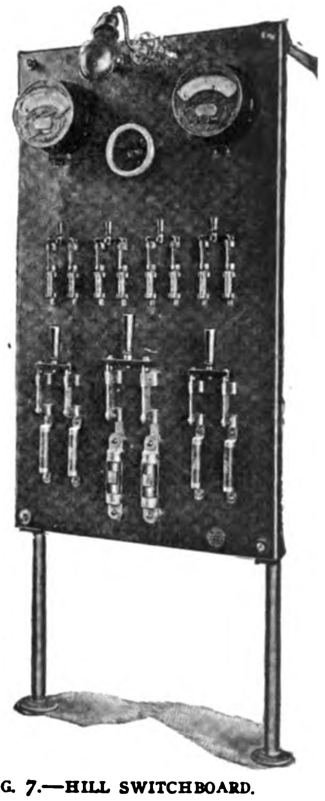

FIG. 7.—HILL SWITCHBOARD.

round pattern, type F instruments and switches made by the Hill company. Fig. 7 herewith shows a complete board.

HIGH POTENTIAL OIL SWITCHES.

The increasing use of high potentials has presented many serious and unusual problems in switching and the protection of the generating apparatus from dangerous overloads. The oil break type, in which the switches and all live metal parts are immersed in oil, is generally conceded to be the best form of switch for handling high voltages, and the most recent development of this type, designed by the Hartman Circuit Breaker Company, of Mansfield, Ohio, is shown in the accompanying illustration.

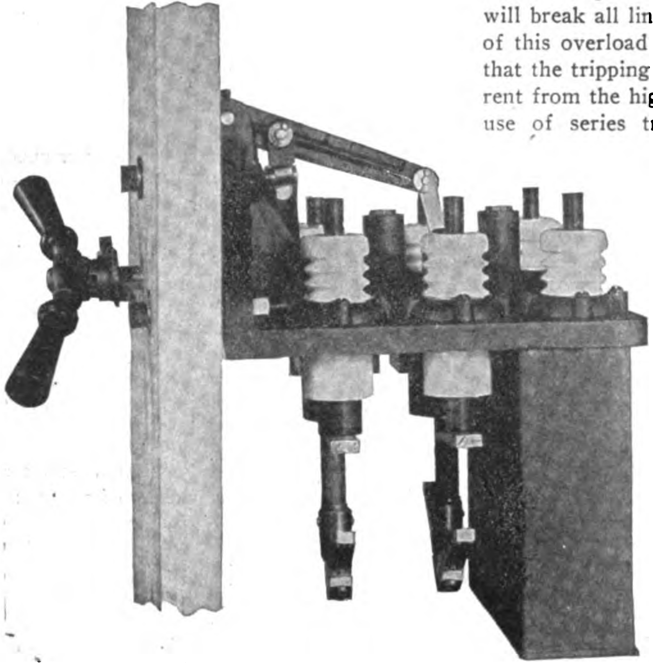

FIG. 8.—HIGH POTENTIAL OIL SWITCH.

Fig. 8 is a view of a three-pole, double-break oil switch designed for installing on the back of the panel, and to be used on circuits up to 11,000 volts. The view shows the switches in the "off" position, with one of the switches enclosed in an oil tank. Each pole of the switch is immersed in a separate tank, which is entirely independent of the adjacent ones and can be readily removed without in any way interfering with the others. The tanks are lined with insulating material formed in such a way that there is just sufficient space for the free vertical movement of the switches, and the quantity of oil used is thus reduced to the minimum. A distinct departure in this oil switch is found in the use of the laminated or brush form of contact, which it is said greatly increases the current-carrying efficiency of the switch and also prevents "freezing" or sticking at critical periods. These contacts are protected by final arcing plates, which, with the corresponding plates on the terminal blocks are removable and can be readily replaced should they become burnt away in the course of time. The form of contact which is used and the isolation of the switches in separate compartments, give the switch a very large breaking capacity. The movable parts of the switch are controlled by means of specially treated wooden rods, which are fastened at their upper ends to a common cross-bar. They are held in normal position by means of a toggle lock. The switch is opened by giving the handle a slight turn in the proper direction. This will cause the toggle to move past the center and the switches will then open free of the controlling handle. Another form of switch is made with automatic overload attachment. There are usually two tripping coils provided for a three-pole breaker, but it can be constructed with a tripping coil in each line. In all cases the operation of any one tripping coil will break all lines. The distinctive feature of this overload attachment lies in the fact that the tripping coils are energized by current from the high potential circuit, and the use of series transformers in connection with the circuit breaker is entirely avoided. The tripping coils instead of being located on the front of the panel are mounted by means of special porcelain insulators on the carrying frame itself. They are separated from each other by barriers of insulating material. The overload attachment has other distinctive features, one of the most important of which is that it cannot be held closed while an overload exists on any line. This apparatus is also constructed with remote electrical control, the operating current being obtained from any convenient source f direct current supply at from 110 to 500 volts. The remote control attachment is said to be very reliable.

IDEAL ELECTRIC MOTORS.

Fig. 9 herewith, shows one of a new line of motors brought out by The Ideal Electric & Manufacturing Company, Mansfield, Ohio. This line is known as Type R, and ranges in capacity from 2 to 35 horse-power. The machines are made in three styles—open, semi-enclosed and enclosed—and can be used for belting, coupling or gearing to machines or shaft, and mounted on the wall, floor or ceiling. The armature core discs are of thin gauge, and the armatures are built directly on the shaft. They are provided with ventilating openings parallel to the shaft, through which air may pass to the ventilating ducts between the discs and the outer ribbed flanges. The winding consists of form-wound coils, the smaller armatures being wound with round wire and the larger ones with flat copper strip. Surface bands are used to retain the coils in the slots. Fig. 10 shows the armature of this machine. The commutator segments are said to be of unusual length and depth, allowing an ample margin for wear. The flanges are of cast-iron and are insulated from the segments with solid "V" rings. The brush-holders are clamped on the stems close to the point of brush contact. Composition graphite and carbon brushes are used, which are fed toward the commutator through a milled trough in the face of the holder. A flat phosphor bronze springs holds the brushes firmly against the face plate, and brush tension is provided through a finger actuated by an adjustable spring. The brushes are said to operate without vibration, and the machines, it is claimed, run practically noiseless. The brush-holder stems, to which the holders are fastened, are insulated from the quadrant and firmly secured to prevent them from working loose. The brushes may be readily and independently adjusted, it being possible to quickly remove any brush while the motor is in operation. The brush area is claimed to be ample, the current density being, it is said, very low and at the same time consistent with economical design. This line of machines is designated to operate at full rated capacities without more than a 30° C. rise in the temperature in the armature or field windings. They are claimed to operate at an overload of 25 per cent. for a period of two hours, and to withstand a 50 per cent. overload for two or three minutes without injurious heating or sparking. The company has also placed upon the market a line of elevator and hoisting motors and controllers and a complete line of belted and engine-type generators in sizes up to 150 horse-power.

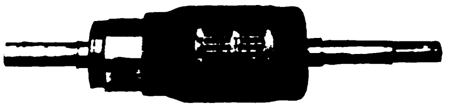

FIG. 10.—ARMATURE OF IDEAL STANDARD MOTOR.

IMPROVED NERNST LAMP.

In the description of the Nernst lamp made by The Improved Electric Light and Supply Company, of New York, which was published in this department last month, it was erroneously stated that the current consumption of the 32-c.p. lamp was in the neighborhood of 100 watts. This should have read 50 watts instead of 100, the latter being the current consumption of the 64-c.p. lamp.

American Electrician.

Vol. XVI. New York, February, 1904. No. 2.

ELECTRIC RAILWAY CONSTRUCTION IN PARIS.

CONDUIT SYSTEM OF THE GENERAL PARISIAN TRAMWAYS COMPANY.

BY FRANCIS PAUL.

An interesting field for the study of electric traction is found in Paris, owing to the fact that the municipal authorities have forbidden the use of the trolley within the city limits, and these conditions have given a good opportunity to test all the known systems of mechanical traction. While the horse omnibus is still to be seen everywhere in the city, most of the principal railways have changed over long ago to mechanical traction. At first steam and compressed air were employed, but nearly all the more recent systems are using electricity. Within the last few years a great number of lines have been installed which use either the surface contact or accumulators. To these must be added the extensive underground conduit system which has been installed by the Compagnie Française Thomson-Houston. It affords a good example of a successful conduit railway, and, in fact, is one of the most important in Europe.

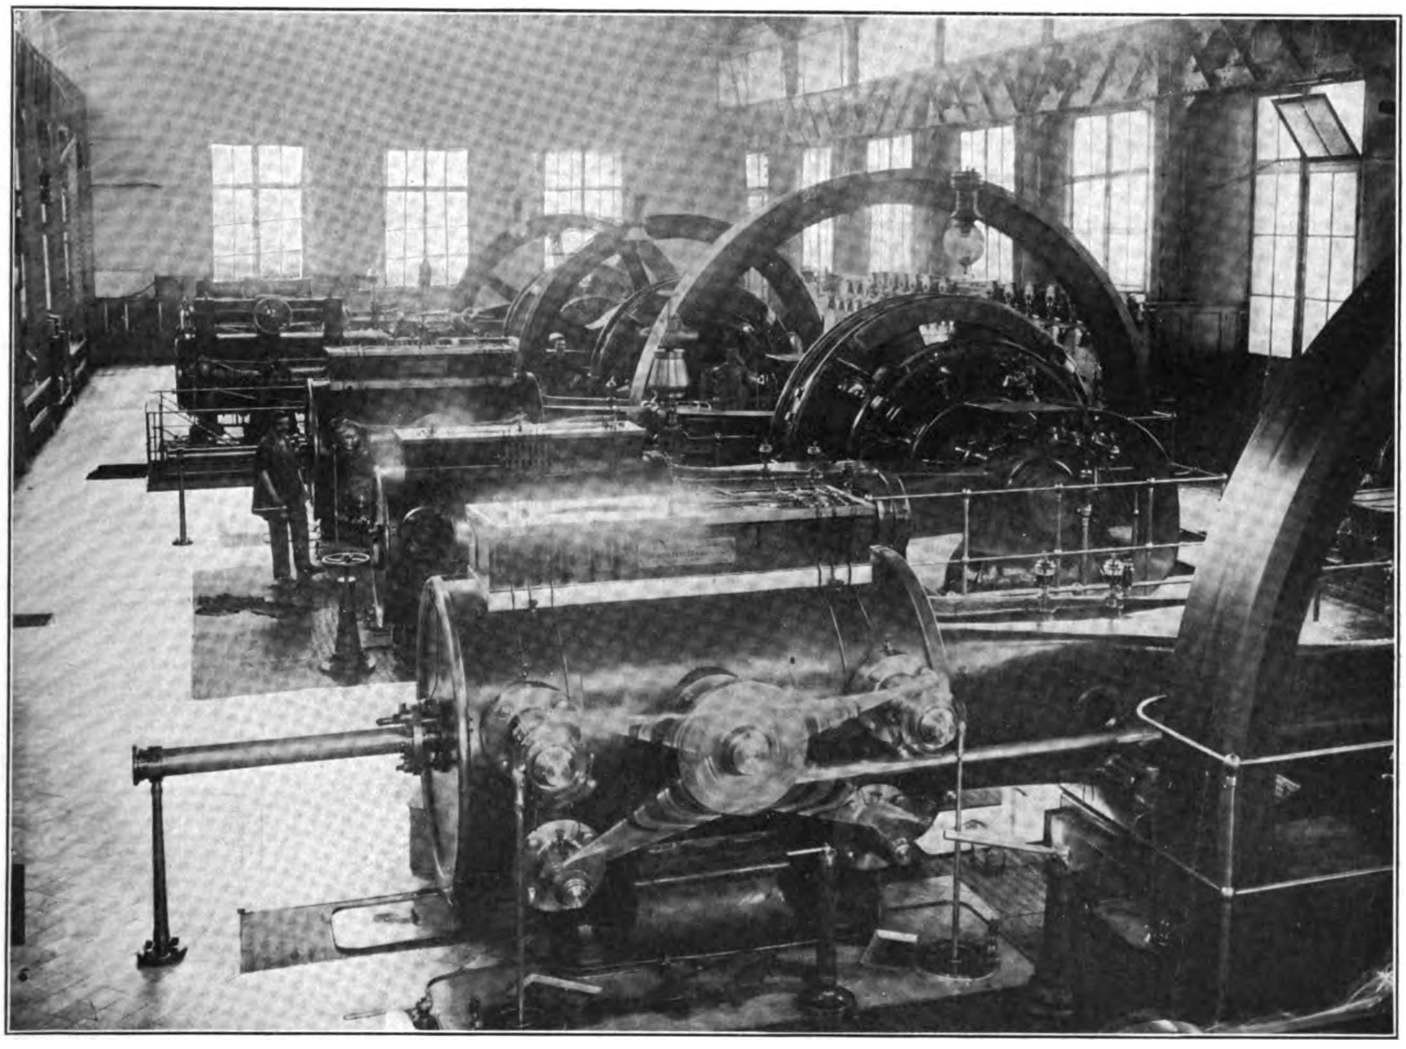

FIG. I.—GENERAL VIEW OF POWER STATION.

The conduit line runs in double track from the Place de la Bastille, located in the eastern part of the city, making a semicircle and ending at the Asnières Gate, to the north, where it joins a short trolley section which runs to the suburb of St. Ouen. The whole system is nearly eight miles long, of which the conduit road forms the greater part. As regards the running of the cars, the conduit line is operated in three distinct sections. The Paris conduit system possesses especial interest due to the extensive scale on which it has been carried out and to the fact that the usual form of central conduit has been replaced by a type of side conduit which has been specially designed to meet the present requirements.

All the preceding lines which have been installed by the same company in Europe, such as the extensive systems of Lyons, Nice and Bordeaux, were laid out on the central conduit system, which somewhat resembles the type of conduit which is used in the United States, upon the lines of the Metropolitan Company, of Washington. It differs from the latter, however, in the fact that the supports of the insulators which hold the contact bars are fixed directly to the base of the conduit rails. The pits in which the insulators are placed are not only covered by a cast iron plate, but also by the paving, which is laid over the manhole covers. This construction suppresses the numerous manholes in the street, conforming to the municipal regulations which have been adopted in many parts of Europe. In Paris, however, it was found impracticable to use the type of central conduit, on account of the wood paving which is used on most of the streets. When the central conduit is laid in the wood pavement, the excessive wear of the latter soon causes the conduit rails to project above the surface and thus form an obstacle to the passage of vehicles. As the ordinary rails of the track are already subject to the same difficulty, it was desired not to increase it still further by using the central conduit. The problem has been happily solved by designing a type of side conduit which will be described somewhat in detail.

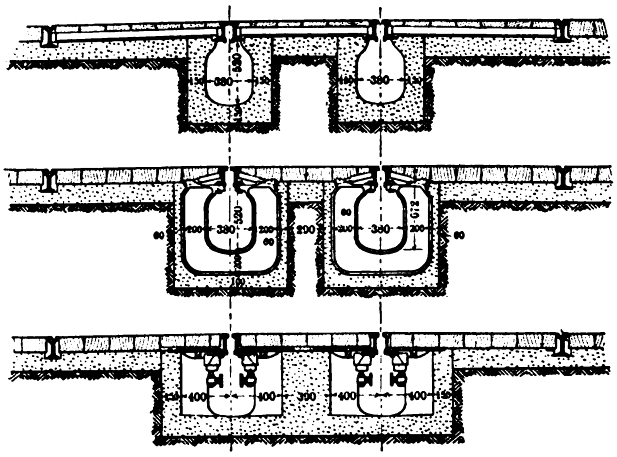

FIG. 2.—SECTIONS OF UNDERGROUND CONDUIT CONSTRUCTION.

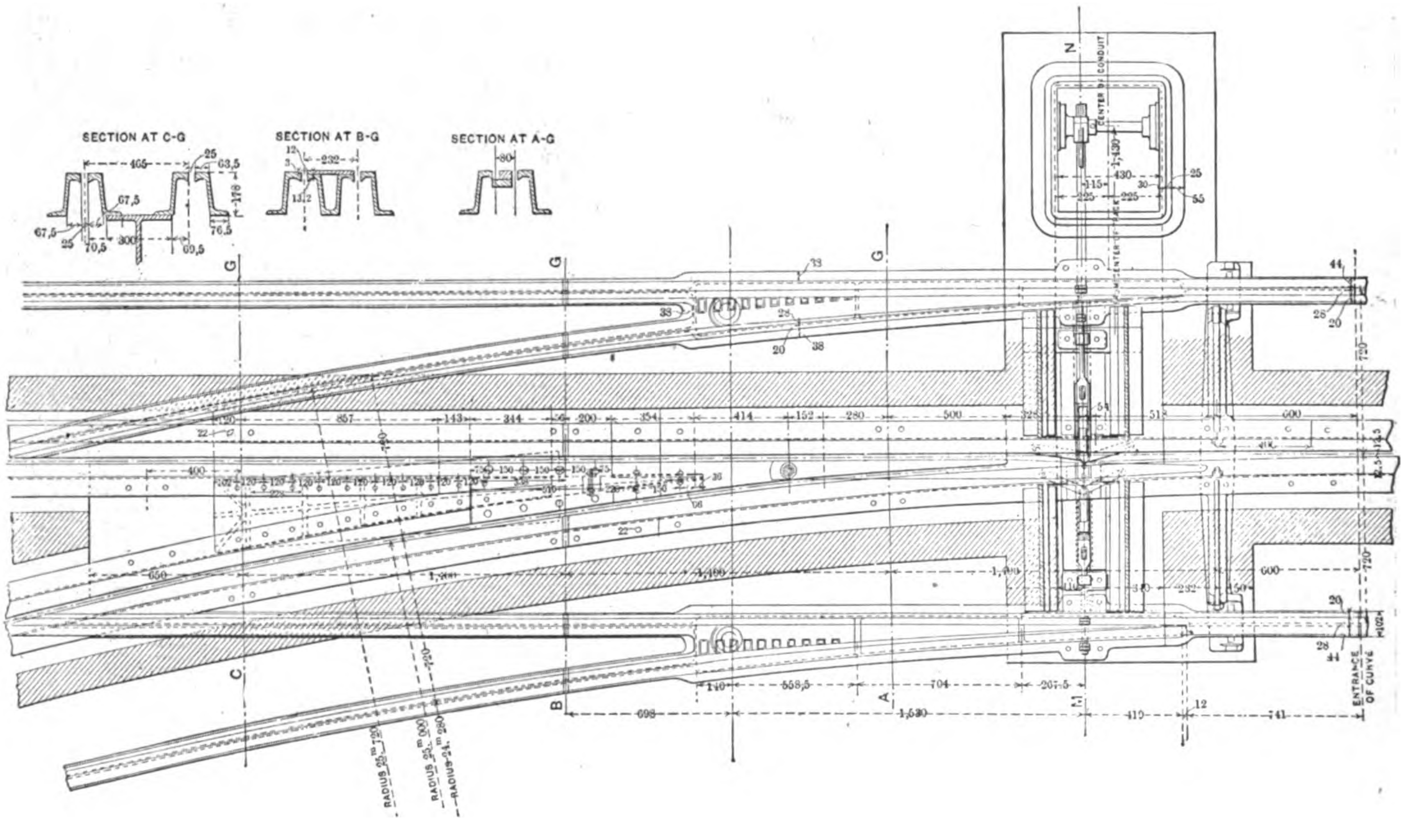

FIG. 3.—SWITCH MECHANISM, WITH SLOT IN CENTER OF TRACK.

The side-conduit system, however, presented a certain number of disadvantages, and means had to be found to overcome these. The following are among its principal drawbacks: First, the obstruction which might occur in the slot of the conduit becomes of double importance owing to the fact that it is now obliged to give passage not only to the contact plow but also to the flanges of the car wheels. Second, the conduit structure is obliged to support the weight and the direct effort of the vehicles. On this account a more solid construction becomes necessary. Third, the insulation of the contact plow becomes more difficult owing to the fact that it receives splashes of mud on its surface, coming from the car wheels. Fourth, it has been found impossible to construct a switch system for the side conduit which gives complete satisfaction.

This last disadvantage is much more important than the others. On the one hand, to take the flanges of the wheels requires the conduit to be made with a large groove, and on the other, the upper surface of the switch should be on a level with the top of the rail and should be solid, while at the same time presenting a considerable width at the points of support. Under these conditions, a switch possessing the necessary mechanical qualities would require a groove measuring from 1.8 to 2 inches at the extremity of the switch point. Such a width might be admissible in some European cities, but it is needless to say that in a city like Paris, where the vehicular traffic is chiefly made up of light vehicles, it could not be employed without occasioning serious difficulties, and it is necessary to avoid it as much as possible. In the present system the question has been solved by using the following method:

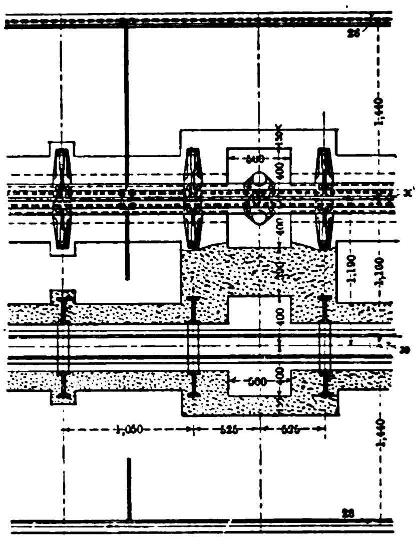

FIG. 4.—PLAN OF UNDERGROUND CONDUIT.

The conduits are placed on the inner side of their respective tracks and are supported by a series of frame castings, which are spaced 42 inches apart. The outer or independent rails of the track are held in place by a series of brace strips, which connect them with the conduit rail and are spaced 84 inches apart. The two conduit rails which lie next each other are braced across by a similar set of wrought iron bars. The general construction will be observed in the sectional view of the track, Fig. 2. The upper section shows the double track with the conduits lying adjacent on the inner side. The large flanged castings are laid in a trench and surrounded by concrete. These castings serve to support the double rail at the top which forms the rolling surface and leaves a sufficient space for passing the conduit plow. The middle section shows the portion of the conduit lying between the supports. It is surrounded by a layer of concrete. The bottom section shows the arrangement of the manhole and cover, and the mounting of the contact rails with their insulators. A plan view of the track is shown in Fig. 4; in the center is the manhole with the insulators for the contact bar, and on either side are the frame castings.

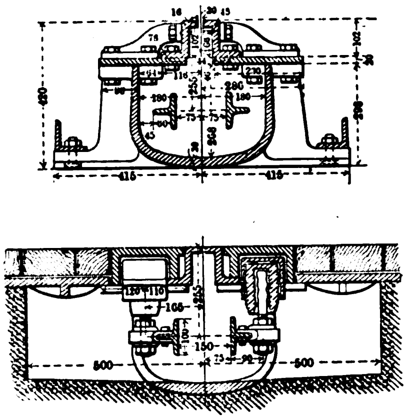

FIG. 5.—SHALLOW CONDUIT.

The conduit system is established by first sinking the frame castings in the roadbed at the proper intervals between the rails of the track. The castings are then connected across to the rails by means of the brace rods and the whole thus forms a solid construction. In the intervals between the frames are placed a series of forms which are made by bending sheet-iron into the form desired for the conduit, and which is defined by the inner opening of the frames. Concrete is then placed around the forms and when dry the latter can be drawn out through the central slot, as they are sufficiently flexible. It only remains to lay the wood paving. This method is simple, and can thus be carried out rapidly. In spite of the different delays which were caused by outside reasons, the Paris conduit was laid at the rate of 375 feet of double track per day. The expansion of the wood paving did not alter the width of the groove, and the conduit was found to resist the highest pressures. As concerns the branch points which occur at the terminals or switching points of the line it was found advisable to pass from the side conduit to the central conduit, as will be observed in Fig. 5. The switch shown to the right is the same as has been used at Lyons, and works very satisfactorily. The plan view and section are shown in Fig. 3. As the opening of the groove at the switch tongue is considerable it is protected by a sliding plate, which moves underneath it. The conduit switch is moved at the same time as the rail switch by a common lever which is placed at the side of the track. The lever is automatically thrown back by the contact plow as it passes.

Where the line crosses the Seine over the Alma Bridge the distance between the masonry arches of the bridge and the street level was found to be too short to allow the regular depth of conduit to be used, and a special form of conduit had to be designed, which would meet the requirements. This type will be observed in the two sectional views of Fig. 5. Here the conduit is made up of sections of a cast-iron tube which are placed together end to end. The sections are about 3 feet long. In the middle the tube is reinforced by a cast web, which forms the base plate for the support. The tube is completed at the top by a cast-steel plate, which is bolted to the upper surface, and serves to support the conduit rails, which have a *Z* section. A series of cast steel brace pieces are bolted to the steel plate and the conduit rail on either side, so as to hold the latter firmly in place. The portion of the conduit which lies within the pit is seen in Fig. 5. Here the casting which forms the tube is open at the sides, leaving only a short strip at the bottom. The method of fixing the insulated supports which hold the conducting rails is shown.

As the use of this type of shallow conduit made it necessary to raise the conducting rails to a higher level, which made a difference in height of five inches above the level of the conductors in the standard conduit on either side, a special device was needed in order to raise and lower the contact plow when the car passed from one type of conduit to the other. This operation had to be carried out independently of that required at the terminals of city line where the plow is to be raised out of the conduit in order to proceed on the trolley section. On two of the less important conduit lines in the United States, the same problem has been solved by simply attaching the contact-plow to its supporting piece or again detaching it when necessary, but for an extensive system such as the one under consideration, where the operation needs to be repeated many times per day, this primitive method would cause a considerable loss of time. It was also desired to avoid the necessity of placing the men in the underground posts, and to perform the operation entirely from above ground.

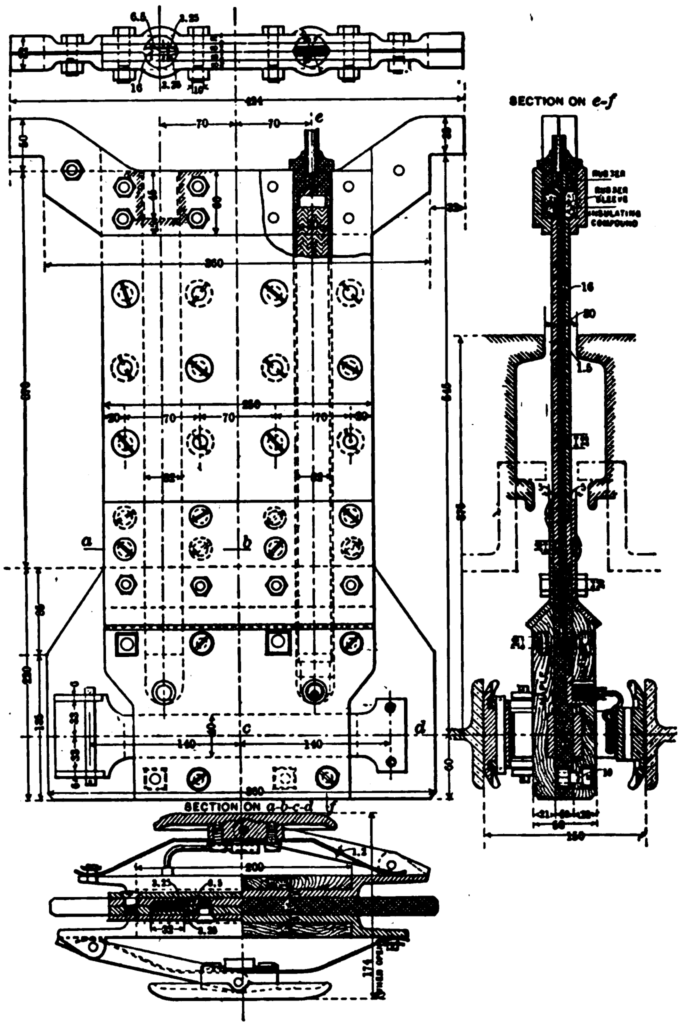

FIG. 6.—SECTIONS AND SIDE ELEVATION OF PLOW.

In Europe this problem has already been studied in connection with some of the leading conduit systems, and has been solved in a very ingenious manner. At Brussels, on the Berlin system, and more recently at Budapest it is recognized that the most simple and practical solution is to maintain the plow underneath the car in all cases, and to devise an apparatus which will allow it to be raised out of the conduit or lowered into it again as required. The types of contact plow which are employed in these cities have been designed so that they can be lifted out through the normal groove of the conduit, and thus can be raised or lowered as may be necessary at any point on the line. In this case, however, the width of groove which has to be adopted becomes considerable, and the design of the contact plow which is used in such cases may be criticized from many standpoints. After a careful study of the subject the contact plow was designed on somewhat the same lines as the form which proved so successful on the Washington conduit system. The plow is provided with two rubbing shoes of cast iron (Fig. 6), which are pressed against the contact rails by light elliptical springs and supported by a pair of horizontal bearing straps which serve to limit their side movement. By the use of these side straps the springs are not required to possess a great mechanical resistance, seeing that the contact shoes are now held by the straps and the latter serve to take up the pressure and the shocks. The springs serve only to secure the slight pressure which is needed between the contact shoe and the bar.

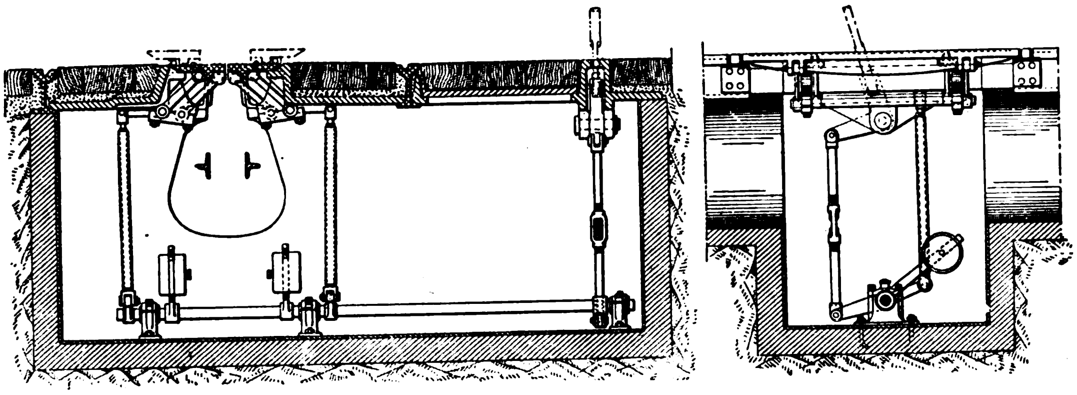

FIG. 7.—ARRANGEMENT FOR WIDENING SLOT TO PERMIT REMOVAL OF PLOW.

In the design of this form of contact plow the constructors introduced some of the principles which have been put in practice by the General Electric Company in order to obtain a great mechanical solidity combined with a sufficient insulation. As will be observed in the engraving, Fig. 6, the plow is built up of sheet iron plates and supports a cross-piece of maple wood and fiber at the lower part which serves to hold the contact shoes. The two wires which pass down between the plates are well insulated from the latter. This type of plow is not intended to be raised out through the slot, as this has not been found necessary in practice.

As to the form of contact plow mentioned, which is designed so as to be raised out of the conduit at any given point, the advantage of such a system is not as great as might be supposed, for in practice it is found sufficient to carry out the raising and lowering operations at the points where the line changes over from the underground to the trolley system or *vice versa*. The operation can, in fact, be easily performed by constructing a passage way for the contact plow at the terminals of the underground system, and adopting a method for rapidly opening and closing this passage by a simple and strong mechanical device. The sectional views, Fig. 7, show the arrangement which was finally adopted for raising and lowering the plow. It was first installed on the Bastille-Charenton line at Paris, which was the first conduit section to be used in the city. As it proved quite satisfactory in its operation, it has now been adopted on the succeeding conduit systems.

At the point where the plow is to be removed, a large underground vault has been constructed. Access to the vault is obtained by a manhole on the right. As shown, the side conduit has now been switched over to a central conduit, and part of the conduit rail has been cut away to leave place for a pair of cast iron trap-doors, which occupy their place. These trap-doors are supported on the outer side by a frame casting, and turn upon a special form of hinge which connects them with the conduit rail. To open up the trap-doors they are raised to the position indicated by the dotted lines by a system of levers which work the hinges and these levers are operated by simply throwing over the lever which is seen on the right, which is provided with a counterweight to balance the weight of the traps and allow one man to raise them easily. On the descent of the contact plow into the conduit it is guided into place by a set of sheet iron pieces.

On arriving at the point for the removal of the plow the motorman operates the traps from above ground by means of the lever, which can be removed from its socket. He then raises or lowers the contact plow by turning a handle at the side of the car, which works the device which will be described. In case of crowded traffic, these operations are performed by a man on the two traps which are placed beside each other for the two tracks. One of the interesting features of the Paris conduit system is the device which is used for raising and lowering the plow. Three different conditions had to be met to suit the needs of the road; first, the plow must be able to travel from one side of the car to the other, taking a lateral movement, so as to pass from the side to the central slot; second, when in its middle position the plow is to be lowered into the conduit or raised out again; third, when the plow is in the side position and working within the conduit, it is to be raised or lowered through a certain distance when it is necessary to pass from the standard conduit to the shallow section, such as is found at the Alma Bridge; fourth; at the proper points the circuits are to be changed over from conduit to trolley, or *vice versa*, by an automatic switching device.

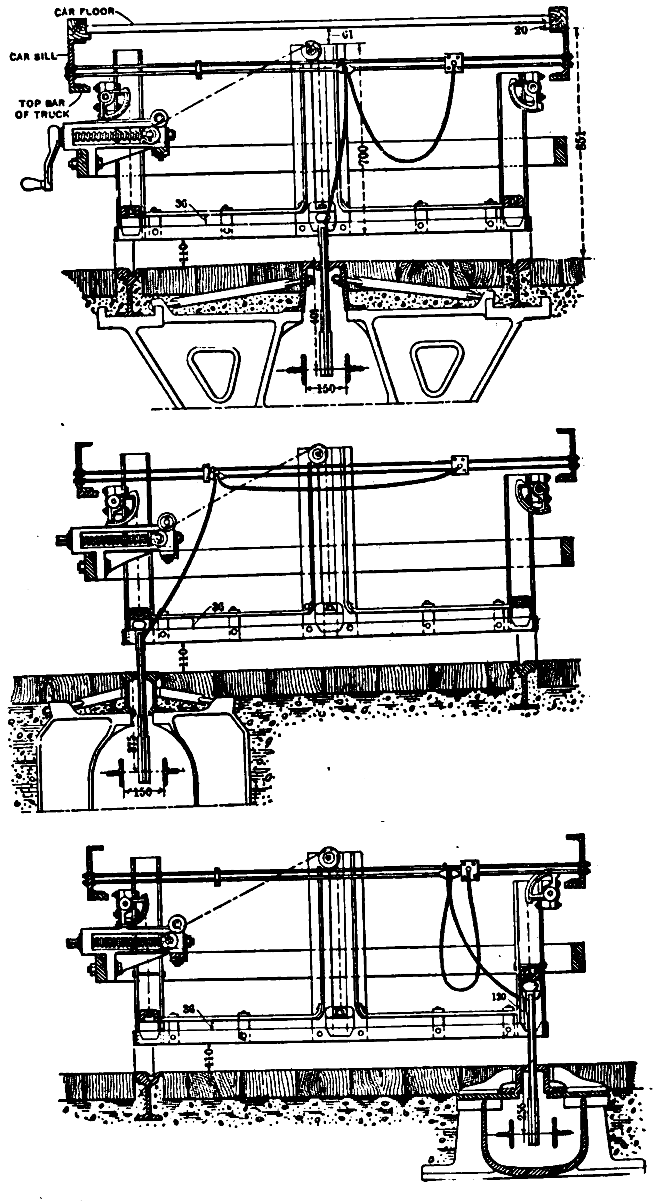

FIG. 8.—SECTIONS SHOWING POSITION OF PLOW IN DIFFERENT TYPES OF CONDUIT.

In Fig. 8 the plow is shown in the three different forms of conduit, from which a general idea of the system may be obtained. The supporting frame of the plow is shown in greater detail in Fig. 9. The plow is raised and lowered by suspension chains which pass around sheaves and are operated from the outside. The device, as a whole, is the same as that used on the first Paris conduit, and on the Lyons and Nice systems, but differs from these as to the method of lifting the plow. On the former lines the lifting chains were attached directly to the plow. This method would not answer in the present system, since the plow is obliged to travel from one side of the frame to the other. The plow is held upon the carrying rails by means of its two upper lugs, as will be noticed in the end view of Fig. 6. Continuous with these rails is a kind of supporting framework, which is placed at the middle (Fig. 9) with a similar one at each end. The lifting chains are fixed to these frames, and when the plow is shifted upon any one of them it can be lifted up, that is, when it occupies the middle or the end position. As will be noticed in the sectional view (Fig. 9), the chains are attached to the frame by means of a lock device, which holds the frame down to the rail. As the chain is tightened, it first unlocks the catch from the rail and then draws up the frame in its vertical guides, and along with it the plow. When the chain is lowered the reverse movement takes place, and the plow comes down into place while the catch is locked in position by a spring.

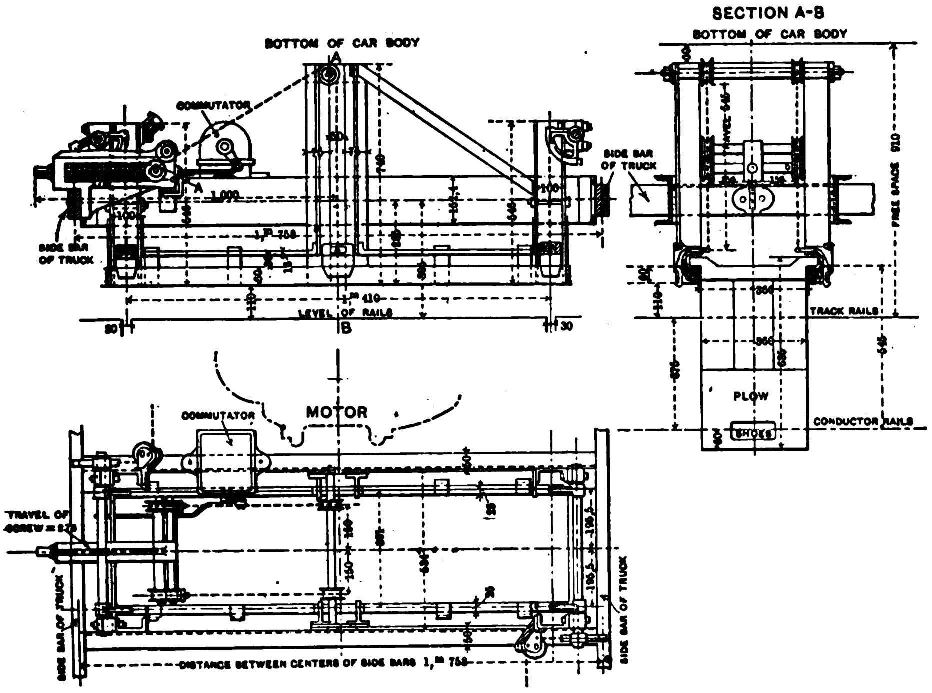

FIG. 9.—METHOD OF SUPPORTING AND RAISING PLOW.

To the left of Fig. 9 will be noticed the device which is used for working the chain. The latter is attached to a traveling carriage which moves back and forth in a guide frame by means of an endless screw. The screw is operated from the side of the car by a removable handle, as will be observed in the upper view of Fig. 8, which shows the plow in the central conduit. At the same time the electrical connections are automatically changed by means of a revolving commutator, which is connected with the screw mechanism by a lever. This commutator is constructed on somewhat the same lines as a controller, having a drum carrying a set of contacts, over which pass the stationary brushes. A quick break is made at the contacts by means of a spring, in order to avoid arcing. The middle section of Fig. 8 shows the method which is used for the side conduit. Here the plow is raised by a chain and sector, which are operated in an analogous manner. The lower section indicates the operation for the shallow conduit, where the plow is to be raised but slightly.

In order to furnish the current needed for this extensive conduit system, a large generating station has been erected towards the western part of the city. The plant is located at a distance of 500 feet from the Seine River, which allows the coal to be brought upon barges. The station occupies a total surface of 28,080 sq. ft., of which 17,180 is covered by the buildings. The station comprises a boiler room, a dynamo room and a very extensive car barn (situated in the vicinity) which is probably the largest in the city.

The boiler room, which is laid out on the ground level, is fitted up with seven multitubular boilers of the Niclausse make, which are disposed so as to form three batteries in all. Each of these boilers presents a heating surface of 1,350 sq. ft. and has a steam producing capacity of 4,000 pounds of steam per hour on the average run, which can be increased to 5,500 at times of heavy loads. The feed water is supplied to the boilers by three pumps. Two of these are steam pumps of the compound type and the third is driven by an electric motor: this latter pump is of the two cylinder pattern. The water for the station is supplied by a well which has been sunk upon the station premises, and delivers about 5,400 cubic feet of water per hour. This is raised from the well by a motor-driven pump which feeds it into a reservoir having a capacity of 3,000 cubic feet. From the reservoir a second and similar pump lifts the water to a filtering apparatus capable of filtering 750 cubic feet of water in 12 hours. The water is then taken to the reservoir which supplies the boilers. A third pump forces the water of the condensers to a cooling apparatus which lowers the temperature of the water from 45 to 20 deg. C. on a volume of 600 cubic feet per hour. In case the well should fail the boiler tank is fitted out so that it can receive water directly from the city mains. The products of combustion are taken off by conduits which occupy the rear part of the boiler plant. The smoke can pass out by a series of movable gates either directly into the chimney or through a Green economizer having 10,000 square feet of heating surface. The coal which is brought upon barges to the wharf is taken thence and stored in the station yards. In feeding boilers the coal is loaded upon small cars which are run on a track

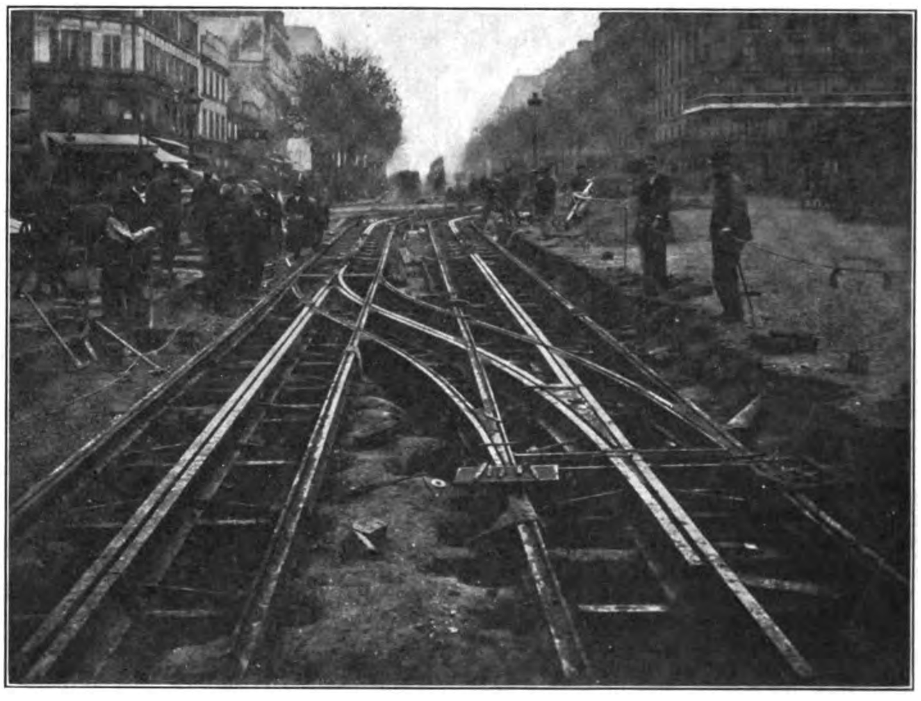

FIG. 10.—CENTER CONDUIT IN COURSE OF CONSTRUCTION.

arranged for the purpose in front of the grates.

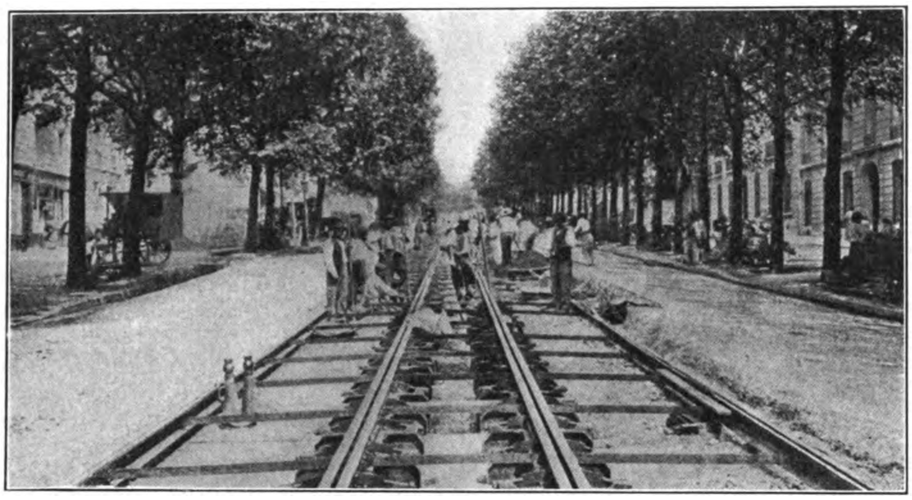

FIG. 11.—SIDE CONDUIT IN COURSE OF CONSTRUCTION.

The dynamo room is adjacent to the boiler room at a level of 10 feet above the ground, and has an area of 13,000 square feet. A general view of the dynamo room is shown in the leading engraving, which shows four of the direct connected generating sets. The plant contains five such units in all. The engines are of the Dujardin horizontal pattern and have a capacity of 300 horse-power each, being of identical construction. The engines are direct coupled to 225-kw. direct-current generators. The engines are cross-compound with a Corliss valve distribution. The high pressure cylinder of these engines measures 16 inches in diameter and the low pressure 30 inches; the piston stroke is 36 inches, and the speed 90 revolutions per minute. The engines are disposed so that they can be changed over from condensing to free exhaust by operating a set of valves provided for the purpose. The condensers have been installed in the basement below the dynamo room, and the condenser pumps are operated from the engines by a suitable transmission.

The five 225-kw direct-current generators for the traction system have been constructed in the Paris shops of the Thomson-Houston Company. The armatures are mounted directly upon the engine shafts together with a large flywheel; they are of the usual drum type built up of laminated iron and provided with ventilating segments. The 8 cast-steel field poles are bolted around the inner periphery of the cast-steel frame and contain a shunt winding of fine wire together with a series winding which assures the over-compounding of the machines. At no load they supply a voltage of 500, and on full load 550 volts. These machines have been designed so that all the parts are interchangeable and it is easy to take out the armature or remove one of the field poles with its coil, without disturbing the rest of the machine.

These machines will stand an overload of 25 per cent during half an hour without overheating. On the ordinary run they deliver a current of 450 amperes and none of the parts heat up more than 45 deg. C.

The switchboard contains 11 panels of white marble, and is made up of 5 panels for the machines, 4 for the feeders, 1 for the lighting and motors of the station and a panel in the center which contains the instruments for checking up the line. The generator panels, which are identical, contain an ammeter, field rheostat hand wheel, field switch, a quick-break switch which is placed in the bus-bar circuit and a Thomson meter. To the instruments on the central panel are connected the ends of the pilot wires which run to different parts of the main line, and the drop of voltage can be constantly observed.

A set of feeders which start from the station supply the traction line at different points. The feeder system is made up of 8 sheathed and insulated cables of 500 square millimeters section, having a total length of 11 miles of cable; 4 similar cables of 250 square millimeters section, with a total length of 4.2 miles of cable; and 4 cables of 150 square millimeters, with the same length as the former. This makes in all nearly 20 miles of cable.

The car-barn, which is one of the largest in Europe, is laid out so as to afford an easy inspection of the material, as well as repairs, and has an efficient motor-operated system for shifting the cars from one track to another. The total surface of this plant is 150,000 square feet, while the car-barn proper occupies a large building of steel construction having an area of 100,000 square feet.

Here are stored the 90 motor cars, 90 trailers, and 2 electric street sweepers which form the present outfit, or a total of 182 cars. A series of 30 or more tracks cover the interior of the building. Across the tracks run three traveling platforms for shifting the cars. Two of these platforms are used for the motor cars and measure 180 feet long by 24 feet wide. They are operated by motors of the railway pattern and standard controllers, and take the current by a set of contact shoes from copper bars placed beneath. The third platform, for the trailers, measures 156 by 15 feet. The current for the motor is taken from a conduit of the standard pattern by means of a contact plow.

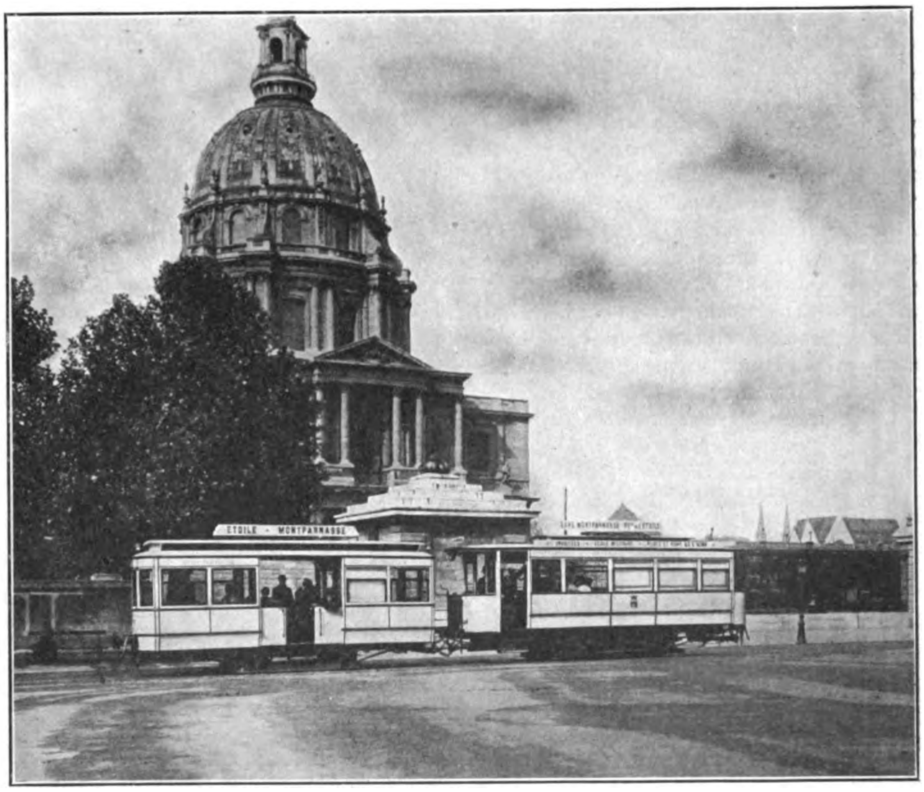

FIG. 12.—MOTOR CAR AND TRAILER.

The type of motor car and trailer which is used on the Paris system is illustrated by Fig. 12, which shows the cars in front of the Invalides. The motor car, to the right, is equipped with two G. E. 58 motors of 37 horse-power, with a controller on each platform. It will hold 36 passengers in the first and second class, but standing room is allowed only on the platforms, as is usually the case in France. The trailers, which are used only occasionally, contain 33 seats.

PREDETERMINING MAGNET WINDINGS.

BY GEORGE W. MALCOLM.

The article on magnet windings, in the January number of the paper, is so closely in accord with my own methods that I trust I may be pardoned the addition of some remarks on the subject, along the line of the article mentioned. I have been in the habit of determining the value of the current required to bring the coil to the working temperature by assuming that that current would in one hour raise the temperature of the coil one-third of the total rise for ten hours, and making the ten-hour rise the criterion of heating. Thus if the rise in temperature after ten hours in circuit was to be 60°, I assume that the current which produces a rise of 20° in one hour will cause the 60° rise in ten hours. This is not always true, of course, but it is near enough for practical work. Representing this by I_h, as in last month's article, and the current required to do the work by I_t, the proper length of the permanent coil is

$$L_t\sqrt{\frac{I_t}{I_h}} = L_c \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(1)$$

L_t being the length of the test coil. Thus far, the procedure is exactly the same as described in the article of last month excepting the length of time taken to determine the heating limit. Beyond this point, however, the method differs. It is my custom to use either No. 8 or No. 14 wire in the test coil, and to determine the size of the wire in the permanent winding by comparison with the size of that in the test winding and the voltages of the two.

Dividing the voltage at the terminals of the test winding by the current passing, when the winding has been raised to the proper temperature as previously described, will give the warm resistance of the winding, of course, and multiplying this by the exciting current required for proper magnetic performance will give the e.m.f. that would be required at the terminals of the test winding to produce the proper excitation when the winding is warm; the ratio between this e.m.f and the e.m.f actually available for the working of the magnet is practically identical with the ratio between the size of the wire required for the permanent winding and the size of that used in the test winding. In formula shape:

$$\frac{\frac{E_h}{I_h}\times I_t}{E} = \frac{d_c^2}{d_t^2},$$ or written in somewhat simpler form:

$$\frac{E_h}{E}\times\frac{I_t}{I_h} = \frac{d_c^2}{d_t^2}\ldots\ldots\ldots\ldots\ldots\ldots\ldots(2)$$

This latter expression is more convenient to handle, the ratio $\frac{I_t}{I_h}$ having been necessarily obtained already. When it is solved, one must, of course, take the nearest higher value for $\frac{d_c^2}{d_t^2}$ that can be obtained with standard wire sizes. In order to facilitate this choice, Table I has been prepared; this gives ratios of wire sizes through a sufficient range to meet all practical requirement. Having found the nearest available ratio of wire sizes from the table, represent it by R_a, and apply the formula

$$\frac{I_t}{I_h}\times\frac{E_h}{R_a} = E_c \quad\ldots\ldots\ldots\ldots\ldots\ldots(3)$$

The value, E_c, thus obtained, will be the e.m.f. necessary to excite the *permanent* winding (of wire having a cross-section of $R_a \times d_t^2$ circular mils) to the proper degree when that winding is warm. This value will not agree with the e.m.f. actually available for the work unless the ratio $\frac{d_c^2}{d_t^2}$ obtained by means of formula (2) happens to be identical with one of the ratios in Table I. In the case of dynamo field magnet windings, the discrepancy will not be worth the trouble of compensating it by modification of the winding, for the reason that the actual voltage at the terminals of the winding in practice is not necessarily fixed at any one value beforehand, an adjustable resistance always being inserted in series with the winding. So far as such a winding is concerned, therefore, the result of formula (3) may be taken as final. This is also true of the shunt field winding of a constant-potential motor unless the machine is designed for operation at some very exact speed, which is very rarely the case.

TABLE I.

Wire in permanent coil smaller than wire in test coil.				Wire in permanent coil larger than wire in test coil.			
N-N_t	$\frac{d^2}{d_t^2}$	N-N_t	$\frac{d^2}{d_t^2}$	N_t -N	$\frac{d^2}{d_t^2}$	N_t -N	$\frac{d^2}{d_t^2}$
1	0.793	11	0.078	1	1.26	11	12.8
2	0.629	12	0.0618	2	1.59	12	16.15
3	0.498	13	0.049	3	2.	13	20.4
4	0.395	14	0.0389	4	2.53	14	25.7
5	0.313	15	0.0308	5	3.19	15	32.4
6	0.249	16	0.0245	6	4.02	16	40.9
7	0.197	17	0.0194	7	5.07	17	51.65
8	0.156	18	0.0154	8	6.39	18	65.
9	0.124	19	0.0122	9	8.06	19	82.
10	0.0984	20	0.0097	10	10.17	20	103.3

Note:—N represents the gauge number of the wire that is to be used in the permanent winding. N_t represents the gauge number of the wire in the test winding. The whole numbers, 1 to 20, in the 1st, 3d, 5th, and 7th columns are the differences between the two gauge numbers. Thus, with No. 8 wire in the test winding, if N—N_t = 6, the value of N is 14, which would be the gauge number of the wire to be used in the permanent winding.

In the case of an ordinary electromagnet, if the value of E_c obtained by formula (3) is more than 15 per cent below the e.m.f. at which the permanent winding is to be worked (it cannot possibly be more than 19 per cent below) it will ordinarily be found advisable to make the following correction:

Representing the number of turns of wire in the test coil by T_t, and the number of turns to be actually put in the permanent coil by T, this latter value will be given very closely by the formula

$$\frac{E}{E_c}\times\frac{T_t}{R_a}\times\frac{L}{L_t} = T\ldots\ldots\ldots\ldots(4)$$

in which L represents the length of coil actually adopted for the permanent winding. This value should be the nearest practical figure larger than the value, L_c obtained by means of formula (1). No allowance for differences in insulation thickness has been made in the foregoing formulas, and none is necessary if the wire in the test winding is not more than six or eight gauge numbers larger than the wire of the permanent winding. The latter, of course, will not contain as many turns as it theoretically should in order to make good the relation

$$d_c^2 \times T_c = d_t^2 \times T_t,$$

on which formula (4) is based, but it will usually be found that the discrepancy produces no seriously objectionable results, if the wire is wound properly; if it is "spun on" indiscriminately, no calculations will apply.

If the tests and calculations have been accurately made, the current taken by the permanent winding, at the voltage, E, will be

$$\frac{T_t\,I_t}{T} = I.$$

If this should be greater than is desired for operating economy, the length of the coil will have to be increased enough to permit increasing the number of turns to satisfy the equation

$$\frac{T_t\,I_t}{I'} = T',$$

in which I' represents the current allowable on the score of economy, and T' equals the number of turns necessary to reduce the current to that value.

If the magnet winding is to be worked at a certain current value regardless of the voltage at its terminals, the size of wire may be approximated by the formula

$$\frac{I}{I_t} = \frac{d_c^2}{d_t^2}\ldots\ldots\ldots\ldots\ldots\ldots\ldots(2\text{-a})$$

instead of formula (2), and the nearest tabulated ratio, R_a, $\left(=\frac{d^2}{d_t^2}\right)$ is taken. The number of turns per coil in the permanent winding is, of course, given by the equation

$$\frac{I_t\,T_t}{I} = T,$$

and if the value I is a fixed one, this number of turns must be put in, even if it necessitates increasing the length of the coil; as a rule, however, the proper number can be obtained by slightly enlarging the girth of the coil, retaining the length at the value adopted from the result of formula (1).

If the temperature of the test coil, when given the proper excitation to the magnet, happens to be correct, so that no test is necessary to find the proper heating current, no correction in the length of the coil will be necessary, and if the permanent winding is put on evenly (not spun on criss-cross fashion) the relation between the size of wire in the test coil and that in the permanent coil will be

$$\frac{E_t}{E} = \frac{d}{d_t} \quad \dots\dots\dots\dots\dots\dots\dots\dots (5)$$

◆

THE TONE TEST.

BY A. DALLAM O'BRIEN.

Since the adoption of the multiple switchboard in telephone central offices, it has been necessary that some means should be provided whereby the condition of any line connected to the switchboard might be ascertained by any operator. It was this necessity that led to the introduction of the familiar "busy" test, which enables the operator to ascertain the condition of any line by placing the tip of one of a pair of connecting cords in contact with the sleeve of the line jack; in the event of the line being busy the operator is notified of the fact by receiving a slight click in her receiver, due to the flow of a current from the jack sleeve through a secondary winding of her induction coil to ground.

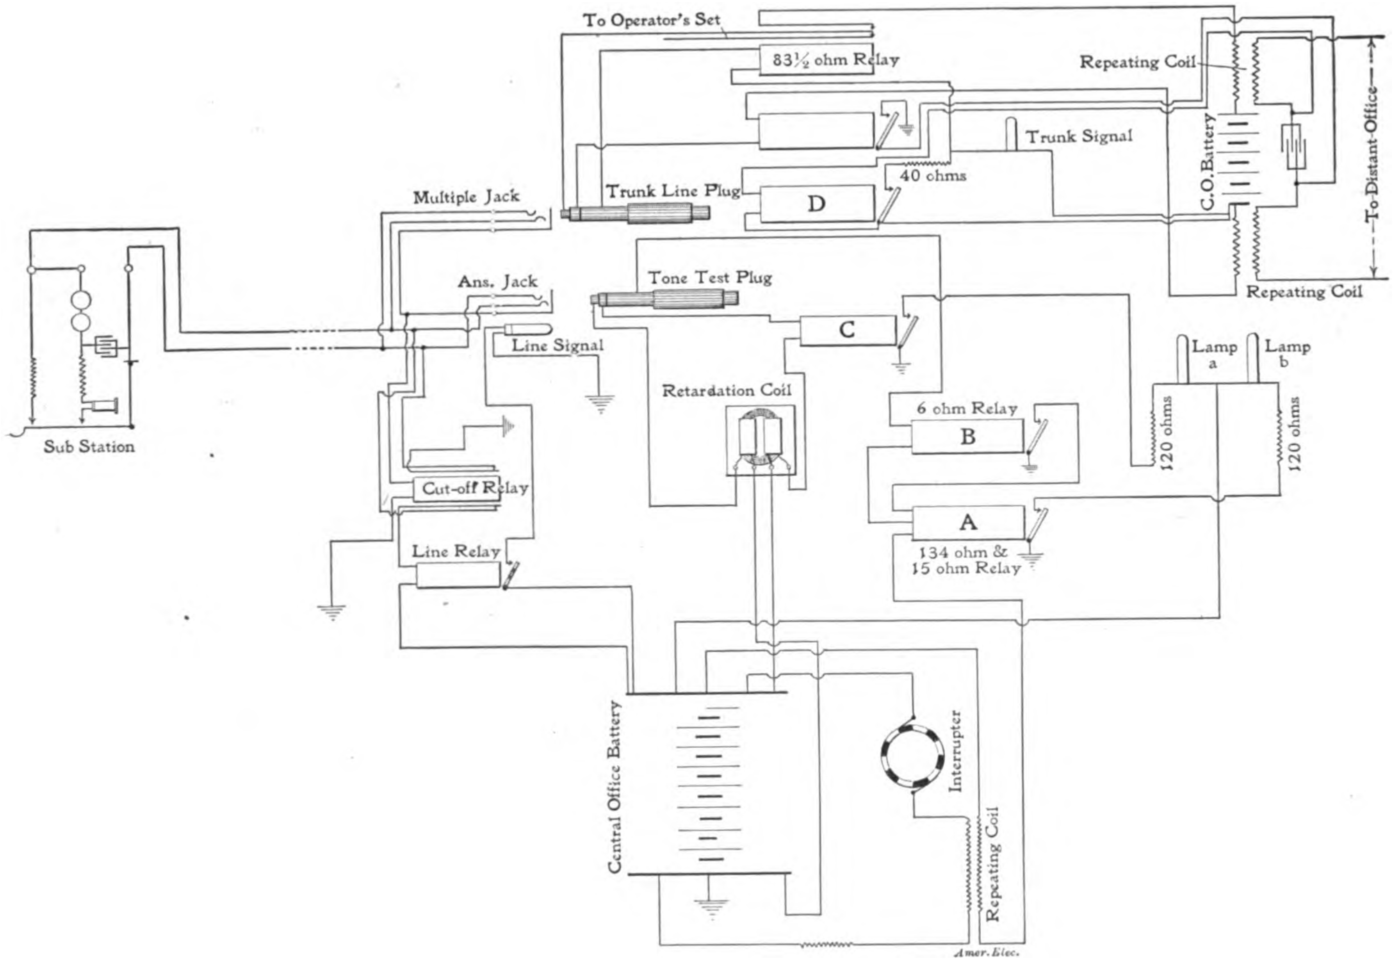

FIG. I.—DIAGRAM SHOWING SUBSCRIBER'S CIRCUIT, TONE TEST CIRCUIT, AND TRUNK LINE CIRCUIT.

With the advent of the common battery system, it became possible not only to expedite the work of an operator but also to give to the operators at the switchboard means of obtaining a more intimate knowledge of the conditions of the connected lines than had heretofore been possible. This end has been very largely accomplished through the use of distinctive test circuits, in which an interrupted current of a certain predetermined periodicity is applied to the sleeve of the line jacks in much the same way as the original "busy" test, the effect of this arrangement being that upon testing the line an operator instead of receiving the usual click hears through her receiver a musical tone of a character depending upon the periodicity of the interrupted current. At the present time, in large central offices several distinctive tone tests are used, the most prominent being the "out of order" test and the "long distance busy" test. It, of course, requires experience on the part of the operator to distinguish the different tests, but as the tones vary considerably a little practice will enable them to be distinguished with absolute certainty.

It is the purpose of this article to describe the principle and operation of the tone test as used in connection with calls completed over long distance and toll lines, as it was to this class of work that tone-test circuits were first applied. The completion of long distance and of toll calls involves practically the same method of operation on the part of the subscriber's operator, and in order to understand fully the significance of the tone test it is necessary that the operation involved in completing such calls should be perfectly clear. Each subscriber's operator's position is equipped with a calling circuit which terminates at the receiver of a recording operator, who is located at the long distance or toll office.

Trunk lines are provided between the local exchange and the above mentioned offices, these lines terminating in cords and plugs at the local offices and in jacks at the other end. Calling circuits are also provided between the offices, these circuits terminating at the receiver of the trunk operator at the local exchange. A subscriber wishing to make a long-distance call removes the receiver from the hook and signals the office in the usual way. The operator answers, and ascertaining that a long-distance connection is desired, instructs the subscriber to hang up the receiver and informs him that "Long Distance" will call him. The operator then places a tone-test plug in the jack of the calling line, and connecting her outfit to the calling circuit leading to the long distance office, informs the recording operator that the subscriber wishes to make a long-distance call. The recording operator makes a memorandum of the number of the calling line and passes it to another operator who connects her telephone set to the calling circuit leading to the trunk operator at the local office and repeats the number of the desired line. The local trunk operator assigns a trunk and places its plug in the multplie jack of the line desired and rings on the trunk or allows the long distance operator to ring, as the arrangement of circuits may require. The calling subscriber is thus connected to the long distance office and enabled to give directly the details of the connection desired. The further operation required to complete the call is not essential, so far as the tone test is concerned.

In Fig. 1 is shown a diagram of the subscriber's circuit to the local office, the tone test circuit and the circuit of a trunk line leading to a long distance or toll office. It must be understood that the arrangement of circuits shown herein is not always adopted, but as the principles involved in any case are the same this arrangement may be taken as a representative one. The circuit of the subscriber's line is the standard three-wire common battery arrangement whereby the removal of the receiver from the hook at the sub-station signals the operator by lighting a small incandescent lamp in the switchboard.

Assuming that the subscriber desiring to make a long distance call has signaled the office and informed the operator of the connection desired and that the operator has placed the tone test plug in the jack, the operation of the circuit can be followed from the diagram. Current from the battery flows through the winding of the repeating coil; thence through the two relays, *A* and *B*, to the sleeve of the tone-test plug; through the sleeve of the jack and cut-off relay to ground, thus operating the relay *B*, and the cut-off relay. The current which flows through the relay *A* under these conditions is not sufficient to operate it. When the long distance operator, having received a memorandum of the call, orders the line up over the calling circuit to the local office, the local trunk operator places the trunk line plug in the multiple jack of the calling line, and the connection between the sub-station and the long distance office is completed. The insertion of the trunk line plug in the multiple jack causes a rearrangement of the resistance connected in the circuit and forms a combination equivalent to that obtained in the circuit of an unbalanced Wheatstone bridge, allowing additional current to flow through the relay *A*, so that the relay is operated and current allowed to flow from the battery through the lamp, *b*, to the armature of relay, *A*, and thence to ground, thus lighting the lamp and notifying the subscriber's operator that the calling subscriber has been taken up by long distance. Upon receiving this signal, the operator removes the tone test plug and is through with the connection.

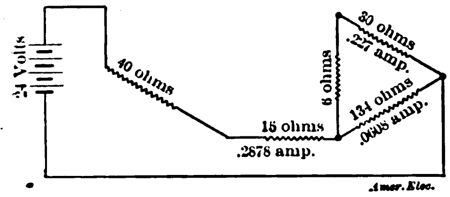

FIG. 2.

In order to show clearly just what occurs when the tone test plug is inserted, it is necessary to consider three different conditions. The first case occurs when the tone test is inserted in the subscriber's jack, and is illustrated diagrammatically in Fig. 2. Here we have the current flowing first through the 40-ohm winding of the repeating coil; thence through the 15-ohm winding of relay, *A*, where it divides, a portion flowing through the 134-ohm winding of the relay and the remainder flowing through relay, *A*, and the cut-off relay, the resistance of the latter being 30 ohms. The current which flows in the various branches of the circuit is indicated in the diagram, and it will be noted that about 0.06 ampere flows through the 134-ohm winding, and in this case relay, *A*, is not operated.

In Fig. 3 is shown the arrangement of the circuit when the local trunk operator has connected a trunk line to the jack of the calling subscriber; and in addition to the arrangement of resistances, shown in Fig. 2, there is inserted the remaining leg of the bridge which consists of the resistance of the trunk signal lamp (120 ohms) and the resistance of the 83½-ohm trunk relay. In order to find the distribution of current in this circuit, it is necessary to form the six equations resulting from the application of Kirchoff's laws and eliminate between them and solve for the value of the current in the different branches of the circuit. The values resulting from this process are indicated on the diagram, and in the solution of this problem it is necessary to state that the resistance of the battery leads has been considered as being negligible. A current of 0.07 ampere now passes through the 134-ohm winding of the relay *A*, and in addition, the current flowing through the 15-ohm winding of the same relay is considerably increased so that the relay is now operated and the signal lamp, *b*, lighted.

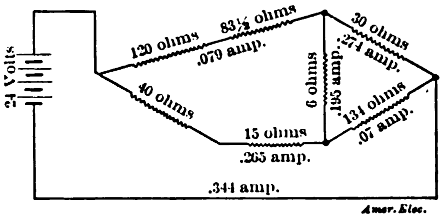

FIG. 3.

The case outlined above only occurs when the local trunk line operator, having made an assignment, connects the trunk with the jack of the calling line and the long distance operator fails to take up the trunk at the long distance end. When the trunk line is taken up by the distant operator, we have the conditions illustrated in Fig. 4. Here we have a 40-ohm shunt closed around the trunk signal, and consequently, instead of having 120 and 83½ ohms in one leg of the bridge, we have the 120 ohms resistance of the lamp in parallel with the 40-ohm shunt, giving an equivalent resistance of 30 ohms. The values of the current in the different branches of the circuit are worked out in the same manner as in the preceding case and are indicated in the diagram.

In Fig. 1 it will be noticed that two batteries are shown. This, however, is done merely for convenience in drawing; one battery is used to furnish all the current for the central office.

The tone test itself is produced by interrupting the flow of current from the battery by means of a suitable commutator, the number of segments on the commutator determining the pitch of the tone that it is desired to produce. This commutator is usually mounted on the shaft of the central office ringing machine and is rotated continuously. The interrupted current flows from the commutator through the primary winding of the repeating coil and a resistance to battery inducing a similar current in the secondary winding, which current flows to the sleeve of the tone test plug and thence to the jack sleeves of the line to which the tone test is connected. If any operator at the switchboard should receive a call for a line which for some reason is being held on a tone-test plug, she will upon testing hear in her receiver the peculiar hum caused by the interrupted current and will know that the line in question is not only busy at that instant but that it will continue to be occupied for a considerable length of time; consequently, the operator is in a position to say to her calling subscriber that the line desired is waiting for a long distance connection and that it will probably be some time before a local connection can be completed.

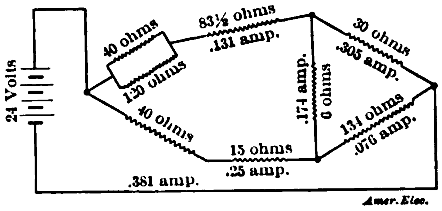

FIG. 4.

By means of the lamp *a*, the calling subscriber who is being held on the tone-test plug is able to signal his local operator in case there should be any delay on the part of the long distance operator in taking him up. By removing the receiver from the hook at the sub-station current is allowed to flow from the battery through one winding of the retardation coil, the relay *C*, the ring of the tone-test plug, thence through the subscriber's instrument; back through the tip of the plug and the other winding of the retardation coil to the opposite pole of the battery, thus operating the relay *C* and lighting the lamp *a*, which notifies the operator that the subscriber wishes to communicate with her. The insertion of the retardation coil in the circuit serves to prevent the impairment of transmission, which might result should the subscriber's operator fail to remove the tone test when the lamp *b* lights, the high impedance of the coil serving to prevent practically any flow of the voice current through the shunt circuit formed by the tip and ring strands of the tone test plug.

The trunk line circuit, shown in the diagram, is of a very common type and offers no difficulties, the only point that it is necessary to consider in connection with the tone test being the operation of the relay *D*, which serves to close the 40-ohm shunt around the trunk signal and extinguish the lamp. This relay is operated from the distant office when a plug is inserted in the trunk line jack, this action grounding the side of the line to which the relay is connected and allowing current to flow from the battery through the relay to ground. When the plug is removed at the distant office, the relay *D* releases its armature, the 40-ohm shunt is removed from around the lamp and the trunk signal is lighted, thus notifying the local trunk operator to take down the connection.

From the foregoing description it will be apparent that from the receipt of the call by the subscriber's operator until the connection is completed through to the long distance office, the subscriber's operator is thoroughly in touch with the situation and in case of delay can take the necessary steps to expedite the connection. At the same time, the calling subscriber is held in such a position that should the necessity arise he can obtain connection with the local office. This form of test has operated so successfully that it is being applied in telephone exchanges to meet a number of requirements, the essential feature being that each test should have a thoroughly distinctive tone in order that complications due to a confusion of signals may not result.

◆◆◆

Fly-wheel Design.—The fly-wheels of slow-running engines are imposing, and have to be designed very carefully to meet the conditions of fluctuating loads, whilst at the same time not exceeding the safe limit. Accidents are happily much rarer than they were, and this is, no doubt, due to the greater skill which is given to the design of the fly-wheel, and also to the fact that most slow-running engines nowadays are fitted with an automatic stop motion.

In a cast-iron fly-wheel rim the safe tensile working stress is reached, at a maximum peripheral velocity of 100 ft. per second, which corresponds to about 80 ft. to 90 ft. per second on the mean circumference; the maximum stress due to centrifugal force being then about 1000 pounds per square inch. If the rim is solid this means a factor of safety of eight, which is about the minimum. Flange-jointed wheels should not be run above 70 ft. to 75 ft. per second, whilst built-up steel wheels may be run at 130 ft. per second.

A good average value for the energy necessary to be stored in fly-wheels for electric lighting purposes is 2.9 foot-tons per electrical horse-power or for traction purposes 4 foot-tons. For a 500-kw. set with a two-crank engine, the rotating mass will weigh about 50 tons, for 1000-kw. about 60 tons, for 1500-kw. about 75 tons, for 2000-kw. about 100 tons, and for a 2500-kw. about 150 tons.—*Exchange.*

TELEPHONE ENGINEERING.

Erection of Cables.

BY F. J. DOMMERQUE.

After the messenger has been pulled into place, the reel with the cable that has to go up first, is taken to the pole ahead of the cable pole and the lagging is carefully removed; the screws must be taken out also, so that they cannot scratch the lead when the cable is unreeled. It is advisable to unpack the cable very carefully for two reasons; first, so as not to damage the cable, and second, so as to preserve the reel in good condition as it can be returned to the cable manufacturer to be used over again, if the factory is not too far. The reel usually has an opening through its center to allow a shaft to pass through; this shaft when passed through is provided with collars at each end, secured by set screws so that the reel is free to revolve but not to slide sidewise. Two wheels are then attached to the ends of this shaft, the wheels being of a larger diameter than the reel, so that the outfit when put together serves as a carriage for the reel. Outside of the wheels an iron fork may be attached so that it can be removed easily when a new reel is to be put on; this fork has a pole attached to it by means of which the carriage is drawn. A reel containing not more than 1,000 feet of cable (this is about all that can be pulled at the time) is mounted upon the carriage and wheeled about 125 feet ahead of the pole where the cable is to start from. The reel is so placed that the cable will reel off from the top. An inspector is placed right at the reel who is to watch for any defects in the cable—principally in the lead sheath —and prevent any defective cable from being hung.

To provide an incline for the cable from the reel to the first pole, a piece of No. 4 steel wire, if such a one is handy as a remnant from the messenger, or else a No. 6 wire, is run from the first pole to the ground near the reel. Now a one-inch rope as long as the cable or rather a little longer, is attached to the cable, which may be done in several ways; one method is to braid over the end of the cable the strands of the rope and terminate them in a head provided with a swivel to which the end of the rope is fastened; another method is to bend a flat iron bar in the shape of a U and have the two side pieces fit the cable; from four to six screws are driven through the two side pieces with the cable end between them. At the bend a swivel is provided to which the rope is attached. At the first pole a wooden pulley block is located with its top just below the messenger to facilitate the running of the cable. It is therefore necessary to station two men upon the first pole, one to lay the rope and the cable over the pulley and guide it while it is sliding along, and the other one to hook the cable to the messenger. One man is to be stationed upon every pole thereafter for the purpose of passing the messenger over the cable supports. At the reel, besides the inspector, three men are needed. At the other end of the rope a winch is stationed driven either by horse, steam or electric power requiring the attendance of two men for the operation of the winch and one to watch the slack. Care must be taken that the velocity of the rope is not too high, else the men will not be able to fasten the hangers fast enough.

There are a number of hangers on the market which may be divided into two general classes, namely, non-metallic and metallic hangers. Hangers of the first class consist of a galvanized steel "goose-neck" to hook over the messenger and a marlin or leather or cotton strap which is impregnated to make it withstand the influence of the weather. This string or strap is looped around the cable. The metal hanger has also a galvanized steel hook to hook over the messenger, this hook being usually a double loop so as to obtain a wider bearing surface; to this a flat strip of zinc is attached which is drawn around the cable until it hugs the cable tight and then it is locked by the hook. Another metallic hanger is made of malleable iron in one piece. It is attached to and removed from the cable by a pair of special tongs.

The non-metallic hanger has the disadvantage that lightning may in its flight along the messenger burn the hangers and let the cable fall to the ground; another disadvantage is that it does not have a fixed position upon the cable.

The solid metallic hanger has the disadvantage of inflexibility; if such a hanger is caught in some obstacle while the cable is pulled along, it is sure to damage the cable.

The zinc strap hanger avoids all these objections and therefore seems the best one; it is also durable.

Marlin hangers cost from $5 to $10 per thousand according to size of cable. Zinc-strap metallic hangers cost about $30 per thousand.

Returning now to the reel, the rope is attached to the cable and pulled over the pulley or sheave at the first pole then along the entire line and finally laid upon the winch to be wound up. Now the cable starts to unreel at a slow speed, say 12 feet a minute, and one man marks off the points where the hangers are to be attached, allowing as a rule 20 inches between hangers (never more than 24 inches at the outside) the next man attaches the hangers at the marked points, and the third one stationed at the reel hooks the hangers upon the steel guide wire. It is not necessary to hook all the hangers, only every fourth or fifth. As the hangers reach each man on a pole, he unhooks them again as soon as they have passed the messenger support. When the cable reaches the last section all men hook all the hangers so that when the cable is in place, all hangers are upon the messenger. If the cable, when in place, is too slack a man can ride the cable in a cable car and straighten out the cable either by hand or by a piece of soft wood and a hammer. Such cable car consists of two trolleys attached to one side of an iron bar; from the bar a seat is suspended. The car is pulled along by a rope.

There is still another method of suspending the cable from the messenger, namely, by means of a continuous marlin string. This method, however, has the disadvantage that when the string breaks at one point an entire section of cable becomes unfastened; it also has the disadvantage of the possibility of lightning burning the marlin mentioned before in connection with marlin hangers. In this method the cable is hung from the messenger in snatch blocks; then beginning from the first pole the marlin string is tied to the messenger and reeled upon a so-called "spinning jenny," which consists of two pieces of wood, forming a hollow cylinder when put together. To the spinner a rope is attached by which it is pulled along to the next pole by a man stationed upon the pole; while gliding along the messenger the marlin string unreels and ties messenger and cable together. A new piece of string is started at every pole. But for the above-mentioned disadvantages it would be a clean-cut way of suspending the cable.

PRELIMINARY WORK TO LAYING OUT A CONTACT RAIL SYSTEM.

BY WM. A. DEL MAR.

This article deals with the practical problems with which a draughtsman has to contend when preparing to layout a system of contact rails. This work really belongs to the civil engineer, but in actual practice it usually falls in the hands of the electrical draughtsman—that unfortunate individual who must know something of every branch of engineering.

When an entirely new railway is being projected the contact rail man has a fairly simple task, for the drawings of the projected track work can be altered to meet the requirements of the electrical engineer. When, however, an existing steam line is being converted, as is the case of the Manhattan elevated road, for example, the contact rail problem involves some complications, because the plans must be made to fit the existing road. In this case, the contact rail engineer has to begin by taking measurements of the track work in order to make drawings of the crossovers and other complications. Two men are required for this work, and they only require a linen tape line to make the measurements with. A linen tape is better than a steel one, as it is easier to swing it out of the way of trains. Furthermore, if any live rail were already installed a steel tape might be burnt by contact with the rail and track. In such a case it is necessary to be careful even with a linen tape as the thin wires which are woven into it for the purpose of giving strength, are apt to be fused by contact with the rail.

A typical turnout is shown diagrammatically in Fig. 1, where the lengths to be measured are given; *F* is the distance from the point of the switch to the point of the frog, and is called the "frog distance"; *D* is the length between the adjacent frogs, and *Z* the distance apart of the track centers. In such a diagrammatic view the lines represent the gauge lines of the track rails. On the other hand, when a contact rail is represented by a line, it is the center line that is given. Fig. 2 shows a rail section in which the dotted line, *G G*, represents the gauge line, which is, of course, on the inside of the track. In Fig. 3 the gauge lines of a frog are denoted by heavy lines. The "point" of the frog is the intersection of the gauge lines, and is indicated by *f*.

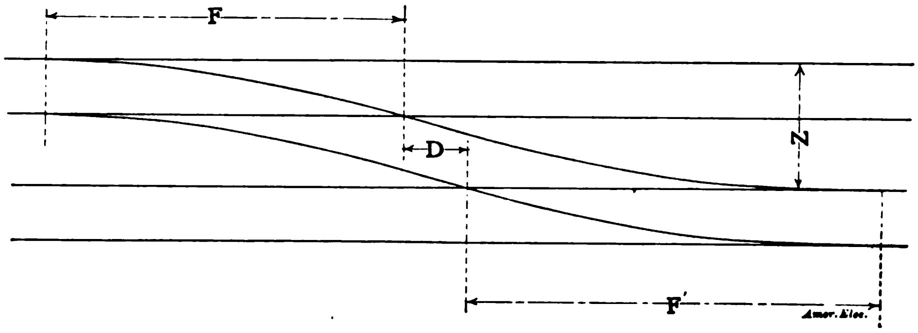

FIG. 1.

It is important to distinguish between the "point" of a switch and the "point" of a curve. The point of a curve is the point at which the curved gauge line is tangential to the straight gauge line. In practice, however, as the curved rail cannot be brought to a mathematical point where it meets the straight one, it is cut off where it begins to be too thin. The place where the curved rail actually ends, is called the point of the switch. The distance in feet between the point of curve and point of switch usually amounts to something like one-quarter of the square root of the radius in feet of the turnout curve. In actual practice, however, this quantity is widely variable, so that the rule given can only be regarded as an approximation.

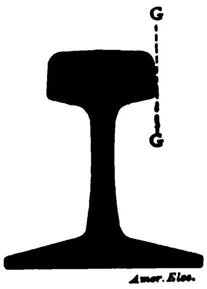

FIG. 2.

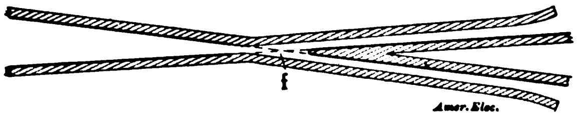

FIG. 3.

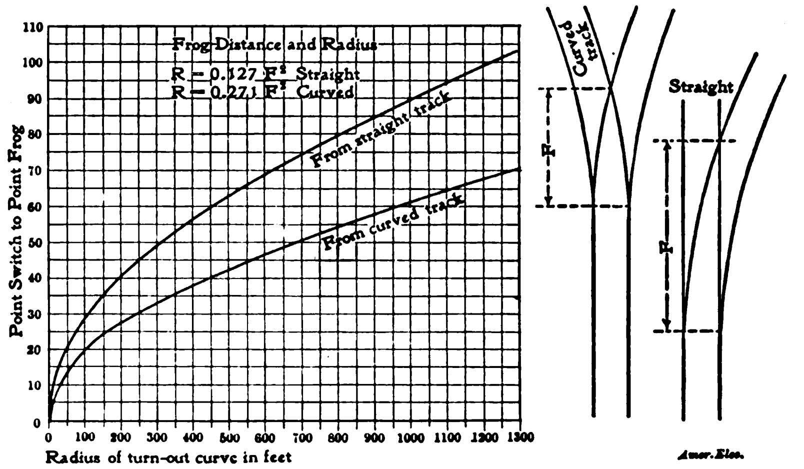

FIG. 4.

Two curves which give the radius of a turnout curve in terms of the frog distance, *F*, are given in Fig. 4. These curves are extremely useful, as the draughtsmen may at a glance find what radius of curve to use in making his drawing from field sketches. Fig. 5 shows the relation between the frog angle and the radius, the frog angle being that between the straight rail and the tangent to the curved one at the frog point. These curves are only correct for the standard gauge of 4 ft. 8½ ins. When drawing out track work, the curves are drawn by means of wooden or celluloid templates consisting of circular arcs of various radii.

Frogs of different angles are distinguished by their "number." The frog number is

$$N = \frac{1}{2} \, \frac{1}{\tan \frac{1}{2} \Theta}$$

where Θ is the frog angle. This relation is shown by the curve in Fig. 6. The frog number is measured by the ratio of the lengths $a + b$ and $c + d$ in Fig. 7. It is useful in the case of a turnout such as shown in Fig. 8, in which case

$$\text{Radius} = 2N \left[B - \frac{Z - G}{\tan \Theta} \right]$$

Where the adjacent tracks are diverging as shown in Fig. 9, the distance between centers of tracks should be measured at every frog and switch point, as indicated at Z_1, Z_2, Z_3.

Occasionally, when laying out the track work from rough sketches, the two curves of a turnout do not meet, as shown in Fig. 10. This often arises from an error in measuring or setting off the track centers.

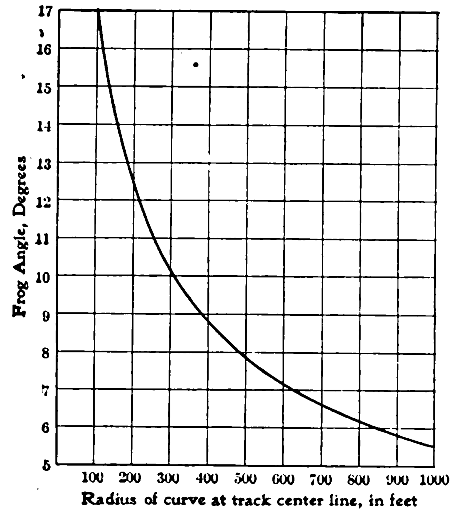

FIG. 5.

Sometimes, however, it happens that these may be correctly done, and yet the curves do not meet. This is due to the fact that the rails are not bent into exactly circular arcs, so that in such a case curves must be chosen that will make the turnout continuous and free from sharp bends.

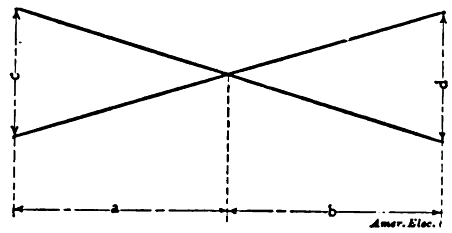

FIG. 7.

The suggestions given above should be sufficient to enable the track work to be drawn from field sketches in a manner sufficiently accurate for the purposes at hand. The next matter to attend to is the contact rail itself. In order to do this, it is first necessary to draw an outline plan of the car that will be used, to the same scale as the track work drawings—say, ¼ in. to the foot. Such a plan is shown in Fig. 11, in which the points *W* represent the the wheels; *S*, the contact shoes, and *K* the king pins. This had better be made of celluloid, with a large pinhole at each point *S*. In order to lay out the contact rail, the car is run along the tracks with the points *W* on the rails and a pencil stuck in one of the pinholes The line traced by the pencil represents the center line of the shoe path, and therefore that of the contact rail. Such a line should be made on each side of the car. In cases where there are sharp curves, it will not do to run the wheel points *W* along the tracks, as an error will arise owing to the truck rotation not being represented. In such a case the king pin points must be run along a track center line.

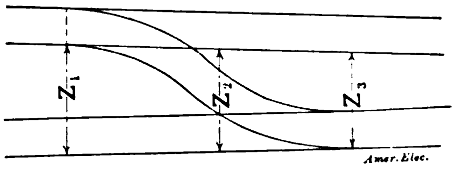

FIG. 9.

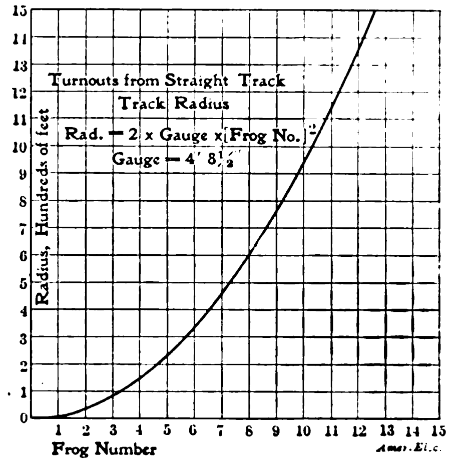

FIG. 6.

The exact location of the contact rail inclines on each side of a track rail intersection depends on a number of conditions, an important one of which is the extent to which the equalizer bar and journal box of the cars project outward. If there be a train bus line connecting all the cars, the end inclines may be situated many feet back from the switch point or frog, but if there is no such bus line the contact rail will probably have to be terminated in a "cross incline" extending as near as possible to the switch point or frog. The various problems which arise in this connection are foreign to the subject of this article, and cannot be dealt with in a general way.

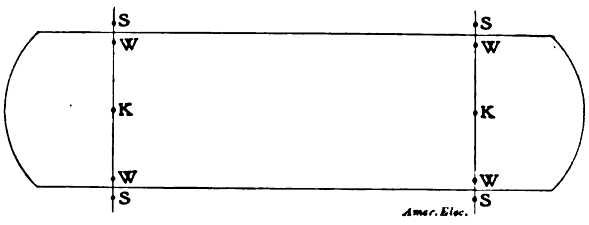

FIG. 11.

THE TURBINE PROBLEM.

BY H. F. SCHMIDT.

The history of the turbine has been given so often that it would be useless to repeat it at this time; but as no adequate presentation of the principles and theories underlying the construction of vapor turbines has appeared, it was thought by the writer that a short discussion would be of interest.

All vapor turbines depend for their operation upon the impulse and reaction of a moving fluid upon the blades of the turbine, and thus far they follow the water turbine in principle, the difference being in the character of the working fluid. The lighter the medium employed, the higher must be the peripheral velocity of the wheels. This is seen at once by examining the familiar formula of hydraulics, $V = \sqrt{2gH}$. This formula is approximately true for gases, but when used for gases, H is the height of a column of the gas the weight of which would equal the existing pressure per square foot. Hence, this formula becomes, $V = \sqrt{2gPv}$, where P is the pressure per square foot and v is the specific volume of the gas in cubic feet at the given temperature and pressure. As this formula only gives the velocity due to the static head, while gases and vapors under pressure expand adiabatically in the nozzle doing work at the expense of the heat energy of the gas, the actual velocity will far exceed that calculated in this way.

The adiabatic expansion is taken into account in the following formula:

$$V^2 = \frac{2g}{w}\, p_1^{\frac{1}{r}}\left(p_1^{\frac{r-1}{r}} - p_2^{\frac{r-1}{r}}\right) = \frac{2g}{w_1}\,\frac{r}{r-1}\,p_1 \left(\frac{T_1 - T_2}{T_1}\right) \qquad (1)$$

which gives the true theoretical velocity acquired by the jet in feet per second. In this p_1 and T_1 are respectively the initial pressure in pounds per square foot and absolute temperature in degrees Fahrenheit; p_2 the final pressure, T_2 the final temperature, w_1, the initial specific weight of the gas, and r the ratio of the two specific heats of the gas (having a value of 1.408 for air and all perfect gases). If to r the value of 1.065 is given, the formula will give very closely the velocity of saturated water vapor, or the following formula which is correct for all saturated and superheated steam-like vapors may be used:

$$V^2 = 2gJ\left\{ c\left[T_1 - T_2\left(1 + \log_e \frac{T_1}{T_2}\right)\right] + \frac{T_1 - T_2}{T_1}\,h_1 \right\} + \frac{2g}{w_1}\,\frac{r}{r-1}\,p_1\left[\frac{T_1^1 - T_2}{T_1}\right] \qquad (2)$$

Here J is Rowland's mechanical equivalent of the heat unit, 778; T_1 and T_2 the absolute temperatures corresponding respectively to the initial and final pressures; h_1 the heat of vaporization at the temperature T_1; T_1', the temperature to which the vapor is superheated; w_1 the specific weight of the superheated vapor at the pressure p_1 and temperature T_1'; c the specific heat of the liquid (which for water is unity), while r will have a value about 1.38 for superheated steam.

In this connection it will be remembered that if the gas comes to rest without doing work, the kinetic energy stored in the moving mass will reappear as heat, and in the case of a steam-like vapor, if initially dry, it will become superheated.

In order to find the sectional area of the orifice for a given power it is necessary to know the weight of medium discharged per unit of area under working conditions; the following formula gives the theoretical weight in pounds per second for a perfect gas per square inch of section at point of least diameter.

$$W_a = \frac{(0.527)^{\frac{1}{r}}}{144}\sqrt{2gw_1p_1\left[1-(0.527)^{\frac{r-1}{r}}\right]} \quad (3)$$

For vapors,

$$W_a = \frac{\sqrt{2gJ\left\{c\left[T_1-T_2\left(1+\log_e\frac{T_1}{T_2}\right)\right]+\frac{T_1-T_2}{T_1}h_1\right\}}}{144V_2\left[\frac{h_1}{T_1}+c\log_e\frac{T_1}{T_2}\right]\frac{T_2}{h_2}} \quad (4)$$

These can only be used when the ratio of pressures is less than 0.527 for gases and less than 0.58 for steam. When the ratio is greater than these values, the formula for gases becomes:

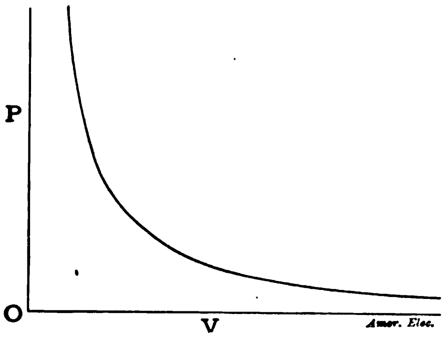

FIG. 1.—ADIABATIC CURVE.

$$W_a = \left(\frac{p_2}{p_1}\right)^{\frac{1}{r}}\frac{1}{144}\sqrt{2gw_1p_1^{\frac{1}{r}}\frac{r}{r-1}\left[p_1^{\frac{r-1}{r}}-p_2^{\frac{r-1}{r}}\right]} \quad (3\text{-a})$$

In these formulas the symbols used have the same meaning as previously given; but in the formula for vapors in cases where the ratio of p_2 to p_1 is less than 0.58 the symbols with the subscript ($_2$) have values corresponding to a pressure of 58 per cent of the initial, regardless of what the actual final pressure may be.

From the adiabatic curve for perfect gases given in Fig. 1, it is evident that as the pressure decreases more rapidly at first than the volume increases, the velocity of the jet will increase more rapidly than the volume. However, a point will be reached at which the volume will increase at a much greater rate than the pressure decreases with a corresponding lesser increase of the velocity than the volume. Hence, it follows that the sectional area of the orifice must at first decrease and then increase again. Theory and experiment show that the pressure at the smallest section of an orifice will in the case of perfect gases be 52.7 per cent of the initial pressure, and for steam 58 per cent. This divides the construction of nozzles into two cases, according to whether the ratio of maximum to minimum pressure is greater or less than the critical value. As long as the ratio is less than the critical value, the weight of medium discharged per unit of area will be independent of the pressure, but for greater ratios the weight is a function of the pressures. A nozzle for the first case simply decreases in diameter, but for the second case a diverging mouthpiece must be added. Theoretically the nozzle might be made almost any length desired, either very long or very short. However, owing to the fact that gases and vapors meet with considerable resistance when moving over surfaces at high velocities on account of the formation of eddies and contraction of the vane, there will be a certain length of nozzle that will give the best results. This length must be determined by experiment as no theoretical formula could take into account all the disturbing influences which affect the velocity. Formula (3) gives the sectional area of the nozzle in square inches at any point at which the pressure p is known.

$$A = \frac{144\ W}{\left(\frac{p}{p_1}\right)^{\frac{1}{r}}\sqrt{2gw_1\frac{r}{r-1}p_1\left(\frac{T_1-T}{T}\right)}} \ldots (4)$$

W is the weight of the gas discharged in pounds per second, w_1 the initial specific weight of the gas in pounds, and r has the same value as before, 1.408. This formula is only true for perfect gases, that for vapors being complicated by condensation during adiabatic expansion. For this case, the following formula may be used to determine the area of the nozzle in square inches:

$$A = \frac{144\ Wv\left(\frac{h_1}{T_1}+c\log_e\frac{T_1}{T}\right)\frac{T}{h}}{\sqrt{2gJ\left\{c\left[T_1-T\left(1+\log_e\frac{T_1}{T}\right)\right]+\frac{T_1-T}{T_1}\right\}}} \quad (4\text{-a})$$

This, it must be remembered, is only true for vapors which condense during expansion. The characters here used to designate the various quantities are the same as for the other formulas for saturated vapors, with the addition that v is the specific volume of the vapor at the pressure p.

Unless the sectional area varies in accordance with this formula, complete expansion cannot take place and the velocity acquired by the jet will be less than had the expansion been completed. A formula for the horse-power per square inch of nozzle area can be obtained by combining the formula for velocity with the formula for the weight per square inch, which for gases will take the form:

$$\text{Horse-power} = \frac{(0.527)}{144 \times 550} \times \sqrt{\frac{2g}{w_1}p_1\frac{r}{r-1}\left[1-(0.527)^{\frac{r-1}{r}}\right]} \times \left[\frac{r}{r-1}p_1\frac{T_1-T_2}{T_2}\right] \ldots (5)$$

For ratios of p to p_1 less or greater than 0.527 the formula becomes:

$$\text{Horse-power} = \frac{1}{550 \times 144} \times \left(\frac{p_2}{p}\right)^{\frac{1}{2}}\left(\frac{2g}{w_1}\right)^{\frac{1}{2}}\left[\frac{r}{r-1}p_1\left(\frac{T_1-T_2}{T_1}\right)\right]^{\frac{3}{2}} \quad (5\text{-a})$$

For steam-like vapors, the corresponding formula will be:

$$\text{Horse-power} = \frac{J}{550} \times \frac{\sqrt{2gJ\left\{T_1-T\left(1+\log_e\frac{T_1}{T}\right)+\frac{T_1-T}{T_1}h_1\right\}}}{144\left(\frac{h_1}{T_1}+\log_e\frac{T_1}{T}\right)\frac{T}{h}V} \times \left[T_1-T_2\left(1+\log_e\frac{T_1}{T_2}\right)+\frac{T_1-T_2}{T_1}h_1\right] \quad (5\text{-b})$$

in which the temperature and specific volume symbols without subscripts are those corresponding to a pressure of 0.58 of the initial pressure (for steam).

Having discussed the fundamental formula for turbines, it next becomes necessary to extend them, and enlarge upon them, so that multiple stage turbines may be considered. As there will necessarily be a large number of symbols used, it will be well to explain, first of all, their meaning.

All jet velocities will be designated by capitals, thus, V_{1a}^2 and V_{2b}^3, indicating the square of the initial jet velocity in the first stage, and the cube of the final velocity of the jet in the second stage respectively; u_a, u_b, u_c, represent the bucket velocities in the first, second and third stages respectively. In order to make the formula perfectly general, let there be n stages in the expansion, and let the bucket wheels in the various stages be of the same, or different diameter; that is, the bucket velocities may or may not be the same as in the Parsons or Rateau turbines.

Before proceeding with the nozzle calculations, it is necessary to find exactly what portion of the expansion must take place in each stage, which, of course, is determined by the bucket velocity in each stage since it is desired to have the initial velocity approximately equal to twice the bucket velocity. Now since it takes an amount of energy $E = \frac{w}{2g}V_1^2$ to impart the velocity V_1 to a mass of vapor $\frac{w}{g}$, it appears that the total work of expansion between the initial and condenser pressures must be divided between the different stages in proportion to the square of twice the bucket velocities, or more correctly, in proportion to,

$$\mu^2 = \left(\frac{V_1\cos\phi + V_2\cos\theta}{2}\right)^2$$

ϕ being the angle of entrance and θ the angle of exit.

Further, since the expansion in each of the nozzles is adiabatic, the entropy of the vapor remains constant, and since the energy transformed into work is equal to the product of the temperature change times the change of the entropy factor, it follows that the temperature range in any stage will equal the total temperature change into twice the square of the bucket velocity of that stage, divided by the sum of the squares of twice the bucket velocities in each of the remaining stages. What is meant here by the square of twice the bucket velocity, is really the square of twice that bucket velocity which makes the efficiency of the turbine a maximum, the formula for which is given in another part of this article.

The temperature range for each stage having thus been determined, and the exact initial velocity having been calculated for each stage, it is only then necessary to calculate the nozzle area required to pass the weight of vapor remaining in that stage. Owing to the expansion being adiabatic, some of the vapor will condense in the first stage nozzles, but as the pressure in the second stage chamber is lower than in the first stage, the water condensed in the first stage nozzles will partly evaporate if drained into the second stage chamber, and can thus be made to do additional work in the third stage nozzles. This process of draining the water of condensation in one expansion into the chamber of the succeeding stage is, of course, continued up to the final stage, at which point the water of condensation escapes with the exhaust into the condenser. Also since the vapor as it leaves the last bucket of the first stage has a velocity V_{2a} its kinetic energy will be $\frac{1}{2}\,\frac{X_{2a}}{g}\,V_{2a}^2$ which, as the vapor comes to rest, will reappear as heat, re-evaporating a quantity of the condensed liquid held in suspension by the vapor, equal to $X^1{}_3 = \dfrac{\dfrac{X_{2a}\,V_{2a}^2}{2g}}{J\,h^1{}_2}$ pounds, and hence there will be a quantity, $X_{1b} = X_{2a} + \dfrac{X_{2a}\;V_{2a}^2}{2g\,J\,h_{2a}}$ acting in the following nozzles $= X_{2a}\;\left(1 + \dfrac{V_{2a}^2}{2gJh_{2a}}\right)$. The amount of liquid thus re-evaporated in each stage must be calculated and added on to the vapor remaining after the expansion in the preceding nozzles. If L_2 is the total heat of one pound of the liquid at a temperature T_{2a}. then the amount of re-evaporating when drained into the second stage chamber in which the temperature is T_{2b} will, if the corresponding heat of evaporation is H_2 be $\dfrac{L_2}{H_{2b}}$ pounds, which amount must be added to that operating in the third stage nozzles and similarly for each of the following stages. Having thus calculated the portion of the original one pound of vapor entering the first stage nozzles which is effective in each of the following stages, the horse-power developed per pound of steam can be found, and hence the weight of steam that must pass through each of the nozzles, from which, by means of the formula for the weight of medium passing through a nozzle per square inch of cross section, and the area formula, all the dimensions of the nozzles can be calculated. The calculation for the nozzles for each stage is then executed in the same manner as for a single stage turbine, the pressure in the preceding stage casing being taken as the initial pressure, and the pressure in the casing of the stage, for which the calculations are being made, is used as the final pressure.

A complete detailed explanation of the method of actually making the calculations for a multiple stage turbine would take far more space than can be given at this time, but the foregoing outline, combined with a little "horse sense" will suffice.

As there is no steam indicator for the turbine, there is no way of finding the actual work done by the fluid; hence the best way to state the efficiency of the turbine is to express it in terms of the theoretical consumption per horse-power per hour. The weight of fluid per horse-power per hour may be obtained by dividing the weight per unit area per hour by the horse-power developed per unit nozzle area. For vapors, this will be as follows:

$$W_p = \frac{1{,}980{,}000}{778\left\{T_1 - T_2\left(1 + log_e\,\frac{T_1}{T_2}\right) + \frac{T_1 - T_2}{T_1}h_1\right\}} \qquad (6)$$

By the same process, the formula for the weight of gas per horse-power per hour is obtained:

$$W_p = \frac{1{,}980{,}000}{\frac{p_1}{w_1}\,\frac{r}{r-1}\left[\frac{T_1 - T_2}{T_1}\right]} \ldots\ldots\ldots\ldots\ldots (6\text{-a})$$

The efficiency of a vapor turbine will be, therefore,

$$E = \frac{1980000}{\text{Actual weight of vapor per h.p. per hour}} \times \frac{1}{778\left\{T_1 - T_2\left(1 + log_e\,\frac{T_1}{T_2}\right) + \frac{T_1 - T_2}{T_1}\right\}h_1} \qquad (7)$$

and for gas turbines,

$$E = \frac{1980000}{\text{Actual weight of gas per h.p. per hour}} \times \frac{1}{\frac{p_1}{w_1}\;\frac{r}{r-1}\left[\frac{T_1 - T_2}{T_1}\right]} \ldots\ldots\ldots\ldots\ldots (7\text{-a})$$

Using the formula for the velocity of vapors and assuming an initial pressure of 150 pounds per square inch absolute and a pressure of one pound absolute in the condenser, the resulting velocity of the jet of steam will be 3950 feet per second. This enormous velocity is almost 75 per cent greater than that of a shot from one of our large modern rifles. In order to obtain maximum efficiency, the velocity of the buckets must be half this value, which is so great that even the most tenacious material known could not withstand the resulting centrifugal strain, even though the wheels were made of large diameter. How to obtain with this enormous jet velocity the maximum efficiency without having prohibitory bucket velocity is the turbine problem.

This has been accomplished in two general ways, in both of which a series of revolving bucket wheels and stationary guide blades are grouped alternately. These methods are broadly represented by the Parsons turbine, which is of the reaction type, and the Curtis turbine, which operates on the impulse principle. Each of these turbines accomplishes the desired result by reducing, in stages, the velocity of the issuing jet of steam. The bucket wheels do not travel at one-half the velocity of the jet, but considerably less, so that the fluid leaving the buckets has a backward velocity relative to the revolving wheel. If it be reversed in direction by a set of guide blades, it may be caused to impinge on a second set of buckets, and so on, until the velocity is practically reduced to zero. In the Parsons turbine, the steam enters the first set of buckets without having been considerably expanded and at a comparatively low velocity; expansion takes place continuously through the buckets and guide blades, and as the velocity is being constantly increased by expansion, it is at the same time being constantly reduced by its passage through the buckets till at last it leaves the turbine almost devoid of motion. Hence, it is evident that as the velocity of the fluid through the turbine is almost constant, and the volume of the fluid is constantly increasing, the area through the buckets and guide blades must be correspondingly increased; and as with this system the entire circumference of the wheels must be used, in order to avoid making the blades of too great radial depth, the diameter of the wheels must be increased from the admission to the exhaust end of the turbine. In this type, the buckets are filled with expansive fluid, which on account of the difference in pressure between adjacent rows of buckets will tend to leak around the moving and stationary blades; it is necessary to have the clearance spaces between the stationary and revolving parts as small as possible in order to avoid excessive leakage. Regulation for changes of load is secured in the Parsons turbine by admitting the steam intermittently, the number of impulses per unit of time remaining the same; and the sole function of the governor is to fix the duration of admission. The result of this is illustrated by Fig. 2, in which the ordinates are pressures and the abscissæ equal intervals of time. The Dow turbine is of this type, but is of the outward radial flow type instead of being of the parallel flow type like the Parsons machine.

In turbines of the Curtis and Rateau type the steam is first expanded in a number of nozzles, attaining an extremely high velocity, which is then reduced in stages by passing the steam through a series of alternately moving and stationary blades. In the Curtis turbine, total expansion is not carried out in the first set of nozzles, but takes place in four or more stages, except in the earlier machines in which there are two moving wheels and two stages of the expansion. In the Rateau machine as many as twenty-five stages are employed, the reason for which is that if expansion is completed in one nozzle, the initial velocity will be so great that in order to have the number of revolutions per minute small and not have the diameter of the wheel excessive, the number of sets of bucket wheels and intermediates which must be employed will be so great that considerable loss in efficiency will result on account of the fact that much of the energy will be expended in overcoming friction and the formation of eddies. If, however, the expansion is divided into a number of stages, the initial velocity in each stage will be much reduced and the number of bucket wheels and intermediates needed in each stage correspondingly reduced, with an increase in efficiency; also since the mean velocity of the jet relative to the buckets is much lower, the loss of energy by friction on the buckets and guide blades is reduced. The frictional loss in the nozzles is slightly increased, but this is of trifling importance. As the expansion is divided into several stages, it is possible to clear each wheel chamber of the water of condensation of the preceding expansion, and as most of the frictional resistance is caused by the entrained moisture in the steam, it reduces greatly the loss due to this cause. Here it may be added that it is good practice to use wheels of large diameter so that a high peripheral velocity can be maintained with safety, with the result that fewer need be employed; which, of course, also reduces the frictional resistance.

In both the Curtis and Rateau turbines, the difference in pressure between the first and the last set of moving vanes is small, consequently the tendency to leak is also small, so that it is possible to have comparatively large clearance spaces between the stationary and moving parts. In the Parsons turbine, the area through the buckets is gradually increased as the volume of the medium increases, while the velocity remains practically constant. In the Curtis turbine the main regulation is secured by changing the number of nozzles in operation, and the finer regulation by throttling a pair of nozzles. This is accomplished by electromagnetic control of small auxiliary valves which admit steam to small cylinders which in turn move the main nozzle throttles. Since for a constant efficiency the rate of expansion must remain constant, it follows that as the pressure in the condenser cannot be made less than a certain value it is necessary to resort to some means of regulating the amount of energy supplied, other than that of throttling the steam; and the reason that the impulse turbine gives such good economy on light loads is because regulation can be secured by changing the number of nozzles in operation. Also, since the entire circumference of the wheel need not be employed, it is possible to obtain the necessary increased area through the buckets by increasing the active arc of the circumference, thus avoiding the necessity of increasing the diameter of the wheels beyond practicable limits. In the Rateau turbine, regulation is secured by the use of an independent governor, which is a slight modification of the well-known Dennis water-wheel governor, which is driven from the turbine shaft by a belt.

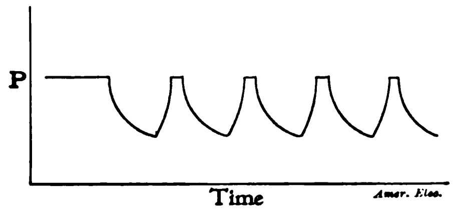

FIG. 2.

The De Laval turbine is the oldest and simplest of all turbines, and the Curtis and Rateau machines are merely special forms of the same type. In the De Laval turbine there is but one set of nozzles and one set of revolving buckets. As has been already pointed out, for maximum efficiency the peripheral velocity of a single-wheel turbine would have to be from twenty to thirty miles a minute, which, of course, would be impracticable, though in the larger sizes of De Laval turbines the peripheral velocity is over nine miles a minute, with a corresponding speed of from twenty-five to nine thousand revolutions per minute. This is reduced by a pair of ten-to-one gears; they are spiral gears cut at opposite angles, being equivalent to a herringbone gear arrangement. The larger one is made of a special bronze, the smaller one being cut directly on the turbine shaft. They are enclosed and run in oil and have been found to give but little trouble in operation, but are very costly and constitute the most voluminous portion of the turbine.

A unique feature of this turbine is the method of mounting the turbine wheel. Running at the enormous speeds at which it is operated, the strain consequent to the centrifugal forces of slightly unbalanced wheels would soon destroy ordinary bearings. To avoid this, the wheel is mounted on a long flexible shaft supported at its ends, thus permitting the wheel to revolve practically about its center of gravity. All strains are thus eliminated, and vibration practically disappears.

The De Laval turbine is governed in much the same way as the Curtis, except that it is not electrically controlled and also that the nozzle control is not automatic. The nozzles must be shut off by hand when the unit is being operated under light load for any considerable period, as the governor, which is of the fly-ball type, merely throttles the steam.

The losses in the turbine, as in all machines, may be divided into two classes—the inevitable and those which may be reduced by improvement in design and construction. It is therefore well to separate them in considering turbine construction. Taking up the various sources of loss in the turbine in the order that they appear in passing from the supply main to the exhaust, the first part to be considered is the nozzle. Here there cannot be any considerable thermal loss as the area from which radiation can take place is extremely small in comparison to the heat energy of the medium passing through it in a unit of time. Nevertheless, losses occur here due to the friction of the fluid on the sides of the orifice, and, owing to the reduced sectional area of the nozzle in comparison with that of the main supply pipe, eddies are formed which materially reduce the velocity of the jet. The greatest loss here is caused by incomplete expansion of the medium in the nozzle as it is impossible to reduce the final pressure below a certain value for practical reasons. Next in order, as the working fluid passes through the turbine, it passes through the buckets. Since the buckets or vanes are constantly passing the nozzles, the jet must enter and leave the vanes from either the top or the sides; hence there will be an unavoidable loss here, which is considerable.[*] In passing through the buckets, losses occur due to friction and on account of the formation of eddies. The first cannot be reduced to any great extent, but the second can be reduced very materially, the best shape for the buckets being determined experimentally. For the reaction type of turbine the cross-section of the buckets should be parabolic, and for the impulse type, circular. In both cases, the edges of the buckets should be tangent to the direction of the jet.

Radiation from the turbine case may be reduced to a small value by proper lagging, and in any case, is not very large when the large quantity of heat stored in the fluid is considered. The heat loss by radiation can be so easily determined that formulas for it are practically useless.

One of the most serious losses of energy is caused by the friction of the gas or vapor on the moving surface of the bucket wheels. This is in a great measure unavoidable, though in the case of vapors it can be greatly reduced by draining off the liquid which collects during expansion. One of the most important arguments in favor of the impulse turbine is the fact that the chambers can be drained, while with the reaction type this cannot be done. The loss on the buckets and guide blades will be also materially diminished for the same reason.[§]

---

[*] The formula for the efficiency of a Pelton wheel may be used for this case:

$$E = \frac{[\mu V_1 \cos \phi - \mu^2 - \mu V_2 \cos \Theta]}{V_1^2}$$

in which ϕ is the angle of entrance, Θ the angle of exit, V_1 the initial velocity, V_2 the final velocity, and μ is the circumferential velocity of the buckets. The reduction of efficiency due to this cause cannot be made less than about 10 per cent. As the components of the initial and final velocities of the jet parallel to the direction of the buckets are less than if the nozzle did not make an angle with the line of motion, there will be one value of the bucket velocity which will make the formula a maximum, and this, of course, will be the proper velocity at which the vanes should move. This value can be found from the relation:

$$\mu = \frac{1}{2}\left(V_1 \cos \phi - V_2 \cos \Theta \right)$$

[§] A formula for frictional loss of this kind, which is based on theory, but contains constants to be determined by experiment, is given herewith. It will serve as a guide to anyone wishing to determine this value experimentally.

$$P_w = \frac{(2\pi)^{n+2} V^{n+1} R^{n+3}}{n+3} K$$

In this formula P_w is the frictional loss in foot-pounds per minute; the exponent n and the constant K, must be found for each gas and vapor for which it is to be applied. It is probable that the value of n is about 2, though it may have different values for different gases. The value of K depends upon the character of the surface, pressure, gas and percentage of moisture. R is the external diameter of the wheel, and N the revolutions per minute.

The foregoing are practically all the losses characteristic of the turbine, though leakage around the buckets and guide blades in the reaction type of machine may be added. The latter cannot be reduced below a certain limit for the reason that it is necessary to have a clearance space between the stationary and moving parts which has already been made as small as possible. Generally speaking, the direction in which further improvements can be made are really not directly in the turbine itself, but in the method of superheating the vapor used in order to reduce the friction, and in the maintenance of a more perfect vacuum.

The possibility of constructing a turbine in which a perfect gas may be used in place of vapor has been suggested, and many inventors have tried unsuccessfully to solve the problem. A gas expanded adiabatically in a nozzle cannot impart velocity to itself unless there is a difference in pressure between the reservoir and space into which it escapes; merely heating a gas is of no avail unless it is also compressed. That this is true may be seen by examining Fig. 3, which shows the work diagrams for a cycle which could be used in a gas turbine. The gas is first compressed adiabatically from $p_0\ v_0\ T_0$ to $p_1\ v_1\ T_1$; it is then heated at constant pressure to a point $p_2\ v_2\ T_2$. From this point it is again expanded adiabatically in an ideal nozzle to the original pressure p_0. The gas now cools at constant pressure back to its original temperature. Had the gas been expanded adiabatically in a nozzle from the point $p_1\ v_1\ T_1$, the velocity would be:

$$V = \sqrt{\frac{2g}{w_1}\,\frac{r}{r-1}\,p_1\left(\frac{T_1-T_0}{T_1}\right)}$$

and the work that this jet could do would merely equal the work done in compressing the gas. If, however, the cycle described above be carried through the velocity would be:

$$V = \sqrt{\frac{2g}{w_1}\,\frac{r}{r-1}\,p_1\left[\frac{T_2}{T_1}\,\frac{T_2-T_8}{T_2}\right]}$$

Subtracting the square of the first expression from the square of the second, multiplying by the weight of the gas (taken at one pound throughout this article), and dividing the result by $2g$, there results:

$$P = \frac{1}{r-1}\,R\,\frac{(T_2-T_1)\ (T_1-T_0)}{T_1}$$

which is the rate of work in foot pounds per second that the jet can perform over and above the work of compression. Therefore, the efficiency of the cycle will be:

$$E = \frac{\dfrac{r}{r-1}\,R\,\dfrac{(T_2-T_1)\ (T_1-T_0)}{T_1}}{J\,C_p\ (T_2-T_1)} = \frac{T_1-T_2}{T_1}$$

This result shows, as might be expected, that Carnot's cycle applies as well to the gas turbine as to the gas engine, and that the theoretical efficiency is dependent solely upon the amount of compression.

It is of interest to consider the various methods of heating the gas and to ascertain which of them is the most economical. Upon examinaion it is found that there are five practical methods. In three of them the gas is passed over a heated surface, the fuel used being either oil, gas or coal. In these systems at least 20 per cent of the total heat of the fuel goes up the stack in the products of combustion; but on the other hand all have the advantage of being simple. However, unless care is taken, the apparatus may be damaged by overheating, as the temperatures are necessarily very high. In the other two methods oil or gas is burned in compressed air and the hot products of combustion used in the turbine. This method has been patented by Dr. C. E. Lucke and has the advantages of being the simplest and most economical method of heating air for such a purpose. The only loss of heat is by radiation from the chamber in which combustion takes place; the combustion of the fuel is perfect, and the danger of burning the apparatus is almost eliminated as the fire-pot is lined with a heavy coating of fire clay. The apparatus consists of an iron pot half filled with broken fire brick or crucibles, into which the air and oil are led through a pipe entering the pot a quarter of the way from the bottom. The air and oil are mixed in explosive proportions, the flame cap being broken up by the pieces of crucible. The writer has experimented with this method of heating air for compressed-air engines, and found no trouble whatever in regulating the temperature of the products of combustion. For a large part of the time the temperature of the escaping gases was so great that the outlet pipe was at a bright red heat. The combustion chamber was under a pressure of 120 pounds per square inch; under which conditions perfect combustion was obtained.

Another method which is used is that of compressing the air enough to produce a temperature which is sufficient to ignite the oil. This has the advantage that the oil and air supply can be more easily controlled and the combustion can take place directly behind the nozzle. A great number of cycles are possible besides those here mentioned, such as an explosive cycle which would obviate the necessity of a separate air compressor, but this is difficult to carry out as the necessary apparatus is too complicated for practical purposes.

The great difficulty with the gas turbine at present is that as it is necessary to compress the air or other gas used, a compressor must be used which would have to be driven either from the main turbine shaft or by a separate engine; also with the first-mentioned arrangement, a small independent compressor would be required to start the turbine. As these auxiliary appliances have a comparatively low efficiency, the gains resulting from the use of a gas internally heated would be reduced. This loss in economy is very considerable and may prevent the wide introduction of the gas turbine until it is considerably reduced. On the other hand, the frictional resistance of a gas is less than that of a wet or saturated vapor, in which condition the vapor is likely to be as it requires a large amount of superheat to entirely prevent condensation during the adiabatic expansion in the nozzle. The initial velocity of the jet for a given efficiency of the cycle is much less for a perfect gas than for a vapor, but the volume of the turbine must be larger for gas than for vapor. This is on account of the fact that the quantity of heat transformed into work by adiabatic expansion per degree of temperature range per unit weight of the medium is much less for perfect gases than for vapors. On account of the fact that high temperatures can be easily and safely employed, resulting in a greater amount of the total heat supplied being turned into useful work, it would appear that the gas turbine would furnish a good field for the efforts of the inventor, and it is probable that the room for improvement over the steam turbine by the use of the gas turbine is as great as the possibilities of the gas engine over the steam engine.

In closing, the writer wishes to state that in the foregoing treatment of the turbine problem no attempt was made to give practical formulas for the design of turbines. The only object was to present in as simple a form as possible the theoretical formulas of mechanics and thermodynamics upon which investigations in regard to the turbine must be based in order to obtain useful and reliable results. Experiment has shown, however, that if the nozzles are properly constructed, the velocity as well as the weight discharged per unit nozzle area, as given by the theoretical formulas, may be used without any correction. The efficiency of a well-designed turbine should be from 50 to 65 per cent. By the aid of this data and the formulas given, the nozzle area and proportions, as well as the bucket velocity, may be predetermined with sufficient accuracy for practical purposes.

A New Process for Electrogalvanizing.—A new process for electrogalvanizing has been discovered by Ignaz Szirmay, of Budapest, Austria, consisting essentially of adding grape sugar (dextrose) to a bath. He says that a pure, glossy deposit of zinc is obtained free from blisters, and adhere so tenaciously that the object may be bent without the coating peeling off. His method is as follows, viz.: 28 pounds of sulphate of zinc are dissolved in 25 gallons of water, preferably warm. Next dissolve separately in boiling water 1½ pounds of sulphate of aluminum, 12 ounces of sulphate of magnesium (Epsom salts) and 6½ pounds of grape sugar. These solutions are then added to the sulphate of zinc solution. The resulting solution should be clear, and have a feeble acid reaction. An anode of pure rolled zinc is recommended. The deposition is carried out at about 65° Fahrenheit with a current of 10 amperes per square foot, and a voltage of four volts. In order to prevent bubbles of hydrogen gas from adhering to the work, it is kept in motion. This also serves to stir up the solution and keep it uniform.—*Exchange.*

Northwestern Electrical Convention

The annual convention of the Northwestern Electrical Association was held this year as usual at the Hotel Pfister in Milwaukee, on January 20 and 21. After disposing of some routine business on Wednesday, the convention opened with an address, by President F. W. Bowen, of Kenosha, Wis. He gave credit to Secretary Mercein for whatever success the present convention might attain, as the secretary was responsible for the programme this year. One feature which he had hoped to make prominent at this convention was a "question box" and "wrinkle department," upon which he had intended to do some personal work during the past year but had been prevented by the burning down of his central station twice during that period, which interfered with his work for the association. Mr. Bowen did not favor the pre-arranged discussion of papers, being of the opinion that many members, if not stifled by an air of pre-arrangement in the programme, would feel free to discuss papers and bring out many obscure points that would otherwise escape attention. The twin subjects of taxation and municipal ownership were, he said, always with us, but he was of the opinion that in future both were more likely to be met in a spirit of fairness than they have been in the past. He had no recommendations in the nature of a "cure-all" to make, but said that when the nature and hazards of the electrical business were more understood by the general public, the fraternity would be better treated by the same public through their chosen representatives. The president's address was followed by the reading of the paper on "Central Station Heating" by W. H. Schott.

In response to questions as to cost of coal per year in a fairly efficient heating plant, Mr. Schott cited a test recently made by Prof. Goss at Purdue University. Using these tests as a basis, with coal at $2 per ton containing about 10,500 B. T. U. per pound, the coal would cost about 8 cents per square foot of radiating surface per season in a hot-water heating system. He thought about 70 pounds of coal per square foot of radiation per season a safe basis on which to figure. With a steam-heating system about 130 pounds of coal per square foot per season is required with automatic temperature regulation. Without this regulation the amount would run as high as 180 pounds.

Mr. Kimball stated that in Kenosha, where an attempt had been made to separate the charges due to electric lighting and heating, it was found that about 77 pounds of coal per square foot of radiation was required in addition to the exhaust steam which was put into heating. This was based on coal having 12,500 B. T. U. per pound.

Mr. Schott said that in the Purdue test everything was charged against the heating plant except the efficiency of the engines and pumps. The engines absorbed 7 per cent of the heat transmitted to them and the pumps 4 per cent. The former took 28½ pounds of water per indicated horse-power hour, and the latter 95½ pounds. In response to a question as to the difference in cost of furnishing heat with and without automatic temperature regulation Mr. Schott said that tests had shown the cost to be about 40 per cent more for heating without automatic regulation than with it. In this figure, labor, fuel and everything were taken into account. Mr. Kimball did not agree to the statement that the difference between cost of supply with and without automatic regulators was as much as 40 per cent. Mr. Almert, of Chicago, inquired of Mr. Schott whether he did not find that in most plants the figures he gave on coal consumption were not double, owing to engineering deficiencies. Mr. Schott thought it was double for old-time plants.

When asked whether he had formulated any figures upon a town's consumption of coal per annum per foot of radiation, Mr. Schott said that in a well-designed plant situated in a place where the temperature averages 30°, as in Central Illinois and Indiana, when using Illinois slack coal, the consumption should not exceed 70 pounds per square foot per season. The actual figures are 63 pounds, but 70 pounds should be allowed so as to cover losses. In the Purdue tests, where they arrived at a 77-pound basis with coal having a calorific value of 10,500 B. T. U., they obtained in the boilers only a fraction over 4000 B. T. U. per pound. This was because (1) the boilers did not have a proper circulation through them, (2) the fire was being controlled by the ash-pit doors instead of by the damper, (3) the boilers had not been cleaned in six months, and 5 feet of the lower tubes were banked in with soot and ashes. These drawbacks were discovered soon after the tests. Replying to the question as to the B. T. U. radiated per hour per square foot, Mr. Schott said that if a temperature of 200° was maintained not less than 246 B. T. U. would radiate per square foot per hour; at 170°, 170 B. T. U.; at 160°, 155 B. T. U.

Mr. Almert asked what the temperature ought to be in the out-going and return pipe for average conditions, and Mr. Schott said that depended upon how fully the system was loaded. A 20° maximum drop would be a fair average with a 30° difference between supply and return at the power house. In replying to a question by Mr. Kimball, Mr. Schott said he did not think it good practice to sell hot water for domestic purposes unless the company received a high price for it. Mr. Harding said in his plant there had been some stealing of hot water for domestic purposes by customers; but since they put in meters they kept a very close tab on leakages. Mr. Schott favored a supply of hot water for domestic uses by placing hot water coils connected with the mains in ranges, boilers or tanks, thus heating the water in the customer's tank by the circulation water rather than have him draw the circulation water out of the system itself. Replying to a question regarding the quick location of leaks, he said that a leak is made known in fifteen seconds with a balanced column system. His practice had been to let the customer furnish his own water; in Little Rock, however, tne city water was very bad, and an ordinance permitted their furnishing water for domestic purposes. In that case, however, the water was purified before it was put into the hot water system. With pipe lines tested to 120 pounds pressure, there was no need of worrying very much about the leakage with expansion joints every 300 feet. Leakage was found in old plants where expansion was not provided for.

The president asked Mr. Schott about how many square feet of radiation he would take care of per horse-power of exhaust steam from an engine with hot water heating. Mr. Schott said that the average during the season would be 17,500 square feet, and at 10 below zero about 10,000 square feet. If a horse-power takes care of over 6800 square feet, it is doing first rate, if the regulation is properly figured.

The president then asked Mr. Schott what would be the relative horse-power required in a building for heating and lighting, or, how near heating and lighting would balance. Mr. Schott said this depended on the kind of building. Assuming a store building with the ordinary amount of lighting, there will be a surplus of steam at all times from the lighting engines over and about what would be required for the heating of the building.

Following the discussion of Mr. Schott's paper, Charles R. Underhill, of Providence, R. I., read the paper on "Coil Windings for Electrical Purposes," by Richard Varley and Charles R. Underhill. Following this was a paper by W. Scheidel on the "Electrolytic Rectifier and Interrupter."

The "Smashing Point of Incandescent Lamps" was the subject of a paper by George C. Keech, of Chicago. He referred to the coining of the phrase "smashing point," by Carl Hering ten years ago, as filling an immediate want. This descriptive phrase invited explanation and discussion. In an incredibly short time the idea that 80 per cent of the initial candle-power of the lamp was the limit of its universal life was universally adopted. The next step toward an ideal lamp was to make one which would automatically die when it had lived out its usefulness. Alex. Dow, of the Detroit Edison Company, stated that 90 per cent of customers' complaints could be traced to dim lamps. A customer, he said, should get an average of 90 per cent of the initial candle-power of the lamp. It is agreed that a lamp is useless after it has depreciated 20 per cent, and although almost everyone realizes that it is economy to remove a lamp at this point, very few practice it; hence, the only really economical lamp to use is one that will burn out at or near its smashing point.

A discussion then followed as to the policy of buying 3.5-watt lamps and operating them at about 3 per cent above rated voltage as against buying 3.1-watt lamps and working them at their rated voltage. From this discussion it appeared that the efficiency and life of the lamps in these two cases would be about the same, but a 3.5-watt lamp at 3 per cent above normal voltage would give about 19 candle-power instead of 16. Some thought it would be better to buy a 20-candle-power lamp of 3.1 watts efficiency rather than operate the 3.5-watt lamp so as to make a 19 or 20-candle-power lamp of it. In response to an inquiry, Mr. Keech said, from a manufacturer's standpoint, the consumer would get a closer selection on a 3.1-watt lamp than on a 3.5-watt lamp. Mr. Harding said for a number of years he had followed the plan of running his lamps 2 volts high during the important lighting hours of the evening, going back to normal voltage (108 volts) about 10:30 p. m., and maintaining it for the balance of the twenty-four hours, until the lighting load came on the next afternoon.

When the convention was called to order Thursday morning, a paper by W. L. Waters on "Double-Current Generators" was read and discussed, the discussion serving simply to bring out the same points that were mentioned in the paper.

A paper on "Rectifiers" by Prof. C. F. Burgess, of Madison, Wis., was then read. Although known for fifty years, it is only recently that the electrolytic rectifier or electrolytic valve has been placed on the market. Fifty years ago it was found that aluminum in certain solutions opposes the passage of the current from it to an electrolyte and of freely altering its passage in the opposite direction. There are many solutions which, in contact with aluminum allow this electrolytic action to become manifest. Some are more efficient than others. It is only recently that improvements have brought the working efficiency of the apparatus up to a point where it can be used commercially. It is not yet all that can be desired, for certain classes of work, such as charging small storage-battery equipments, it offers advantages. One limitation is that a single cell cannot be used with a pressure much over 50 to 60 volts; cells must be placed in series where higher pressures are necessary. An efficiency of between 50 and 60 per cent was showed by tests in the Wisconsin University laboratories and this efficiency is practically constant regardless of the size. Another limitation of the rectifier is that pulsations of the current, while interfering in no way with its use for charging batteries, may produce a humming sound and heating by eddy currents motors operated by such current, and also a humming sound in telephone lines operated from batteries which are being charged by this pulsating current. Because of the pulsating nature of the current obtained from such a rectifier it is not possible to correctly measure it with direct-current instruments. Electrolytic rectifiers may be subdivided into two classes. In one an aqueous electrolyte is supplied; in another, a non-aqueous or fused electrolyte.

Mr. Carl Hambuechen, of the University of Wisconsin, has discovered that aluminum acts most efficiently as an asymmetric conductor when placed in moulten sodium nitrate or similar salts. Upon this discovery is based the second class of electrolytic conductors which employs the fused electrolyte. An average efficiency of from 10 to 30 per cent higher than that of the aqueuous solution may be maintained with the sodium salt on account of the more efficient valve action of the aluminum and the lower resistance of the electrolyte. It has a further advantage in that the development of heat is utilized in keeping the material in a state of fusion and at a high degree of activity. With the aqueous type, the elevation of temperature beyond thirty or forty degrees Centigrade causes such a rapid decrease in efficiency that artificial means are necessary for dissipating heat. One of the essential parts of this rectifier consists in a special wound transformer which allows connection to a 110-volt or other convenient source of alternating-current supply. This transformer has various terminals by means of which the ratio of transformation may be regulated. Connections are made also from the windings of the transformer to two aluminum electrodes and an iron electrode. The electrodes are contained in an aluminum case surrounded by an asbestos cover passing through and being held in place by a stone top. When the rectifier is not in use the electrolyte is perfectly solid and non-conductive. By passing a low-voltage high-volume alternating current lengthwise through the iron electrode for four or five minutes, the cell is brought into working condition, after which the heating current is switched off and the cell is maintained at the desired working condition by the natural heat losses when operating within 25 per cent of the normal load. In the aluminum electrodes 1/8 in. x 1 in. x 2 in., the normal load is 10 amperes at a rectified pressure of from 25 to 30 volts. The current may be several hundred per cent higher than this value for a short time without detriment, and a 50 per cent overload causes excessive heating and evaporation of the salt only after several hours' run. The total weight of apparatus for an output of this capacity is about 30 pounds, most of which is in the transformer. All the attention which the device requires is the addition once in each day of operation of a small amount of salt through an opening in a stone cover. This salt is added for the purpose of supplying losses of the electrolyte by vaporization and neutralizing the tendency of the electrolyte to become alkaline by the decomposing effect of the current. While thus maintaining the salt in working condition, aluminum electrodes have been operated for over 800 hours without excessive corrosion, and the iron electrodes last a considerably longer time. Estimates of the cost of the additional salt and the renewal of electrodes place the figures at below 3/10 of a cent per kilowatt-hour.

A considerable rambling discussion followed this paper, and it seemed to be the opinion of the central station men present that it might open up a new field for their alternating-current output.

Mr. Cutter suggested that the efficiency of a small motor-dynamo set for automobile charging was not over 60 per cent and it was much more cumbersome and costly than an electrolytic interrupter. It was also suggested by Mr. Lansingh that the light weight of this rectifying apparatus would permit of its being carried by an automobile, so that charging could be done anywhere that alternating current could be obtained.

The report of the nominating committee was then presented, and the following officers were elected for the ensuing year: T. F. Grover, Fond du Lac, Wis., president; George H. Lukes, Evanston, Ill., first vice-president; E. A. Daniell, Menominee, Wis., second vice-president; Thomas R. Mercein, Milwaukee, secretary and treasurer; W. H. Schott, Chicago, D. C. Jackson, Madison, Harold Almert, Oak Park, Ill., directors. It was voted to hold a meeting in St. Louis in September in conjunction with the other electrical organizations who hold meetings there at that time. The morning session then adjourned.

On Thursday afternoon, a paper on "Standard Practice in the Use of Alternating-Current Electrical Apparatus," by J. J. Gibson, was read. This was an extended review of the subject indicated in the title. The discussion of this paper was limited, as the author was not present.

A paper by J. M. S. Waring on "Storage Batteries for Small Central Stations," was then read. After his paper Mr. Waring showed a number of lantern slides illustrating various points in connection with storage battery installations. Some of these slides showed a plate known as the "box negative," which was introduced about a year ago by the Electric Storage Battery Company and has superceded the former type. The pellets of active material are held in place by a perforated lead sheet on each side of the plate, to prevent the loss of active material. He explained that with this type of negative, blistering which might make contact with positive to negative was prevented, and this did away with the necessity of probing the cells to knock the blisters off. There was then some discussion as to the value of a storage battery auxiliary in a small central station supplying a small electric railway where the load is always extremely fluctuating. Mr. Waring cited tests by a firm of consulting engineers in Chicago at the substations of an interurban railway. Without the battery fluctuations of voltage were 16 per cent as against 3 per cent with the battery.

The battery in use by the Milwaukee Electric Railway & Light Company in its central station was cited. This consists of two 550-volt batteries, either one of which can be used on the railway or can be divided up to operate on the three-wire Edison lighting net-work. Ordinarily one battery is used floating on the railway bus bars, and the other is floating on the lighting bus bars. In case of a break-down on either system, both batteries are put on the system needing the help.

A paper by James Lyman, of Chicago, on "Steam Turbines," was then read, but the lateness of the hour did not permit of discussion, and the convention listened to a lecture by Prof. R. A. Milliken, of the University of Chicago, on "Radium."

Abstracts from Foreign Contemporaries

Ferranti Alternating-Current Integrating Wattmeter.—A new alternating-current wattmeter possessing certain novel features has recently been introduced by Messrs. Ferranti, Limited. The meter, which is described in the London *Electrician*, is of the induction-motor type, measuring the energy consumed on an alternating-current circuit, whether the load is inductive or non-inductive. The accompanying illustrations show clearly the construction of the meter, and indicate the simplicity of its parts. The aluminum rotatable disc *D*, mounted on the spindle *S* and geared to the train of wheels *CT* actuating the index hands, serves the double purpose of an armature receiving the driving torque of the meter coils and also the retarding torque of the permanent magnets *PM*. One shunt coil, *ShC*, placed round the coil *C* of a special tubular electromagnet, *TM*, constitutes the shunt system. The core of this magnet has three outward radial poles, P^2, alternating with four inward radial poles, P^1, from the shell or tube of the shunt magnet, the plane of these poles being horizontal and parallel to the disc; this tubular magnet is placed below the disc. The series system consists of a slotted armature, *SA*, above the disc, the series coil *SeC* being wound in these slots. A wave-form of winding is used, somewhat similar to the winding adopted by Mr. Ferranti for his alternators in 1884; it will be noted that the slots of the series armatures are almost directly above the poles of the tubular magnets. If the shunt circuit be sufficiently inductive, the eddy currents produced in the disc by the shunt field will be in phase with the impressed e.m.f. These eddy currents are acted on by the series field, which is in phase with the load current, giving a driving torque on the disc proportional to the e.m.f. of the circuit multiplied by the amperes and by the cosine of the angle of lag of the main current behind the e.m.f., this being the true watts supplied to the circuit through the meter. The retarding torque due to the permanent magnets is proportional to the speed, and the disc therefore revolves with a speed which is proportional to the watts.

The meter can be calibrated by slightly altering the relative positions of the shunt and series magnets, by means of the two screws S^1 and S^2. The driving torque of the shunt alone, even with the maximum possible displacement of the series armature, is extremely small, and as it will be noted that the armature is fixed by a powerful clamp, *Cl*, and the two screws S^1 and S^2, the possibility of the meter developing any tendency to creep on the shunt is very remote. The constant of the meter is also readily adjusted by lowering or raising the series armature by means of the nut *N* on the threaded spindle *TS*, the effect of this being to strengthen or weaken the action of the coils, and after adjustment the series magnet is securely fixed by means of the strong clamp *Cl* and the screw S^3. On all conditions of circuit, inductive or non-conductive, on overloads up to 50 per cent and under variations of voltage to 50 per cent above or below the normal, the meter is claimed to be very accurate, and practically independent of variations in frequency, wave form or temperature. The meters are fitted with removable jewelled brass settings, *J*, which enables a defective jewel to be easily replaced by a new one at any time without altering the calibration of the meter, all parts being interchangeable.

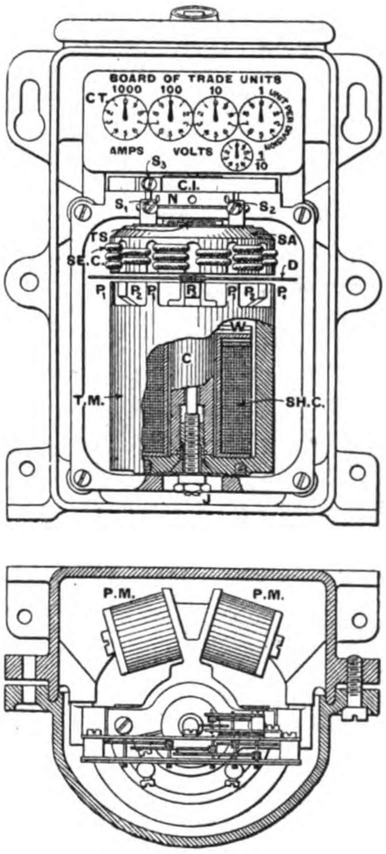

FIG. I.

The Economy of Superheated Steam.—In a paper on this subject read by Mr. E. A. Reynolds before the Rugby Engineering Society, the author said that the principal object of superheating steam is to prevent, or, at any rate, reduce, transfer of heat, and to prevent initial condensation; for although the steam gives up some of its heat to the metal on admission, there is no condensation, the only effect being a reduction of volume and a fall in temperature. The relation between pressure, temperature and volume is given by the equation $PV = 93.5T - 91P^{\frac{1}{4}}$, where *P* is measured in pounds per square foot absolute, *V* is the volume in cubic feet of one pound of steam, *T* is the absolute temperature in degrees Fahrenheit. On putting *T* equal to the temperature of saturated steam, this formula gives very closely the volume corresponding to different pressures. On calculating *V* for various temperatures of superheat, it will be seen that at 300° Fahrenheit of superheat the volume of the steam is increased by about 50 per cent. Owing to this increase of volume superheated steam requires a less quantity of heat to produce a certain volume than saturated steam at the same pressure, so that by using superheated steam less heat enters the cylinder at each stroke than when saturated steam is used; and as the same amount of heat is converted into work in each case, this shows where the economy of superheat lies. It has been found that to obtain a certain velocity of steam in a pipe, superheated steam requires a smaller drop in pressure than saturated steam; for this reason the steam pipes may be made smaller, thus giving a higher velocity, and yet keeping the pressure drop the same. With superheated steam the amount required for a given power is less than with saturated steam, and the pipes may be made still smaller. Another advantage is that separators are unnecessary; the absence of water in the steam mains also does away with all risk of getting water into the cylinders through priming. A test tthe author made a short time ago on a small simple engine running non-condensing at 65 pounds pressure in the steam chest and a cut-off of 0.3, showed a gain of 35 per cent in weight of steam used by using steam superheated 220° Fahrenheit. The water consumption came out at 20 pounds per i.h.p., which compares favorably with compound engines working as a high steam pressure. In tests of various engines that the author has made, he has found very little difference in the percentage gain with triple or compound expansion, the compound showing a little more than the triple. The gain obtained is about 15 per cent at 100° Fahrenheit superheat, 20 to 21 per cent at 150° Fahrenheit, and 23 to 25 per cent at 200° Fahrenheit, measured in weight of water used. The gain, of course, varies with the point of cut-off, and the ratio of expansion. In each case the temperature was measured outside the throttle valve. In a trial

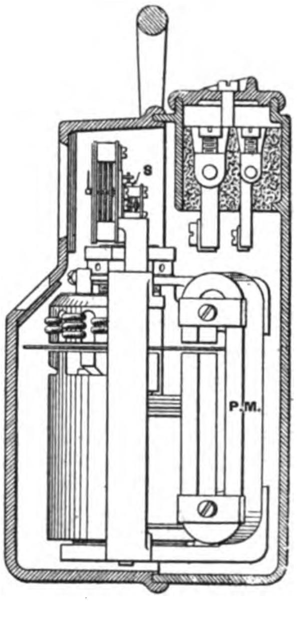

FIG. 2.

on a triple engine, when the temperature was measured inside the steam chest, the percentage gain curve came out exactly a straight line up to 180° Fahrenheit superheat. There is little gain due to superheating in any cylinder after the stage is reached in which the steam is kept dry throughout the whole expansion, and the only object of taking the superheat higher is to obtain dry steam as far as possible during the whole expansion in the engine. The same effect, however, would be obtained by reheating the steam in the receivers between the different cylinders, so that it enters each cylinder superheated sufficiently to ensure it being dry at the end of the expansion in that cylinder. This is most easily effected by passing the superheated steam through coils in the receivers on its way to the steam chest of the engine, so that it may give up some of its superheat to the steam that has already expanded in the previous cylinder, and then pass to the steam chest at a lower degree of superheat. The utility of this method is that in which the steam is kept dry throughout the whole expansion, and the only object of taking the superheat higher is to obtain dry steam as far as possible during the whole expansion in the engine. The same effect, however, would be obtained by reheating the steam in the receivers between the different cylinders, so that it enters each cylinder superheated sufficiently to ensure it being dry at the end of the expansion in that cylinder. This is most easily effected by passing the superheated steam through coils in the receivers on its way to the steam chest of the engine, so that it may give up some of its superheat to the steam that has already expanded in the previous cylinder, and then pass to the steam chest at a lower degree of superheat. The utility of this method is that although we get the advantage of a high degree of superheat we do not get the disadvantage of a high temperature in the engine. With the use of high superheat temperatures there are, of course, large internal stresses due to the unequal expansion of different parts of the body of the engine. For this reason it would seem best to have the cylinders separate and perfectly cylindrical externally, and valve boxes and other parts to be firmly bolted on with heavy flanges when these are necessarily outside the cylinder.

Aron Two Rate Meter.—E. S. Shoults describes in a recent issue of the London *Electrical Review* the Aron two-rate meter shown by Fig. 3 herewith. To the left of the meter is shown an ordinary clock, which is electrically wound, having two extra dials on the top, one of which makes a revolution once in twenty-four hours and the other showing seconds. The first is necessary owing to the fact that the clock having only a twelve hour dial no distinction is made between day and night. The second is provided so that the regulation of a large number of the clocks can be carried out in as short a time as possible. Underneath the clock itself are two more dials with twenty-four divisions giving the twelve hours for day and night respectively. These dials are provided with pointers which can be revolved counterclockwise and so set at any hour by hand, the pointer on the left dial generally representing the beginning, and that on the right the end of the high rate period. By this means the twenty-four hours can be divided into two parts, the shorter one generally corresponding to the peak when the charge per unit is a maximum, and the longer one to the period during which the charge is greatly reduced. The distinction between day and night is made by the black and white colors of the dial centers. On the right hand side is the meter. This is a regular Aron meter except that the dials are placed in a vertical row, and an extra set is provided so that by means of the change-over gear fitted at the bottom of the dials, the record will be made alternately on the left and on the right set of dials according to the setting of the two pointers underneath the clock dial. An indicator on the meter side shows which set of dials is in use, the whole arrangement being visible through the windows.

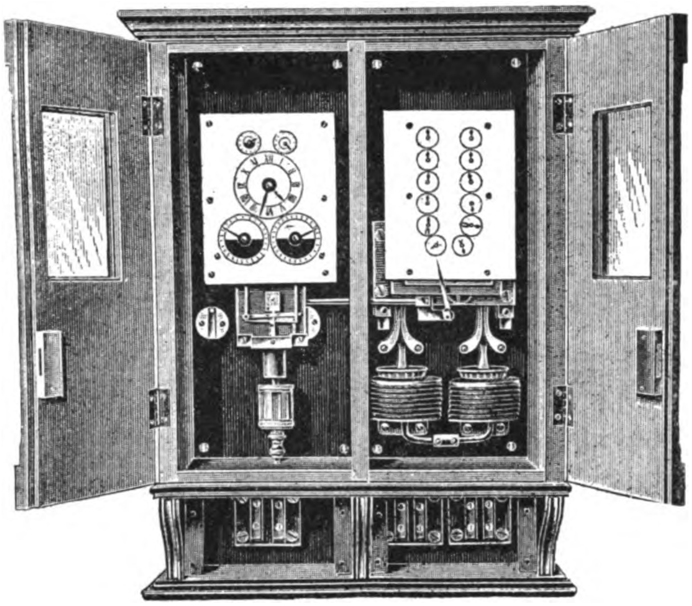

FIG. 3.

Combined Stop and Isolating Valve.—Figs. 4 and 5 herewith, taken from *Engineering* of London, show a valve the chief feature of which consists in its closing automatically in both directions in case of accident. If a tube should burst in a water-tube boiler, for instance, the valve automatically closes and prevents any escape of steam from the boilers at work through the defective boiler. The valve also acts as an ordinary stop valve. Another feature of the valve is that it automatically connects the boiler in which steam is being raised with the boilers at work and under full steam. The steam pressure on the outlet or upper side of the valve keeps it closed until the pressure in the boiler being set to work is sufficient to open it. Boiler attendants are at times deceived by inaccurate steam-gauges, and are liable to turn on steam and connect the boiler when there is a considerable difference in pressure. Many accidents have resulted from this cause. The horizontal

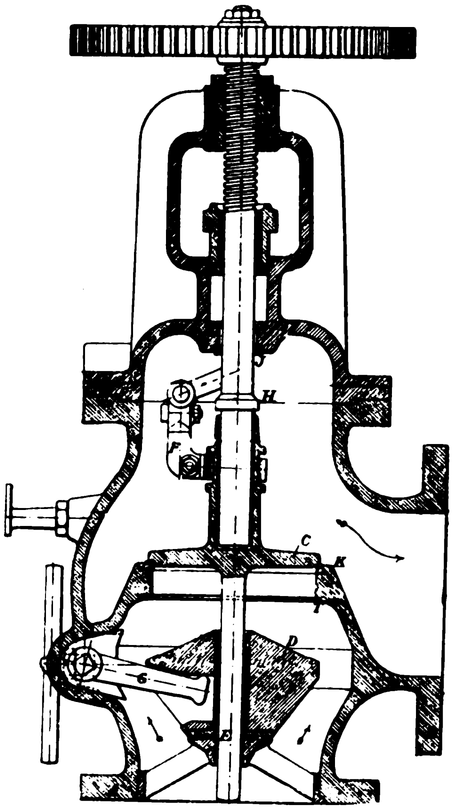

FIG. 4.

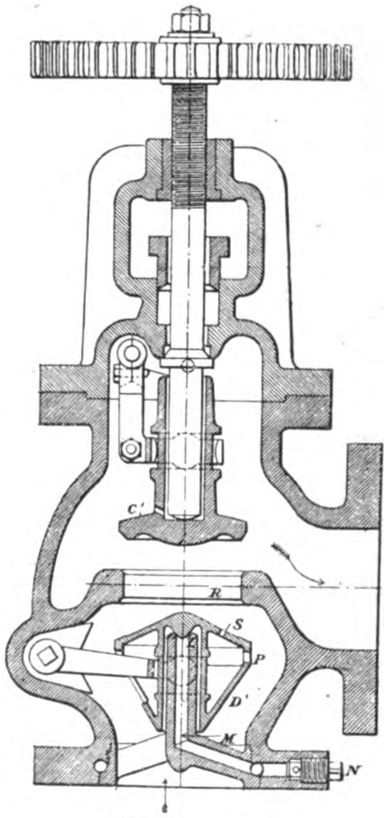

FIG. 5.

flange *A* is connected to the boiler, and the vertical flange *B* to the steam-pipes. The arrows indicate the direction of the flow of steam. The combined valve consists of two separate valves—the upper valve *C* and the lower valve *D*, both being loose on the spindle. When the valve *C* is screwed down, it acts as an ordinary stop-valve and shuts off the boiler; and when the spindle is raised, the valve is opened by the flow of steam from the boiler, when the pressure on both sides is equal. The valve *C*, being loose on the spindle, acts as a non-return valve, and immediately closes in case of accident to the boiler, and prevents escape of steam from the other boilers. The lower valve *D* operates in the opposite direction—that is, in case of steam-pipe fractures or any other mishap on the outlet side of the valve. Under normal working conditions this valve is kept in position by its own weight and a certain pressure of steam caused by a partial vacuum formed by the flow of steam past the valve, which exerts a suctional action in the space between the valve and spindle, as indicated by arrows at *E*. The valve can be set to close at any desired difference in pressure by an adjusting screw. When once adjusted, a padlock or seal may be applied to prevent anyone tampering with the valve. When an accident has occurred and the automatic valve *D* is closed against its seat *T*, it is kept in this position by the steam pressure until the stop-valve *C* is closed. When this is done, the steam pressure on both sides of the valve *D* is equalized by a small quantity of steam passing to the upper part of the valve through the space between the valve and spindle; this causes the valve to return to its normal working position. Handwheels for testing are connected by means of spindles to the levers *F* and *G*, and in this way the valves *C* and *D* can be controlled from the outside and kept in working order. A valve facing *H* is formed on the spindle, which, when the steam stop-valve *C* is fully open, comes in contact with the seating *J* immediately under the stuffing-box; this protects the packing, and also admits of new packing being put in while the valve is under full steam.

Fig. 5 illustrates the type of valve used when it is desired to place the valve at an angle or in an inverted position. This valve is in all respects the same as shown in Fig. 4, excepting as regards the design of the isolating valve *D'*. The special object of the arrangement of the isolating valve *D'* is to keep it in position under normal working conditions, quite independent of the position of the stop-valve. For this purpose valve *D'* is provided with a small valve which rests in a seat formed at the top of the hollow guide-spindle *M*, which opens to the atmosphere at *N*. The valve is thus kept in position by direct pressure of steam. In case of accident, the increased velocity of steam, consequent upon the difference of pressure, easily overcomes the pressure required to keep the valve in position under normal conditions, and closes the valve *D'* on the seating *R*. The valve *D'* is kept by the steam pressure against its seating, *R*, and can only be released by shutting the stop-valve *C'*, when steam passing through the small openings *P* and *S* causes an equal pressure on both sides of the valve. The valve *D'* will then return to its seating and resume its normal position. When the valve *D'* closes, due to the occurrence of an accident, this is at once indicated by a small steam jet discharged from the opening *N* into the atmosphere. By adjusting the size of the opening *N*, the isolating valve *D'* may be set to close at any difference in pressure. The valve *C'* acts in a similar way, and is in all respects the same as described in Fig. 4.

SOME RECENT ELECTRICAL PATENTS

Constant-Current Transformer.—It is well known that for transforming alternating currents from constant potential to constant current use has been made of a transformer containing relatively movable primary and secondary windings embracing a common core, the regulation for constant current being obtained by the automatic variations of the inductive relations between the primary and secondary windings due to the repulsion set up by the currents carried by those windings, which forces them apart. This well-known transformer embodies the disadvantage of a low power factor at very light loads. With a view to remedying this disadvantage, the modification of the Thomson transformer shown by Figs. 1 and 2 herewith has been devised by Malcolm H. Baker. This consists of a primary winding, *2*, mounted on a laminated core, *1*, the magnetic circuit of which is not quite closed; a movable secondary winding, 3, adapted to slide over the primary winding and one leg of the core, and a counter-weight, 6. When the movable secondary, 3, is at its lowest position, as shown in Fig. 2, the mutual induction between the two windings is, of course, maximum, and this, therefore, is the full-load position. When in this position, if some of the lamps are cut out on the circuit the current in the secondary winding will, of course, increase, thereby increasing the repulsion between the two windings and causing the secondary winding to rise until equilibrium is again restored. As the winding rises, it interlinks less and less of the magnetic flux passing across the air-gap, so that the secondary voltage becomes less and less; equilibrium is restored when the secondary current falls to normal value. The secondary coil assumes the position in Fig. 1 at no load; that is to say, when all of the translating devices are short-circuited. It is obvious that the power factor of this transformer is higher at no load than it would be if the magnetic circuit were completely closed about both coils; also that it is lower at full load than it would be if the magnetic circuit were completely closed. Patent No. 748,146.

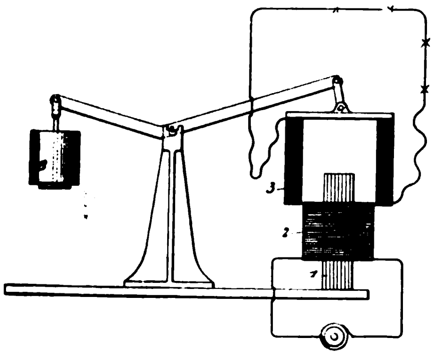

FIG. 1.

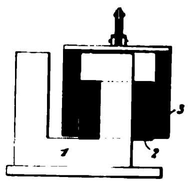

FIG. 2.

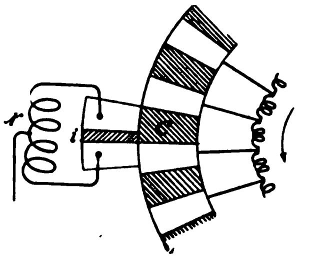

FIG. 3.

Series Alternating-Current Motors.—In order to overcome the tendency to excessive sparking which is characteristic of any series alternating-current motor built along the ordinary lines, Rudolph Ziegenberg has devised and patented the peculiar arrangement illustrated by Figs. 3 to 5, inclusive. This arrangement consists of a double commutator brush, the two parts of which are separated by a relatively thick insulation, *i*, and connected to an inductive winding, *N*, as in Figs. 3 and 4, or to a section of the field winding as in Fig. 5. When connected to the inductive winding, as in Fig. 3, this winding is made the secondary of a small induction coil as illustrated in Fig. 4. The object of this arrangement is to induce a counter electromotive force in the coil undergoing commutation which will neutralize the e.m.f. generated therein by the alternating flux in the armature core—the transformer e.m.f. Referring to Fig. 4, it will be seen that one terminal of the primary winding of the small induction coil, *W*, leads to the middle of the secondary winding, so that the field current passing through the secondary winding does not affect it. In Fig. 5 the e.m.f. applied to the double brush is taken from the main field winding and is equal, of course, to the difference of potential between the two points of the field winding to which the double brush is connected. The object of

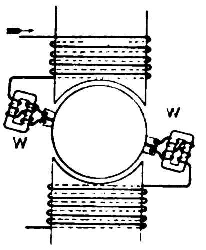

FIG. 4.

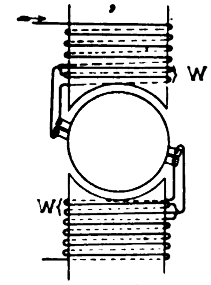

FIG. 5.

the inventor is merely to counteract the e.m.f. induced in the commutated coil by the alternations of the flux in the armature and not to produce what in a direct-current machine would be termed a commutating em.f. In order to prevent either half of the brush from simultaneously touching two commutator segments, the insulation between the commutator segments is made unusually thick, as indicated by the shaded portions, *C*, in Fig. 3. Patent No. 748,907.

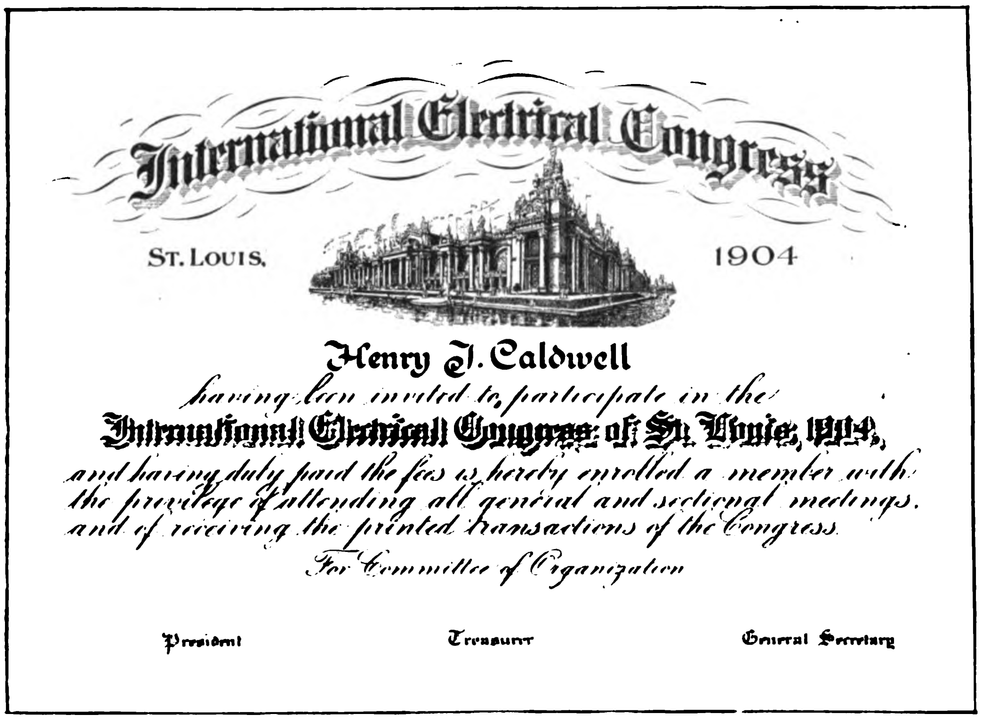
THE INTERNATIONAL ELECTRICAL CONGRESS AT ST. LOUIS.

According to the present indications, the International Electrical Congress to be held at St. Louis, September 12 to 17, 1904, will be one of the most successful that has yet been held, both with respect to the number of adhesions and to the value of the transactions. Up to date about 3550 circular letters of invitations to join the Congress have been issued to persons or associations in North America. In response to these nearly 900 acceptances of membership have been received. About 350 similar circular letters of invitation have been recently sent to other countries. It is intended to issue in all about 5000 invitation circular letters in American and about 6000 in foreign countries. Many persons, both in America and abroad, who do not expect to attend the sessions in St. Louis, will probably join the Congress in order to secure a copy of the *Transactions,* which wil form one and perhaps two large actavo volumes. The collection of fees has commenced, and upon receipt of a fee the member will be forwarded a Certificate of Membership, a *fac simile* of which is shown herewith, without the signatures. The full size of the certificate is 8½ in. x 11 in. (21.5 cms. x 28 cms.) and it is printed on heavy paper of excellent quality.



International Electrical Congress

ST. LOUIS, 1904

Henry J. Caldwell

having been invited to participate in the

International Electrical Congress of St. Louis, 1904,

and having duly paid the fees is hereby enrolled a member with the privilege of attending all general and sectional meetings, and of receiving the printed transactions of the Congress.

For Committee of Organization

President Treasurer General Secretary

Special letters of invitation have been issued to prominent electricians and electrical engineers requesting papers for the Congress in the various sections; 146 were sent to foreign authors and 134 to American authors. There has not been time to receive replies from many of the foreign authors, but 21 acceptances have up to date been received from abroad, and 46 acceptances from North America. Sixty-seven papers are thus already promised for the Congress, and the number is steadily increasing. A considerable number of invitations to contribute papers have yet to be issued. It is hoped that the Congress will convene with a full program in each section, and that at least half of the papers may be from foreign countries. According to the plans of the Committee of Organization, papers for the Congress program are specially invited, but papers voluntarily offered will be submitted to the officers of the sections to which the papers belong, and may be included in the program by invitation at their request, if the subjects are desirable, and if the schedule allotted to each section will permit, it being the desire of the section officers to secure and offer the best possible program and presentation.

The following section chairmen and secretaries have been appointed by the President, and have already done much work in organizing their sections:

Section A, General Theory: Prof. E. L. Nichols, Cornell University; Prof. H. T. Barnes, McGill University.

Section B, General Applications: Prof. C. P. Steinmetz, Schenectady; Prof. Samuel Sheldon, Brooklyn.

Section C, Electrochemistry: Prof. H. S. Carhart, University of Michigan; Carl Hering, Philadelphia.

Section D, Electric Power Transmission: Mr. C. F. Scott, Pittsburg; Dr. Louis Bell, Boston.

Section E, Electric Light and Distribution: Mr. J. W. Lieb, Jr., New York; Mr. Gano S. Dunn, New York.

Section F, Electric Transportation: Dr. Louis Duncan, Mass. Inst. Technology; Mr. A. H. Armstrong, Schenectady.

Section G, Electric Communication: Mr. F. W. Jones; Mr. B. Gherardi, New York.

Section H, Electrotherapeutics: Dr. W. J. Morton, New York; Mr. W. J. Jenks, New York.

The Committee of Organization of the Congress consists of Elihu Thomson, President; A. E. Kennelly, General Secretary; W. D. Weaver, Treasurer; Bion J. Arnold, Vice-President and Chairman of Executive Committee; C. F. Scott, Dr. S. W. Stratton, Prof. H. S. Carhart and Prof. W. E. oldsborough, Vice-Presidents.

All communications should be addressed to the General Secretary, Dr. A. E. Kennelly, Harvard University, Cambridge, Mass.

The De Mare Electromagnet.

To the Editor, American Electrician:

Sir:—I do not know to what cause to attribute the errors which have been committed in your comment on my type of electromagnet. (AMERICAN ELECTRICIAN, November, 1903, page 553.) At any rate, the winding, characterized as "freakish," was not inspired by the contemplation of any stator winding whatever; time is too short to dwell on this point at length.

The theory of electromagnets is not violated; there is simply a better utilization of the current. It is only for this reason that I decided to make public this type of winding. For example, two electromagnets may be constructed with the same iron, they may have the same weight, the same cross-section, the same length, the cores may be wound with the same quantity of wire (weight, length, diameter), and these two electromagnets may differ in nothing but the method of winding; under these conditions the electromagnet with the solid core is [only] able to hold a weight ten times smaller than the laminated electromagnet of my system, with equal excitation. This may appear to you extraordinary but it is so, as you can easily find out by making the experiment.

F. DE MARE.

Brussels, Belgium; Dec. 7, 1903.

P. S.—There is no similarity between my electromagnets and those described in the number of February, 1901.

[As M. de Mare does not state what errors were committed in the comment to which he objects, we are unable to assist him in determining the cause of them. His statement as to the performance of two magnets is an arbitrary assertion, not an argument; moreover, if two electromagnets "differ in nothing but the method of winding," one of them cannot very well have a solid core while the other has a laminated core. We stated clearly, as we thought, that the lamination of the core was an advantage, the object of our criticism being the disposition of the winding only. We did not state that the de Mare magnet was similar to the magnet described in the February, 1901, issue; we merely said that the results obtained were similar in both cases. We will gladly publish any demonstration of the soundness of M. de Mare's views with which he may favor us, provided such demonstration be based on the recognized laws of electromagnetic phenomena.—EDITOR.]

NOTES.

The Annual Meeting of Electrical Contractors.—The annual meeting of the United Electrical Contractors' Association of New York State was held on January 19 at the Building Trades Club. The following are the officers-elect: President, Mr. Marshall L. Barnes, Troy, N. Y.; vice-president, Mr. James R. Strong, New York City; secretary, Mr. Frederick Fish, Rochester, N. Y., and treasurer, Mr. J. C. Stearns, Buffalo, N. Y. An enjoyable banquet was given by the Electrical Contractors' Association of New York City in the evening at Delmonico's. Mr. J. C. Hatzell made the welcoming address, in which he congratulated the delegates on the results of their day's labors and told them that they might justly consider themselves among the great captains of industry since they moved, or helped to move, the wheels of commerce. It required, he said, no great stretch of the imagination to predict that electricity would eventually be the sole motive power for these wheels.

Electrical Equipment of a Modern Newspaper Building.—Some details of the electrical equipment for the new home of the *New York Times*, at Broadway and Forty-second Street, New York City, have been given out. A remarkable feature of the equipment is that although 1000 kilowatt-hours of power will be required daily, this will not be supplied by an isolated plant but by the New York Edison Company. The following is a list of the uses and applications of electricity in the building:

One hundred and eleven motors—4 Hoe octuple presses; 1 press, job; 1 press, electric proof; 8 Kohler safety devices for controlling press movements; 2 autoplates, turning out eight stereo plates per minute; 38 linotypes; 3 pumps, house; 3 pumps, sewage; 1 pump, air compression for pneumatic tubes; 1 pump, air vacuum for cleaning carpets and offices; 1 pump, ink; 1 paper conveyor, for carrying printed papers from presses to delivery room; 7 elevators, passenger and lift; 4 Leonard system of control for elevators; 1 gallery lift; 8 trolley hoists for paper rolls; 8 fans for metal pots and for ventilating press room; 6 gymnasium; 1 machine shop lathe; 1 machine shop lathe; 1 stereo molding machine; 1 stereo tail cutter, round; 1 stereo shaver, round; 1 stereo router; 1 stereo shaver, flat; 1 stereo trimmer, flat; 1 stereo saw; 1 stereo jig and drill machine; 3 refrigeration.

Light—4000 incandescent, 15 arc, Cooper Hewitt lamps, search, signs, bulletin service, elevator flash, cigar lighters, carriage call.

Heat—Stereo matrix; restaurant, including plate warmers, coffee urns, tea kettles, egg boilers, griddles, self-dumping oyster cooker for stews, toasters; stereo pastepot; soldering irons; hair curler for ladies' toilet; heating pads; heating tailors' irons.

Dental—Mallet, gold annealer, sterilizer, dental engine, mouth lamp, porcelain baking furnace, reflector for working on dark days, X-ray apparatus, cautery.

The Electric Railway Test Commission of the St. Louis Exposition held its second meeting in New York on January 27. All of the commissioners, namely, Mr. J. G. White, chairman, and Messrs. H. H. Vreeland, James H. McGraw, George F. McCulloch and W. J. Wilgus, were present, and a great deal of work was accomplished in furthering the plans for an elaborate series of tests of electric railway equipment at the Exposition.

A great deal of interest has been manifested by electric railway engineers in the proposed tests, and the value of the engineering data which in all probability can be accumulated in this way is not to be overestimated. The work has been divided into four main divisions, and four committees of engineers who are specialists in the several divisions of electric railway work have been appointed to prepare a schedule of the tests to be made of the equipment offered in each class. These special committees are to arrange tests of City and Suburban Equipments; Interurban Equipments; Heavy Traction Equipments, and A New System of Electric Traction. The committees are expected to submit their reports to the Commission on or before February 22, and the next meeting of the Commission will take place in New York on February 29, at which time the reports will be considered.

Lighting at the St. Louis Fair.—The contract for lighting the World's Fair, which is the largest illuminating contract ever let, has been awarded. It provides for supplying the exposition with 300,000 incandescent lamps. An idea of the distribution of these lamps may be had from the fact that 12,000 are to be placed on the Palace of Education alone. The classical outline of that building eliminates brilliant color effects, but furnishes a splendid setting for night effects produced by electric lights. It has been decided to place on each of the monumental standards which dot the main avenue of the exposition on the border of the waterways 24 incandescent lamps. Each of the standards has four cast-iron pendants, on each of which there will be six lights. The "Pike" or Midway will be furnished with sufficient lights to render it brilliantly illuminated. Each of the standards along the central avenues will hold 24 lamps, so distributed that 12 will hang on each arm of the supporting post. The lamps contracted for will be used exclusively for exterior lighting. The interior of the exhibit buildings, which will be closed at sunset, will be lighted by arc lamps, the chief object of this lighting being for patrol purposes. The western half of the facade of the Educational Building has been equipped with lamps as a test section for the purpose of trying the effects of lights between the columns. These tests have proved satisfactory in every way.

Erection of a 5000-kw Turbo-Generator.—C. G. Y. King, mechanical engineer of the Chicago Edison Company, gave a very interesting lecture on January 8 before the Chicago Electrical Association on the erection of the 5000-kw. turbo-generators in the mammoth plant of the Commonwealth Electric Company of Chicago. Mr. King illustrated his lecture with a large number of lantern slides, showing the different stages of the work and the parts of the steam turbines, and also some photographs and plans of the station. He illustrated, among other things, the method adopted for adjusting the foot-step bearing at the lower end of the vertical shaft, so that the proper clearance could be maintained between the moving and stationery blades of the turbine. He also illustrated the electric valves by which the admission of steam to the turbine is regulated. In the original design of the foot-step bearing which takes the weight of the turbine it was intended to adjust this bearing by means of a nut under the turbine with the expectation that once adjusted it would remain permanently in proper adjustment; but, as Mr. King remarked, "it would not stay adjusted, not even for five seconds," and means are now provided whereby the adjustment can be regulated by a hand wheel on the operator's platform of the turbine. The engineer can therefore make this adjustment at any time. The balanced steam valves electrically operated which admit the steam to the turbine nozzles, were also illustrated. These valves are of the poppet type and are normally held closed by the steam pressure behind them. When steam is to be admitted through this valve, a small steam valve operated by a solenoid relieves the steam pressure which holds the poppet valve shut and unbalances the valve so that it opens; the area exposed to steam pressure tending to open the valve in this case being greater than the area exposed to the pressure tending to close the valve. A number of these valves are provided and the governing of the turbine is effected by opening and closing these, each valve being either full open or entirely closed. There is no throttling action. The revolving field magnets of these turbo-generators have six poles. The speed is 500 revolutions per minute, which of course gives a frequency of 25 cycles per second. The generators are 9000-volt 3-phase machines. In connection with these steam turbines, surface condensers are used. Each condenser has a wet and a dry air pump, driven by a Corliss engine and a centrifugal pump, to supply circulating water. The power station is located between two slips of the Chicago River; the condenser circulating pumps take water from one slip and discharge into another slip on the downstream side. Speaking of the design in the power station, Mr. King likened it to a comb, the turbine room or row of turbines corresponding to the back of the comb, and the batteries of boilers to the teeth of the comb ranged at right angles to the turbine room. Each turbine has a battery of boilers sufficient to supply it independently of the other batteries of boilers.

ESTABLISHED 1889.

American Electrician

A Journal of Practical Electrical and Steam Engineering.
WITH WHICH IS INCORPORATED
Electrical Industries.

CECIL P. POOLE, Editor.

Published on the first of each month by the
McGraw Publishing Company,
114-118 Liberty Street, New York.
Telephone Call, - - - 7606 Cortlandt.
Branch Offices:
Philadelphia: 929 Chestnut Street.
Chicago: Monadnock Block.
Cleveland: Cuyahoga Building.
London: Hastings House, Norfolk Street, Strand.

Address all communications to
AMERICAN ELECTRICIAN.

Copyrighted, 1902, by McGraw Publishing Co.

Entered at the New York Post Office as second class mail matter.

Subscription, - $1.00 Per Year
In the United States, Canada and Mexico.
FOREIGN COUNTRIES, $2.00.

NOTICE TO SUBSCRIBERS.

Subscribers will find on addressed wrappers of their papers the date on which their subscriptions expire. This will be the only method of acknowledging the receipt of subscription payments.

In requesting change of address both the old and the new address should be given.

NOTICE TO ADVERTISERS.

Changes in advertisements should reach the office of the American Electrician by the 15th of each month in order to appear in the following issue. New advertisements can be received up to the 25th of each month.

Vol. XVI. FEBRUARY, 1904. No. 2.

The American Electrician has a larger paid circulation list than any other electrical journal in the world.

Superheated Steam.

In a paper read before the Rugby (England) Engineering Society, Mr. E. A. Reynolds brought out some interesting features concerning the use of superheated steam; an abstract of his remarks is printed in our Contemporaries department this month Possibly the most important of his conclusions was that most of the advantages of superheated steam are obtainable with a compound engine by applying the superheat after the steam has passed through the high-pressure cylinder, without entailing the disadvantages incident to very high initial temperatures. Of course, superheating receivers are by no means novelties, and we have long since learned that the chief benefit derivable from the use of superheated steam is the elimination of condensation. But the immense amount of work done by Schwoerer, Schmidt and others in the perfection of individual superheaters and engines built with a view to using superheated steam from the beginning of the cycle would seem to have been misdirected if it is unqualifiedly true that all the desired improvement could be obtained by superheating after the first stage.

In most discussions of superheated steam economy, the water consumption of the engine is made the criterion of its performance; it is scarcely necessary even to suggest that, in the absence of figures relating to the coal consumption per pound of steam delivered to the engine and the calorific value of the coal, the weight of steam per unit of delivered work means little or nothing. In some cases (not published very widely) it has been found that the saving in actual coal and water consumption per unit of delivered work did not offset the fixed charges on the superheating equipment and the increased wear and tear on the engine. In many other cases, however ("many" being relative, since there have not been a great number of total cases as compared with the number of engines operated with saturated steam), the actual saving has been worth while. Of course, the possible saving by superheating depends on the type of engine and also on its size; the margin is considerably greater for a simple than for a compound engine, and slightly greater for the latter than for a triple-expansion engine.

One of the interesting, though academic, features of the superheated steam problem is that the advantages theoretically obtainable by adding extra heat were recognized to a certain extent about 75 years ago. The newness of the matter is restricted to the practical investigations and experiments made by Schmidt and others in Europe. A mine owner in Cornwall, England, in 1828 built a brick jacket around his engine cylinder and maintained a fire within this jacket, by means of which arrangement he increased the amount of delivered work per unit of coal by about 50 per cent. (It is fair to assume that the initial economy was pretty low.) The celebrated John Ericsson made some fugitive experiments with superheated steam about 1835, and in 1852 a Frenchman named Rafford took out patents for apparatus for superheating steam. The work in this direction was discouraged by the difficulties of lubrication, however, the present mineral and heavy cylinder oils being then unknown, and when the practicability of multiple-expansion engines became established attention was diverted from the use of superheat by the conspicuous gains obtained with such engines. Having practically exhausted the possibilities of multiple-expansion, the old problem of superheating was naturally revived by engine designers.

Electrolytic Rectifiers.

In the report of the convention of the Northwestern Electrical Association which appears in another part of this number will be found an abstract of a paper read by Prof. C. F. Burgess in which he describes generally a new electrolytic rectifier that has been built at the University of Wisconsin and manifests an apparently optimistic attitude toward it. It does not appear, however, that the future of this class of apparatus can be highly favorable, even though unusually good results may have been obtained in this case. While it may be preferable to a rotary converter in very small sizes, an electrolytic rectifier cannot compare with a converter in medium and large sizes, and the advantages of a combination of transformer and electrolytic rectifier are somewhat doubtful.

It is at least of theoretical interest, if not of practical importance, that electrolytic rectifiers must cause dissymmetry of the alternating-current wave in the other parts of the circuit which supplies them. It is true that arc lamps and unbalancing of the load on polyphase circuits will change the wave form, but always symmetrically so that there are no even harmonics in any part of the circuit, whereas the rectifier changes the wave form dissymmetrically. It is of decidedly practical importance, however, to note that this type of rectifier may require a much longer time to deliver a given battery charge than would be required with a rotary converter or a motor-generator. It is the result of observation that an open-coil, direct-current dynamo takes longer to charge a given battery than a closed-coil machine, the ammeter readings being the same in both cases. This appears to be due to an effect caused by the rapid current variations. Pof. Samuel Sheldon discovered that applying alternating current to a storage battery does not leave the battery unchanged by the superposition of equal and opposite electrolytic effects, as one might naturally expect it would, but causes a progressive sulphating of the plates. It would appear from this that, even where the charge impulses are much larger than the discharge impulses, a material portion of each charge would be used up in decomposing the sulphate produced by the reversals. At all events, this explanation fits the facts perfectly. For this reason, unless the reverse-current impulses through an electrolytic rectifier should be of negligible magnitude, the time required for charging a given battery will be considerably longer than with a rotary converter.

In charging storage batteries with a pulsating or undulatory unidirectional current, the arithmetic mean value of the current is what should be indicated by the ammeter, for this is the measure of the electrolysis going on in the batteries. This is precisely what is indicated by a direct-current ammeter, while the indications of an alternating-current ammeter, namely, the geometric mean values, are proper for power purposes. This is more particularly the case if the reverse current required to close the hypothetical valve be not a negligible quantity. That is to say, if the reverse current required to form the non-conducting film or films which arrest the further flow of the very current which forms them, be of a sensible magnitude, it will be added to the useful current by an alternating-current ammeter, but will be subtracted, as it should be, by a direct-current instrument.

The New York Central Equipment.

As previously announced in our columns, the New York Central & Hudson River Railroad Company is perfecting its plans for hauling all trains into and out of New York City by means of electricity. The corps of experts engaged to work out the details of the plan have decided to use direct-current locomotives for hauling the trains, and to make the change from steam to electric traction at Croton on the Hudson River division, and at White Plains on the Harlem division. Two power stations will be established, one on the upper east side of the city, near the junction of the Harlem and East Rivers, and the other between Yonkers and Tarrytown, about 45 miles from the Grand Central Station. The generators will be three-phase alternators, driven by steam turbines, as also announced previously. There will, of course, be rotary converter sub-stations at suitable intervals for feeding the distribution mains. The locomotives will be of 2200 horse-power each and equipped with gearless motors; the maximum speed ability is to be 75 miles an hour for a single locomotive hauling a 500-ton train. The details of the system of working conductors have not yet been made public, but it is understood that the third rail will be used everywhere except in the terminal yards, where the multiplicity of switches makes the use of a hooded rail almost impossible and an unprotected rail would be murderous. Here some form of overhead working conductor will probably be employed.

This is one of the most striking examples of the wisdom of putting important work in the hands of experienced and conservative specialists that has been presented for many years. The only feature of the whole plan that might be considered in the least degree of problematical expediency is the use of a comparatively untried type of steam turbine, and in view of the character of the contract made with the builders and the reputation of the latter the risk involved by the decision to use this turbine is undoubtedly negligible. The decision to use direct-current motors is indicative of the conservatism of the engineering committee. While alternating-current traction is most promising and is certain to come ultimately, its fitness for work of the magnitude involved here has not been demonstrated, and this was certainly not an appropriate occasion to indulge in an initial demonstration and weed out the objectionable features which inevitably would have developed. The system *must* work reliably from the very first moment that it displaces the steam system of haulage.

Meters.

The vagaries of the gas meter have long been a favorite theme for vigorous discussion by patrons of gas companies, and it is very probable that to past experience with these unsatisfactory contrivances more than to any other one cause was due the stubborn opposition to the introduction of electric meters that was manifested by electric light users when meters first reached the really commercial state. Leaving aside the marvellous tales told by persons who may have been influenced by bitter prejudice or ulterior motives, it is undeniably true that gas meter records are in most cases inconsistent with the actual service rendered the consumer. We have personal knowledge of cases where the meter showed a very considerable consumption of gas during a period when the consumer's premises were locked up, all the keys in the householder's possession, and all of the family continuously sojourning miles away; the piping and jets had been thoroughly tested for leaks before closing the house and were again tested upon the return of the occupants. There are, again, indisputable cases of decreased service being accompanied by increased gas bills.

Most of the discrepancies between records and service that have been charged against the gas meter are impossible in the case of the electric meter, and the others are highly improbable. A meter may run fast (or slow) and it may creep when there is no load; these constitute practically the whole category of its vices. It is utterly impracticable to increase the pressure on the mains enough to affect the meter record appreciably, and the quality of the current cannot be impaired without lowering the meter bill, *i. e.*, some worthless meter-operating medium cannot be sent through the wires instead of electricity. Moreover, while the mysteries of the meter dials are, as a rule, beyond the average consumer, he can readily see if his meter creeps without load, and prove it beyond dispute. And there is no known method by which a reduction in the number of lamp-hours used can produce an increase in the record of the meter. Everything considered, therefore, the average user of artificial illuminants is much safer at the mercy of an electric meter than with the time-dishonored gas meter.

DESIGN FOR A TWO CYCLE GASOLINE MOTOR.

BY J. C. BROCKSMITH, M. E.

The accompanying working drawings show a two-cylinder two-stroke-cycle air-cooled type of gasoline motor that is particularly adapted to light automobile work. The advantage of a two-cycle motor lies in its extreme simplicity, it being entirely free from valves, cams, gears, etc., and their consequent noise and liability to derangement. The machine is still further simplified in the present design by the use of air-cooling flanges, thus avoiding the use of a water circulating system with its pumps, piping and radiators, all of which are likely to cause trouble.

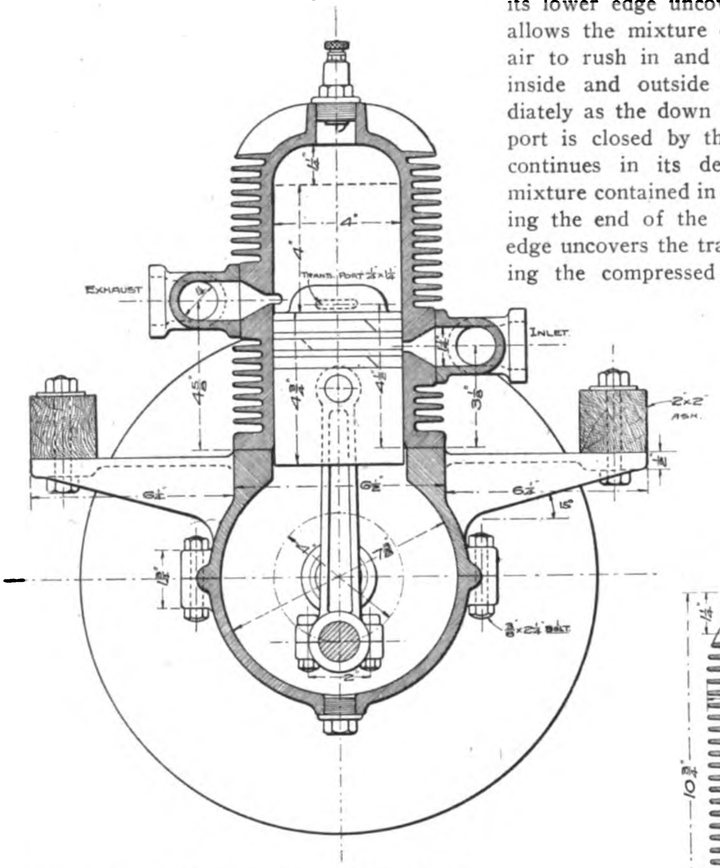

FIG. I.—FRONT SECTION OF GASOLINE MOTOR.

A further advantage of the two-cycle motor is that it ordinarily receives an impulse at each revolution of the crank shaft and in the case of a two-cylinder motor at every half revolution of the crank shaft, thus making it comparable to a four-cylinder four-cycle engine as far as regularity of turning effort is concerned.

The two-cycle type of gas engine has some disadvantages, first of which is its inability to operate at very high speeds and its consequent restricted output per unit of weight. From the nature of its cycle of operations the incoming charge and outgoing gases in the cylinder cannot avoid intermixture to some extent, this becoming greater with increased speeds, so that the combustion of the charge is not as complete as in the four-cycle engine and consequently it cannot deliver as great an amount of energy per stroke. It has been sought in the present design to minimize this intermixture of the charge with the exhaust by a novel arrangement of the transfer passages and deflecting surfaces on the piston head. The operation of the engine, considering only one cylinder at a time, is as follows:

On the upward stroke of the piston a partial vacuum is formed in the crank case which is air-tight and has no communication with the outside air until the piston reaches the upper end of its stroke, when its lower edge uncovers the inlet port and allows the mixture of gasoline vapor and air to rush in and equalize the pressures inside and outside the chamber. Immediately as the down stroke begins the inlet port is closed by the piston, which, as it continues in its descent, compresses the mixture contained in the crank case. Reaching the end of the down stroke its upper edge uncovers the transfer port, thus allowing the compressed mixture to pass into the cylinder.

On the next up stroke the transfer ports are first closed by the upper edge of the piston and the mixture contained in the cylinder is then still further compressed by the piston until it occupies the clearance space at the top of the cylinder, which is about 25 per cent of the stroke volume. At the end of the up stroke a spark passes at the plug and the compressed mixture is ignited and drives the piston downward When it reaches nearly the end of its down stroke the exhaust port is uncovered by its upper edge, slightly in advance of the uncovering of the transfer passages, and the expanded gases pass out. Immediately following this the transfer ports are opened and fresh mixture, which has in the meantime been compressed in the crank case, rushes in. The incoming charge enters in two streams from diametrically opposite points in the cylinder wall, whence they are deflected upward by curved vanes on the piston head; this action has the effect of clearing the cylinder of the exhaust gases by forcing them down and out and leaves the cylinder filled with nearly pure mixture ready to be compressed and ignited on the next up stroke of the piston. This cycle is repeated over and over, and the same thing occuring in the other cylinder, with the cranks at 180°, gives two impulses in each revolution.

It is obvious, of course, that the two compartments of the double crank case must be entirely independent of one another and also that they must be of such volume that the mixture will be compressed to some point slightly greater than the exhaust pressure. This, however, is susceptible to some adjustment by the insertion in the crank case of blocks of wood or metal in the space not actually necessary for the rotation of the cranks.

Fig. 1 is a front vertical section through the completed motor, which shows the size and location of the various ports and passages, the piston acting as its own valve in the manner above described in addition to its usual function of driving member. The cylinder has a 4-inch bore and 4-inch stroke, the bore being unusually large for an air-cooled motor. It need not be feared that this will result in overheating, as the engine is intended to operate at a moderate speed and output and in addition to this the fact that the activity in the cylinders is less will contribute to cool running. The maximum speed should be about 750 r.p.m. when the power will be about 6 horse-power.

The crank case is split along a horizontal

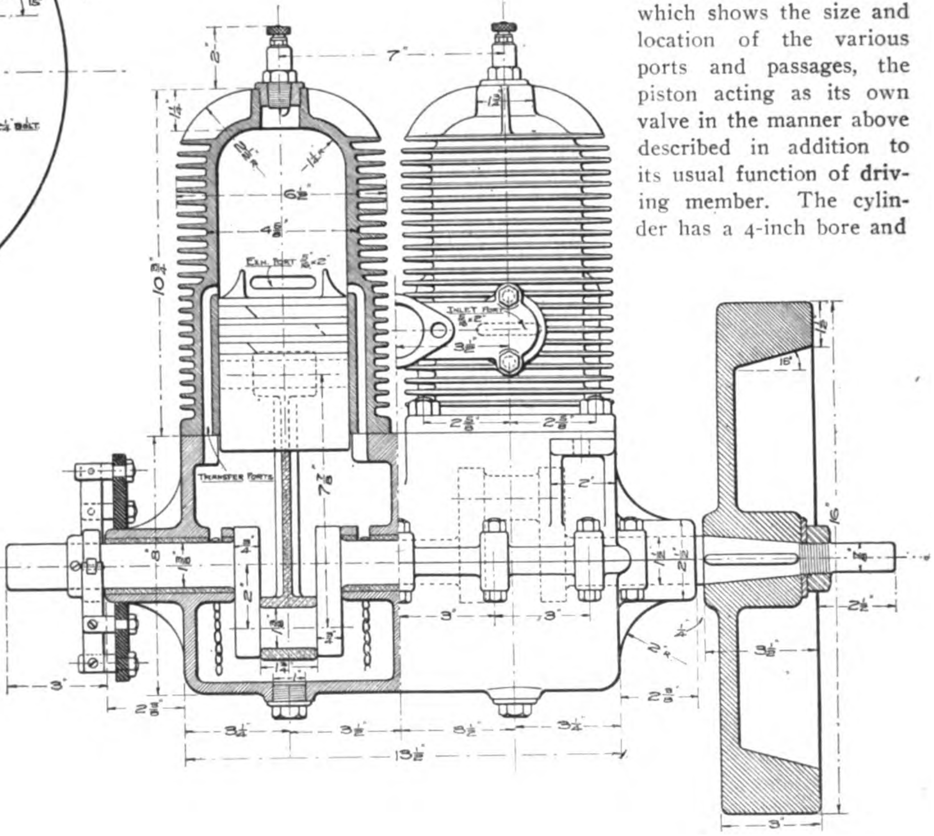

FIG. 2.—SIDE SEMI-SECTION OF GASOLINE MOTOR.

plane and is of comparatively small diameter, the flywheel being placed outside. Arms cast on the top half of the case enable it to be bolted to the framework of the car so as to afford proper clearance for rotation of the flywheel. The piston is long and has three rings for packing. These are made of greater width than the ports in the cylinder walls so that there is no liability of their becoming caught.

Both the inlet and the exhaust sides of the cylinder are provided with branch pipes which allow the piping to the engine to be reduced to the simplest possible arrangement, *i.e.,* one supply pipe and one exhaust pipe.

The spark plug is tapped into the center of the cylinder at the top, where it is in a good position to ignite the charge and is also accessible for inspection and cleaning, which is sometimes necessary.

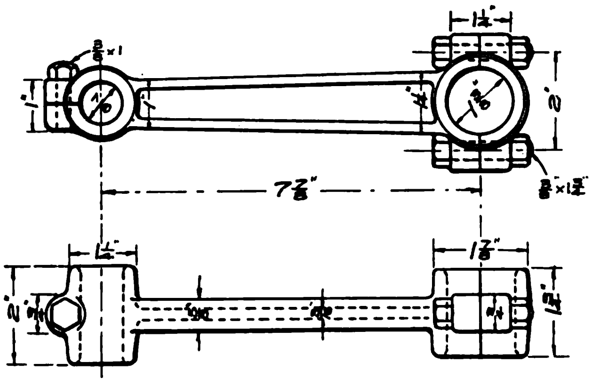

FIG. 6.—DETAIL OF CONNECTING ROD.

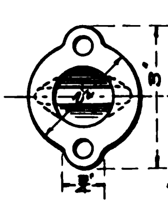

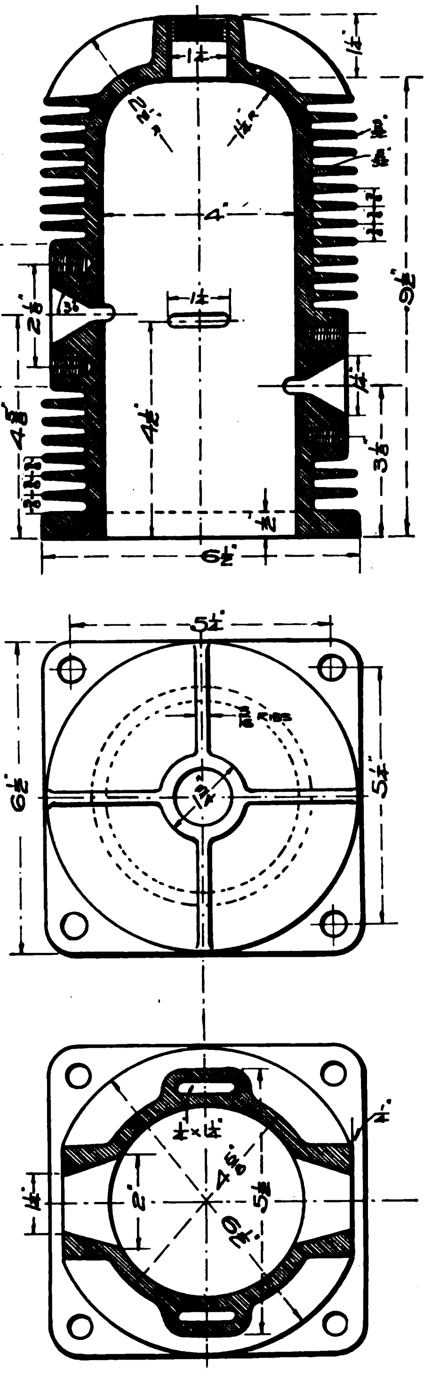

FIG. 3.—DETAILS OF CYLINDER.

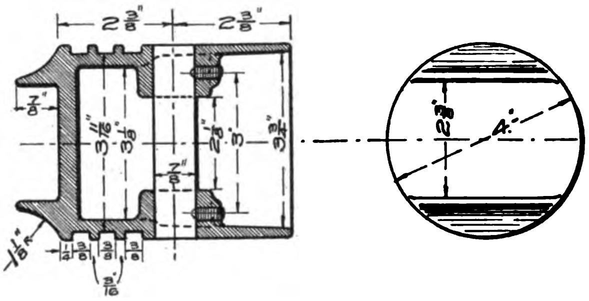

FIG. 5.—DETAIL OF PISTON.

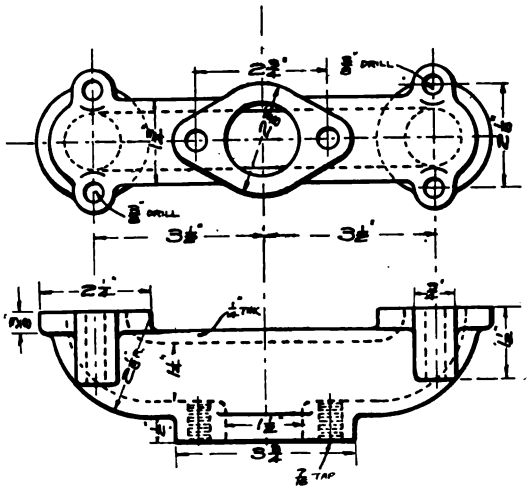

FIG. 4.—DETAIL OF BRANCH PIPE.

Fig. 2 is a semi-sectional side view of the complete motor. This shows the transfer passages which connect the cylinder with the crank case; it also brings out the shape of the deflecting vanes on the piston head, and the branch pipes which connect the two cylinders. The contact maker is shown in this view located on the bearing boss, and is adapted to be rotated about the cam, thus varying the time of ignition in the customary manner, to obtain various speeds. The shaft is extended somewhat on this end so that a starting crank handle may be fitted on.

The other end of the crank shaft carries the flywheel, which is of the cone clutch variety, and is extended somewhat beyond the hub of the wheel for the purpose of centering the male portion of the clutch.

There are three main crank shaft bearings, all of which are bushed with phosphor bronze bushings and may be lubricated by means of chain oilers from oil contained in the crank case or by means of felt wipers, as may be desired. The other parts are oiled by the splash, including the cylinders, which may be provided with splash plates if found necessary. Oil plugs are provided on the crank case for draining off the used oil and renewing the supply.

Fig. 3 gives the details of the cylinder; a vertical and a horizontal section of the cylinder are shown and also a top view. The cylinders should be cast in good close-grained grey iron. Two are required, just alike.

The cylinder wall is 5/16 inch thick and is provided with 23 flanges 15/16 inch high for the purpose of increasing the radiating surface and thus maintaining the temperature of the cylinder wall at such a point that lubrication can be effectually accomplished. The flanges are made tapering in thickness from 5/32 inch at the base to 3/32 inch at the apex. This is mainly to facilitate moulding, which is difficult at the best.

The vertical section shows the size and proper location of all the ports in the cylinder wall, the inlet and exhaust ports being both 5/16 x 2 inches and the two transfer ports ¼ x 1¼ inches each. The horizontal section of the cylinder is taken through the center lines of both inlet and exhaust ports, and helps to make clear the location of the transfer passages cored out in the cylinder wall.

The end view of the cylinder shows four 3/16-inch ribs across the top of the cylinder head and also the boss which is bored to 1¼ inches so as to take a 1¼-inch boring bar for use in boring out the cylinder. It is afterward threaded and bushed to receive the spark plug. This view also shows the flange at the bottom of the cylinder and the layout of holes by means of which the cylinders are bolted to the crank case. The holes are drilled ½ inch for studs or cap screws. This flange is, of course, faced at the same operation as boring the cylinder.

Fig. 4 is a detail of the branch pipe which connects the two cylinders on both the inlet and exhaust sides of the engine. Two such pipes are required; they may be cast of iron or aluminum alloy as desired. It is probable that the aluminum alloy can be used for both sides, although there is some question of overheating the metal on the exhause side and thereby causing it to become brittle and crack. The pipe is cored with a 1¼-inch round hole, the walls are ¼ inch thick, and where connection is made to the common pipe the size opening is 1½ inches. The pipe is bolted to pads on the cylinder by means of ⅜-inch studs or cap screws. These joints need not be very accurately fitted, as there is no great pressure at these points, and they can further be packed with asbestos washers if necessary.

Fig. 5 is a detail of the piston; this is of cast iron, and two are required. It has three grooves turned for ⅛-inch rings. The rings should be turned up about 1/64 inch or more larger than the finished bore of the cylinder and ⅛ inch thick. They are then cut through with a diagonal slot taking out about 3/64 inch, and should be fitted to the bore of the cylinders so that the ends stand a little apart so that when they warm up during running and expand they will not seize. The body of the piston should be turned two or three one-thousandths small for the bore of the cylinder, as the pistons in an air-cooled motor are more liable to stick than in a water-cooled machine, and should therefore be a comparatively free fit when cold. The grooves should be turned a nice fit for the rings, which can then be snapped into place and pinned to the piston with the joints at 120° intervals and occupying the positions indicated in Figs. 1 and 2 so that the joints are not required to traverse that portion of the cylinder wall which is broken by the ports.

The wrist pin is ⅞-inch cold rolled steel and is held in position by means of two ¼-inch set screws in the inwardly projecting bosses on the piston. An improved lubrication of the wrist pin bearing can be secured by drilling a hole through the pin from end to end and connecting this with a hole at right angles that enters the bearing surface. A small groove could also be turned in the piston communicating with the hole in the wrist pin; the bearing would then receive a good supply of oil gathered from the cylinder wall.

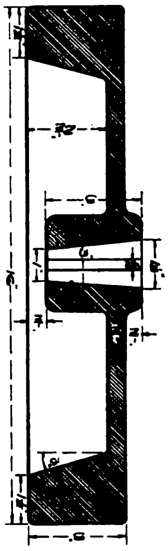

FIG. 8.—DETAIL OF FLY-WHEEL.

Fig. 6 is a detail of the connecting rod, which is intended to be a phosphor bronze casting; two are required. Provision is made at both ends of the rod for taking up wear. The box at the crank end of the rod is made 1⅜-inch bore for one cylinder and 1½-inch bore for the other, to correspond to the crank shaft sizes. The body of the rod is of "I" section with a 3/16-inch web.

Fig. 7 shows the crank shaft. This is preferably made from a solid open-hearth steel forging, the cranks themselves being cut out of the solid metal. It would save the builder considerable time in machining, however, if he can secure a good sound steel casting which could be made very nearly to finished size and thus leave a minimum amount of metal to be removed in finishing.

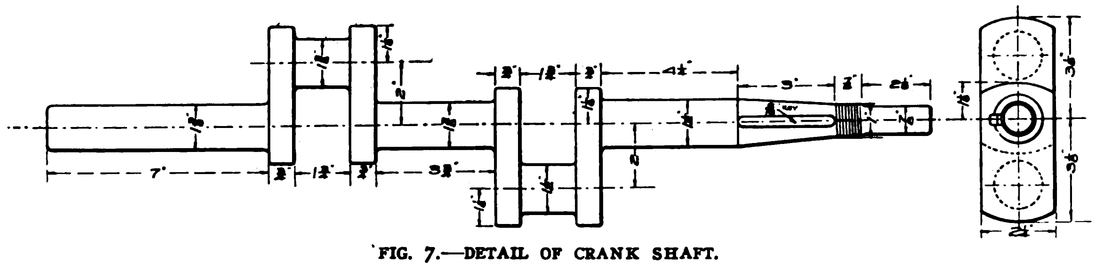

FIG. 7.—DETAIL OF CRANK SHAFT.

In machining the cranks it will be necessary to make a couple of cast-iron dogs to slip over the ends of the shaft, fastened by set screws, upon which to locate the centers for turning up the crank pins. The crank shaft itself should be left about 1/16 inch oversize until the crank pins have been finished, when the gaps may be blocked and a finishing cut taken over the shaft. All angles on the crank shaft should be filleted to ⅛ inch radius or more.

Fig. 8 is a detail of the flywheel. This is of cast iron and is to be turned all over, the inner surface of the rim being finished to a 15° angle for use as a cone clutch. The hub is bored taper and keyed. This wheel will weigh about 85 pounds finished and should be amply heavy to insure smooth and regular motion.

Figs. 9 and 10 show respectively the details of the upper and lower halves of the crank cases. These are intended to be cast of aluminum alloy containing about 25 per cent of zinc. They can also be made in cast-iron, where it is desired to reduce the cost, and could then be considerably thinner (about 3/16 to ¼ inch thick) and still have ample strength. In finishing the top half, the pads on which the cylinder is bolted are first planed and then the surfaces of both halves where they bolt together should be finished. The lugs may then be drilled and the two halves bolted together, after which the seats for the main bearing may be bored. Particular care should be exercised to make a tight job of the joint in the crank case. A thin asbestos gasket may be inserted if it is found necessary, but it is much preferable to obtain the desired result without the use of packing, relying only on the careful surfacing of the metal and the numerous bolts for drawing the parts together.

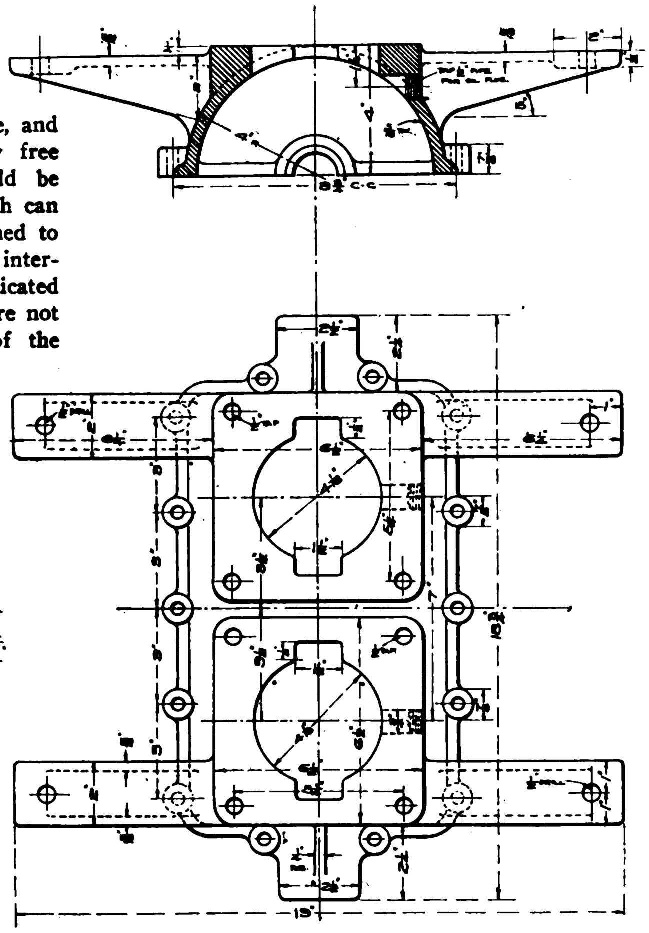

FIG. 9.—DETAIL OF UPPER HALF OF CRANK CASE.

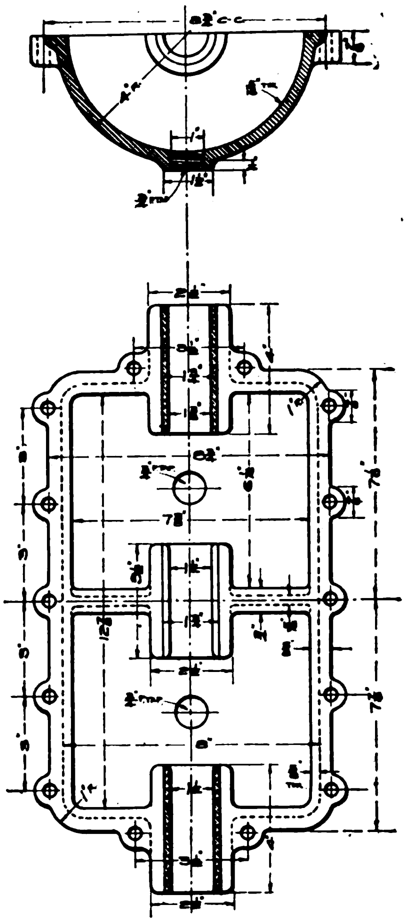

FIG. 10.—DETAIL OF LOWER HALF OF CRANK CASE.

The bearing bushings are to be of phosphor bronze 3/16 inch thick; the two outside bearings may have one-piece bushings, but the center bushing must be split, of course, one-half being pinned into each of the crank cases.

The ½-inch tapped holes in the top of the crank case can best be laid off from the cylinders when the parts are all in their proper positions. Two holes are tapped into the side of the top case for oil filling plugs. In making a pattern for the crank case the work will be much simplified if a complete pattern is made for the bottom half only. To this can be added, as change pieces, the pads and arms which differentiate it from the top half of the case. In this way castings for both top and bottom halves can be obtained with a minimum amount of pattern making.

Fig. 11 is a detail of the contact maker for use with jump spark ignition. A spark is required in each cylinder once at each revolution of the crank shaft, of course. The cranks, however, are at 180° and hence two contacts 180° apart are employed, one connected with the primary belonging to the first cylinder and the other to that belonging to the other cylinder. This is the method employed where a separate spark coil is used for each cylinder. The other way involves the use of a single coil and commutation of the high-tension current, which is not considered to be very practical. Fig. 11 shows the construction of the device, which consists of a cam on the crank shaft of the engine operating two small rollers attached to spring-steel blades which have a platinum contact riveted to about the middle of their length. The rollers are adjusted to just clear the circular portion of the cam, and once in each revolution the cam presses each of the contacts together and makes connection with the battery. The stationary contacts consist of a machine screw having a bit of platinum riveted or brazed into it.

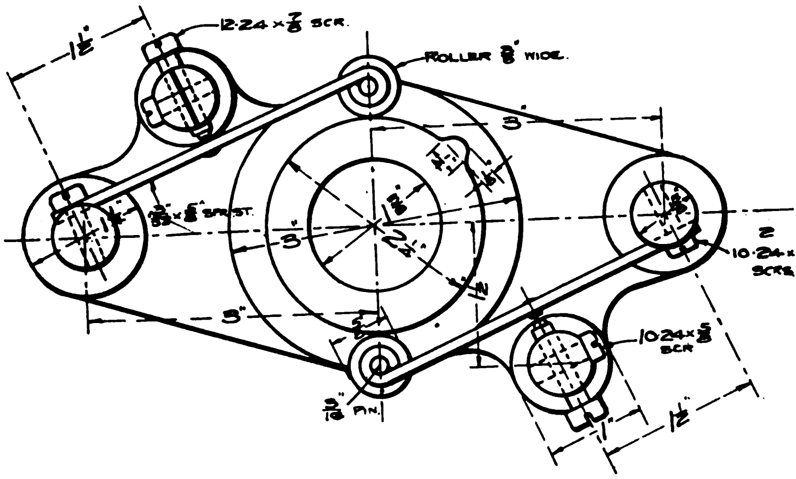

FIG. 11.—DETAIL OF CONTACT MAKER.

The plate upon which the contacts are mounted is bored for and centered upon the main bearing boss and may be rotated about the boss to change the point of ignition. This plate may be made of aluminum or brass and only the stationary contacts need to be insulated from it. That is to say, the spring blades are grounded on the frame of the engine, which is a necessary part of the scheme of connections.

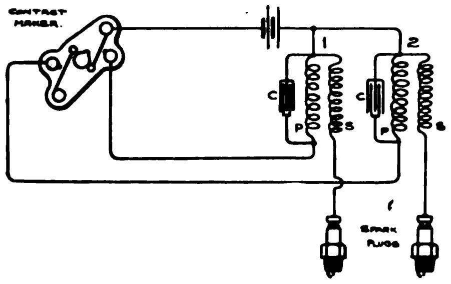

FIG. 12.—DIAGRAM OF IGNITER CONNECTIONS.

Fig. 12 is a diagram showing the connections between the contact maker, spark coils, battery and plugs. There will be five wires in all running to the engine, three to the contact maker and two to the spark plugs. The latter two should be very heavily insulated, as the sparking current is of very high voltage and most ordinary insulations allow a serious leakage of current. For the spark coils and plugs the builder will do well to purchase standard articles, as these details have been worked out by manufacturers only after much costly experimenting, so that the amateur will save both time and money in securing finished product.

In order to operate the motor on gasoline some form of float-feed carburettor is necessary which will give a constant and reliable mixture at all speeds. Here again the builder will do well to purchase an article of reputable make. A really good carburettor is quite a difficult proposition in itself.

◆

VALVE GEARS.

Effect of Connecting-rod Angularity.

BY C. C. MAJOR.

The function of the valve of a single-valve steam engine is to admit steam into one end of the cylinder behind the piston, to cut off the supply of steam at any desired point in the stroke so that the expansive force in the steam may be utilized; also to allow the exhaust steam to escape from the cylinder after it has given up its energy to the piston and to close the exhaust port in order that a certain volume of steam may be retained in the cylinder to form a cushion for the piston and other moving parts of the engine. Before taking up the description of the various styles of valve gears and valve diagrams, it is advisable to consider the effect of the angularity of the connecting-rod on the steam distribution. The harmful effect of this angularity increases as the length of the connecting-rod decreases and *vice versa.* Consequently, it is desirable to have the connecting-rod as long as is consistent with good design for other parts of the engine. Usual practice makes the connecting-rod from four to six times the length of the crank.

For every crank position there is a corresponding piston position and the distance the piston travels from either end of its stroke for any given angle through which the crank has turned may be computed mathematically or found approximately by a graphical method.

In Fig. 1, let *M-C-N-H-M* be the crank circle; *O-M,* the length of the crank, and *R,* the length of the connecting-rod which is taken four times the length of the crank. When the crank is at its dead-center *M,* the cross-head will be at *A,* the end of its travel farthest from the cylinder, and when the crank is at its opposite dead-center, *N,* the cross-head will be at *B,* its nearest point to the cylinder. Since the piston and cross-head travel together, the distance *A-B* may be considered the path of the piston instead of the cross-head, and the distance the piston travels will be reckoned from *A* and *B.* When the crank-pin has traveled from *N* to *C,* the crank has turned through an angle of 60° and the piston has moved from *B* to *L* on the forward stroke; and when the crank-pin is at *H,* its corresponding position on the return stroke, the piston will be at *K* and will have passed over the distance *A-K.* From the centers *K* and *L,* with the connecting-rod length *R* as a radius, draw the arcs *H-E* and *C-F.* Then $N\text{-}F = B\text{-}L$ and $M\text{-}E = A\text{-}K$.

To find *N-F* and *M-E* the following simple formulas may be employed:

$N\text{-}F = O\text{-}N - O\text{-}G + F\text{-}G$ and

$M\text{-}E = O\text{-}M - O\text{-}D - D\text{-}E;$

$O\text{-}D$ and $O\text{-}G = r \cos a,$

and since $D\text{-}E = F\text{-}G = x,$ then

$$N\text{-}F = r\ (1 - \cos a) + x \ldots\ldots\ldots\ldots(1)$$

$$ME = r\ (1 - \cos a) - x \ldots\ldots\ldots\ldots(2)$$

The length of the crank r for any given case is known, and $r \cos a$ can be readily obtained from tables for any rotation of the crank, and it is necessary to find the value of x before we can solve for *NF* and *ME.*

From *H* draw the perpendicular *H-D* out to the center line *M-N* and about the center *K,* to the radius *R,* draw the arc, *P-H,* cutting the crank circle at *P* and *H.* Then

$x : H\text{-}D :: H\text{-}D : 2R - x,$

and since $H\text{-}D = r \sin a,$ then

$x : r \sin a :: r \sin a : 2R - x;$

$x\ (2R - x) = r^2 \sin^2 a,$

hence, $x = R - \sqrt{R^2 - r^2 \sin^2 a}.$

Substituting this value of x in equations 1, and 2, we have for the travel of the piston

$$N\text{-}F = r\ (1 - \cos a) + R - \sqrt{R^2 - r^2 \sin^2 a} \ldots\ldots\ldots\ldots(3)$$

$$M\text{-}E = r(1 - \cos a) - R + \sqrt{R^2 - r^2 \sin^2 a} \ldots\ldots\ldots\ldots(4)$$

Applying these formulas to a given case where $r = 1$ foot, $R = 4$ feet, and the angle $a = 60°$, by substituting these values in equations (3) and (4):

$N\text{-}F = 7.0$ inches.

$M\text{-}E = 4.99$ or practically 5 inches.

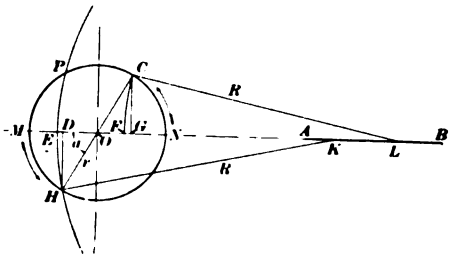

FIG. 1.

Formulas (3) and (4) are simple, yet they involve some knowledge of algebra and trigonometry and require a table of the functions of angles. Approximately the same results may be obtained by a graphical method as shown in Fig. 2. As in Fig. 1, *M-C-N-H-M* is the crank circle, *O-N*, the length of the crank, and *R*, the length of the connecting-rod, which is equal to four crank lengths; *A-B* is the travel of the cross-head and therefore of the piston. When the crank is passing the dead-center *N*, the piston will be at the head end of the cylinder as represented by *B*. For an angular rotation of the crank through 60°, the piston will travel to *L*, or 30 per cent. of its stroke. Then when the crank has turned through the equal angle *a*, from *M* to *H*, the piston will have traveled from *A* to *K*, or 20 per cent. of its stroke. With a 2-foot stroke as assumed in Fig. 1, these distances are 7.2 inches and 4.8 inches respectively. No attempt was made to make these figures tally with those obtained by computation, and they are only approximate. The larger the diagram, the more accurate will be the results obtained.

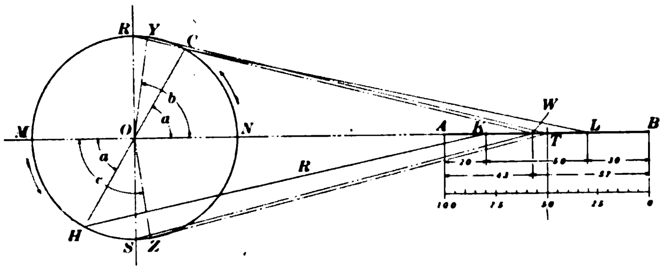

FIG. 2.

As the piston moves forward from *B* and reaches the position *T*, midway of its travel, the crank will pass through the angle *b* for the forward stroke and through the angle *c* on the return stroke. When the crank has turned through 90° from *N* to *R*, the piston has reached *W*, 57 per cent. of its stroke, and will therefore travel 43 per cent, the remaining portion of its travel, while the crank is turning through the second 90° from *R* to *M*.

The connecting-rod makes an angle with the horizontal at all times except when the crank is at the dead-centers, and it is evident from the above diagram that this angularity causes the piston to travel a greater distance from the head end than from the crank end of the cylinder for equal angles made by the crank after passing the dead-centers.

Unless counteracted by the design or setting of the valve, cut-off will occur later in the head end. Consequently steam pressure is exerted on the head end of the piston for a greater portion of the stroke than on the crank end, and therefore the rotative effect will be unequal, causing the angular velocity of the shaft and belt wheel to vary during each revolution. In most cases this variation would prove more objectionable than the effect of unequal steam distribution on the economy of operation of the engine. The method of counteracting the effect of the angularity of the connecting-rod will be discussed in a subsequent article.

BOILER ROOM PRACTICE.

BY W. T. EDWARDS.

It has been said that the first things a good engineer or fireman sees upon entering a boiler room are the gauge glass and the steam gauge. Certainly the first duty of a fireman upon taking charge of a boiler room is to ascertain whether or not the water is at the height in the boiler that is indicated by the gauge glass. This can be done by means of the gauge cocks, which should be kept clear and constantly used.

It is, of course, well known to experienced firemen and engineers that the water glass is prone to become clogged by scale and should therefore be blown out at intervals. It may not be quite so well known, however, that in blowing out the glass, the bottom connection should always be blown out first, with the upper valve opened and the two connections be allowed to blow clear together.

The safety valve should be tested at intervals to make sure it will lift from its seat easily. In order to avoid the labor of clambering over the top of the boiler or boilers, it is an excellent plan to run a stout cord (sash cord is a good kind) from the end of the safety valve lever, through pulleys to a point within easy reach from the firing floor. By means of this cord the valve may be tested without inconvenience once or twice a day, which is none too often.

Firing is not merely a trade; it involves an artfulness that is entirely incongruous with a fireman's surroundings and the amount of manual labor required. The handy man who may be able to "turn his hand" to anything with fair success will fail utterly when he tries to keep up steam on hard-worked boilers. Almost every fireman has his own pet method of firing, but the conditions under which the boilers are worked have a great deal to do with the thickness of the bed of fuel. The practice which seems to give the best results under average conditions is to keep the bed of coal perfectly flat and about 4 to 6 inches deep, firing lightly and spreading the coal evenly over the fire, and if the furnace has two doors, firing alternate sides. By using the scoop only part full of coal it will be found easier to place the coal just where it is wanted and with less danger of spilling it on the floor.

The practice of forcing a fire in order to get up steam in a short time can not be too strongly condemned. It subjects the boiler to strains for which it was never designed and that iron and steel will not stand. These strains shorten its life and induce leaks in seams and around flues. Sometimes, as a means of still further extracting a few stray heat units from the gases, they are returned to the rear of the boiler, where the flue is situated, over the boiler between it and the arch covering. This may be a means of a small saving but it should not be permitted, as it causes gases to come into contact with a part of the boiler shell that has not a direct water backing. This practice is prohibited by boiler insurance companies for the reason stated.

The fact that boilers expand when heated is of course well known; consequently every one who has a boiler to set provides means for the boiler to expand easily by placing rollers between the rear lugs and the bearing plates under them. This is very good, but in nine cases out of ten the boiler will be bricked in so tight that it can not possibly move without distorting the setting; such practice seems to be the height of absurdity. A good plan is to have a Z-bar riveted to the side of the boiler about level with, and parallel to, the top row of tubes, and the side walls carried up and racked over until the inside face of the wall is quite up to the Z-bar. The courses of brick are so spaced that a joint comes fair with the top of the Z-bar; then two or three courses are laid so as to come within about two inches of the boiler shell. The boiler should be set so that it hangs free and clear, and it is to be preferred that it be supported independent of the brick setting, but if that can not be done conveniently the rear lugs which bear on the rollers should have enough space to permit them to move without coming in contact with any brick work.

The back arch has been a source of trouble when turned against the rear head; this can be overcome by riveting to the rear head an angle one leg of which will extend over one side of a cast-iron V-shaped skew back that extends from one side wall to the other and forms a header for the back arch to head against. The Z-bars on the sides and the angle on the rear head form an almost gas tight joint and yet allow freedom of movement for the boiler. It should be said that the Z-bars and the angle should preferably be of cast iron as the gases have a very bad effect on wrought iron and soft steel.

The boiler may be covered with a layer of sand about two or three inches thick, and a sectional covering substituted for the usual brick arch. This covering can be made after the method of making slab floor of concrete and expanded metal. The expanded metal is cut into sections long enough to reach from the side walls to the center of the boiler on top, the sections of course conforming to the shape of the boiler, and they should be fairly narrow as the completed sections will be pretty heavy. The expanded metal should then be laid over the entire boiler, fitting around the dome and manhole, the top connection to the water column, and any other pipes that may be there. Then these sections of expanded metal are covered as a whole with a plaster made of magnesia, asbestos and clay, to a thickness of about three inches, fitting up to within about one inch around the dome and the same distance clear of the manhole. The plaster should be well worked into the openings of the expanded metal, as it is necessary to incorporate the metal with the plaster in order that the sections be of the required strength to hold together. While the plaster is still soft it can be separated along the lines of separation of the metal and then allowed to harden, these joints afterward being filled with the same plaster. The space around the dome can be filled with sand up to the top of the covering.

The advantages claimed for this way of covering in a boiler are, that it is easy to remove and replace in the event of the boiler being inspected, the sections being in such condition as to be ready to replace after inspection is completed, and that it does not require the services of a bricklayer to remove or replace. The ease with which it can be removed and replaced makes it more likely that the inspection of the boiler will be more frequently done and more thoroughly attended to. The function of the sand is to fill in all interstices about the boiler setting where it comes against the boiler and is of a sufficiently yielding nature to permit the boiler to move under the influence of temperature changes.

The grate does not as a rule receive the necessary attention and study to get the best results. Grate bars usually fail by twisting and warping from the unequal effects of the fire, thus causing one to rise above or sink below the others; the depressions so formed fill with ashes, and the elevations serve to collect clinker, the draft being thereby choked and fuel wasted. This unevenness is moreover a source of trouble when cleaning the fire, making this operation difficult if not almost impossible. Thin bars are conceded to be the best, but they are also the most liable to failure because of their thinness, therefore some provision must be made to keep them in proper position. This is usually accomplished by means of projections from the sides of the bars called "snugs," which are of proper size to keep the bars the right distance apart. The bars are generally cast in pairs so that the two bars with their proper spacings form one piece. There is, however, the disadvantage in having the bars cast in pairs that one bar may be in perfect condition but must be discarded because its mate has become deformed. The bars should be from ⅝-in. to ¾-in. broad on top and diminish to about one-half that thickness at the bottom to allow free escape for the ashes and thereby prevent clogging and shutting off the supply of air. The entire area between the bars should equal from 35 to 50 per cent of the grate area. The grate area should be ample, as it is much easier to reduce, by bricking in, than it is to enlarge the area. If the distance from the fire doors to the bridge wall can be kept down to 6 feet, so much the better, as it will be easier to throw coal to the back of the grate. The height of the boiler above the grate should not be less than two feet; more is better, and some consider as much as four feet to be desirable. The ash pit should be at least two feet deep below the grate and is sometimes made water tight, in order to hold water which is supposed to prevent clinkers forming.

It can not be too strongly urged that the water be supplied to the boiler by two ways; these are usually a pump and an injector. This is a precaution against disaster by an accident to one or the other. The method of introducing the feed water into the boiler that seems to find favor with most engineers is the one where the feed pipe enters the front head about level with the top row of tubes and passes to within 12 or 15 inches of the rear and, turning, follows the side of the boiler to the bottom, where it ends in a tee; by this arrangement the water, having to pass through the length of pipe in the boiler, is heated almost to the temperature of the water that is already in the boiler, and it is discharged into contact with the boiler at about the coolest part. In addition the feed pipe being located in front of the boiler, it is more accessible in case of accident to it, than it would be if located at any other place. It should be equipped with a check and globe valve, of course.

Every one who has to do with boilers knows that scale is one of the worst enemies to be met, but few realize the benefit derived from clean boilers. Experiments have been made to prove that scale is not detrimental to the steaming efficiency of the boiler, but the experiments were conducted under conditions so entirely different from those existing in a boiler when working under pressure that the results do not prove anything that could be taken as conclusive. The various experiments made to prove that scale is detrimental furnished results so nearly uniform that it is easy to believe them. These results show that about 1/16 inch of scale requires that about 15 per cent more fuel be burned to do the work than if the boilers were perfectly clean. The percentage of extra fuel increases as the thickness of scale increases. Experience proves that in some railroad works locomotives having been run some months require to have the load cut down and if run without cleaning for a short time longer are apt to "lay down" on the road. A continued use results in retubing the boiler; this course occupies less than one year's time, and is due solely to poor water and the resulting scale. Scale also causes bagging of the boiler shell; the scale prevents the water coming in contact with the iron and allows it to become heated to a dangerous point.

The boiler is not the best place in which to precipitate the matter held in solution in the water, and expensive water softening systems are not available for every plant. There is one apparatus, however, that has proved very efficient, and not very expensive, for the purpose of preventing the collection of sediment, and formation of scale in the boiler. This apparatus consists of a skimmer or funnel located inside the boiler, pretty well toward the rear and facing the front; it is placed so that the mouth extends partly above the water level. In the boiler there is continual boiling up of steam which keeps all the sediment for a time near the surface of the water; within the funnel or skimmer there is comparatively quiet water, and the scum or solid impurities collect there and sink to the bottom or neck of the funnel and from there are carried into a settling tank situated either behind or to one side of the boiler, through a pipe that enters the settling tank near the top and continues down nearly to the bottom. The water passing through this pipe does so at a comparatively high velocity which serves to carry the sediment from the boiler to the tank. The tank being very large in comparison to the pipe, the water while in it has little or no velocity, thus giving the sediment a chance to settle; when the water rises to a certain point in the tank where a return pipe is situated it returns into the boiler. The tank is equipped with a blow-off, through which the collected sediment may be blown out every day.

Kerosene is used to prevent scale, and, when used in small quantities, is highly recommended. It is usually introduced before filling the boiler with water, and as the water rises in the boiler it carries the oil with it, thus coating every part of the interior of the boiler with a thin film of oil. This prevents the new scale adhering to the metal, and gets under the old scale, loosening it and separating it from the boiler. About two quarts of oil per week for a boiler 48 inches in diameter by 12 feet long and about three quarts for one 60 inches in diameter gives the best results. Many of the boiler compounds or scale solvents sold are of a harmful nature, and the secret compounds should be avoided most carefully, as they generally consist of caustic soda or lime. It is usually lime, which is colored up in order to conceal its presence. Sometimes these compounds are adulterated with useless and harmful matter that should never be put into a boiler.

When it becomes necessary to clean a boiler it should be thoroughly cooled before anything is done. This may be accomplished by opening the fire doors and dampers, and keeping the flue doors closed; this arrangement permits a current of air to pass through the hot furnace, hot tubes and so on out through the stack. The air by coming in contact with the hot furnace and setting is fairly well heated by the time it reaches the tubes, as may be seen, the furnace and setting gradually giving up the heat that remains in them to the air become cooler, and the air is fairly warm by the time it reaches the tubes and the danger of the tubes being cooled down too quickly is avoided, as the setting and boiler cool down together. If the flue doors only are opened, the air will pass directly to the stack without having passed through the furnace or boilers.

When replacing manhole or handhole plates it is well to scrape the boiler at the place where the gasket bears; there may be some particles of the old gasket still adhering to the boiler shell and they will cause trouble by preventing the new gasket from seating itself, thus causing leaks. Before the new gasket is placed for the last time it should have a good coat of graphite;

this will prevent it sticking to the metal. Also, if the nuts are put on with graphite it will be found much easier to remove them, and the chances of twisting off a stud will be lessened.

◆

TELEPHONE CABLE DEPARTMENT ACCESSORIES.

BY CHAS. H. COAR.

Before entering into a description of the articles herein illustrated, it may be well to inform the reader that the efficiency of each article has been proven by actual usage.

The practical cable splicer knows how awkward it is to boil out a splice, especially aerial splices, when he has to hold his paraffine kettle in one hand and use the ladle with the other. The drip pan shown in Fig. 1 is so designed that it eliminates many of the difficulties attending the boiling out process. The pan, which should be made of galvanized sheet iron, is of somewhat similar shape to the rain gutters one sees on houses. A pan of the dimensions specified in the sketch is convenient, although the size could be altered to suit local requirements. The end pieces, *a*, are cut out in such manner that the pan may partly enclose the cable. The outlet, *c*, allows the drippings to flow from the pan. By placing a paper in the pan to prevent sticking, it will be useful also in catching the dropping solder while the joint is being wiped.

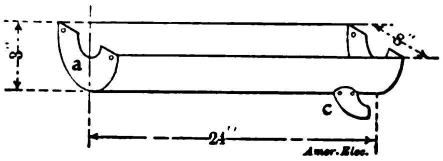

FIG. 1.—DRIP PAN.

In most boards for making cable forms an arrangement of pegs or nails is used to terminate the different wires. A board which has some advantages over this method is shown in Fig. 2. Instead of using pegs, holes are bored through the board. After the different wires are threaded through the holes, the form may be laced more readily than it could be with the arrangement of pegs, which would be in the way. By turning the board over, after the form is laced, the insulation may be peeled from the wires to a scale without altering the shape of the form. The size of the board would depend upon the form to be made on it, of course.

Fig. 3 represents a box for holding tags preparatory to marking the different wires of a cable, which presents some advantages over the old methods of stringing the tags together or hanging them on hooks which are fixed in a marked board. Tags strung together become twisted or mixed, and it takes but a small gust of wind to raise the tags from hooks.

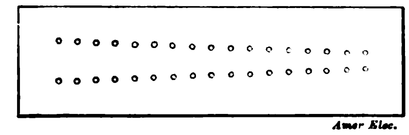

FIG. 2.—CABLE FORM BOARD.

The box here shown is constructed to hold a round tag, but the shape of the tag would not alter the box to any great extent. The backs of the two halves of the box, which are made of one-inch lumber, have grooves cut in them to a depth of half an inch, both lengthwise and crosswise, in such a manner that squares are formed as shown in Fig. 3. The grooves, *a*, running crosswise, are cut at an angle of 60 degrees with the surface of the board; in this way the inserted tags have a slant given them which enables one to readily pick them out. The grooves running lengthwise are cut perpendicular to the board surface and fitted with thin strips which divide the squares from one another. The squares may then be numbered as shown in the sketch, which represents a box having a capacity for 100 tags. The sides of the box are built of 1/4-inch lumber, which should be of such width as to form ledges at least 1/4 inch above the faces of the back boards. The two parts are hinged together so that they may be closed and prevent the loss of tags during transportation.

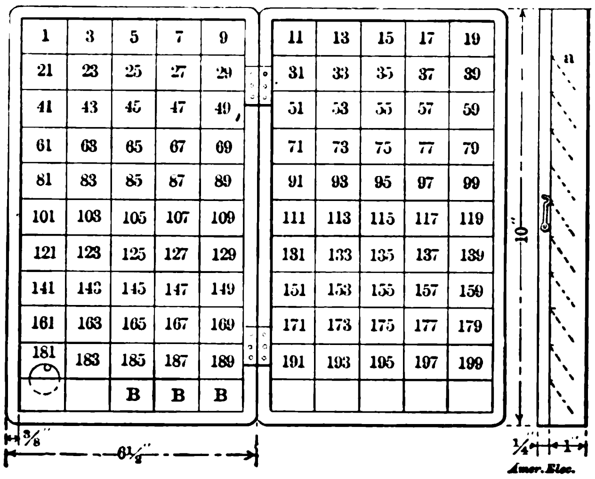

FIG. 3.—TAG BOX.

Some of the good features of this box are: (1) The tags are inserted at least half an inch in the slots, so that they are held firmly and protected at the same time; (2) as the box is numbered in rows of tens, one may easily locate the different numbers; (3) in case an error is made in picking out a number, it will be detected by the absence of a tag number; (4) all the tags are in sight.

A cableman's telephone circuit is shown in Fig. 4, in which *a* and *c* are five-point jacks; *b* and *d* are three-point jacks; *e* is a two-wire metallic-circuit plug connected to a head receiver; *f* is a two-wire metallic plug with flexible conducting cords which have snaps suitable for connecting the plug to telephone circuits handily; *G* is a bridging generator, and *B* is a 1000-ohm ringer. The plugs, *e* and *f*, are adapted to fit any one of the four jacks.

The operation of the set is as follows: By putting plug *e* in jack *a* and plug *f* in jack *b*, the set can be used to talk over either the magneto or central energy systems; but as the condenser is in series with the secondary coil one would not be able to raise the exchange in central energy systems with this arrangement of plugs. This would allow one to use a circuit in such systems without the knowledge of the subscriber or line operator.

By placing plug *e* in jack *b* and plug *f* in jack *c*, with the snaps on the wires of a line, one could call central and converse, using the line battery in a central energy system. It will be seen by tracing the circuits with this arrangement of plugs, that the receiver and transmitter are in series with each other across the line the set is being used on, and as the condenser is cut out, so to speak, one would be able to actuate the signals in central energy systems. This arrangement is also provided in order that the local batteries in the set may not be used when it is possible to use line battery for talking. By putting plug *f* in jack *d*, one could use the generator to call or a ring could be received. As the condenser is in series with the ringer, it could be bridged on a line in case one wished to receive a call, or it could be used to find ringing current upon any wire in this manner. The condenser prevents the ringer from short-circuiting direct-current circuits. The apparatus could be mounted in a convenient case in which a compartment could be provided for storing the head receiver and plugs. The case should be provided with a hinged door in order that the batteries may be readily changed. The transmitter might be set in a wall of the box with its mouthpiece flush with the outside of the case, like that of the old Blake transmitter.

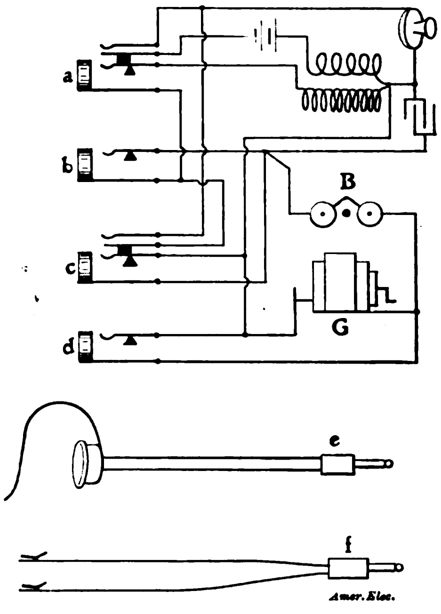

FIG. 4.—CABLEMAN'S TELEPHONE CIRCUIT.

Fig. 5 illustrates a method for testing out conductors in a cable which is applicable to both live and dead lines. The apparatus consists of a three-point jack, *g*, a five-point jack, *h*, a condenser, *k*, a singly-wound induction coil, *i*, with a vibrator, and the conducting cords terminating in a metallic plug, *j*. A common buzzer may be substituted for the induction coil, as the same effect could be produced with it. A local circuit, *L*, having a telephone at each end, is used to converse and receive the testing signals. The pair of wires to be tested is indicated by *T*. By placing the plug *j* in the jack *h* the vibrator is set in motion, which causes a pulsating current to flow in the battery circuit and charges the condenser, *k*, which discharges to ground over the conducting cords.

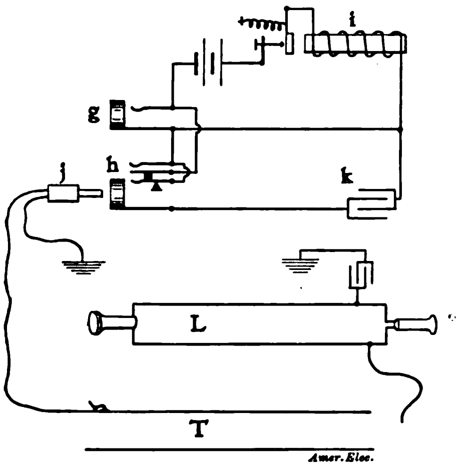

FIG. 5.—DIAGRAM OF CONNECTIONS FOR TESTING CABLE CONDUCTORS.

The operation is as follows: One conducting cord is grounded, and the remaining one is connected to the wire to be tested. The parties doing the testing are connected by the two telephones in the circuit *L*, one of which is grounded through a condenser, as shown. When contact is made with the line wire to which the conducting cord is connected, it causes the condenser discharges to flow through both telephones in multiple to reach ground. The parties doing the testing hear the clicking at the same time, so no delay is caused in changing from wire to wire in testing. While the set is connected to a cable just enough inductive reactance, due to the buzzer, will distribute itself throughout the cable to enable the man at the opposite end from the buzzer to tell when it is working. After one has become practically familiar with this method he can tell open or grounded wires by the sound received in the telephone. One may use this arrangement on lines having battery on them, as the condensers prevent grounding or short-circuiting. The set can be used to test fuses and for short-circuits by placing the plug in the jack *g*, which puts the batteries, buzzer and conducting cords in series.

By reference to Figs. 4 and 5, it will be noticed that the rest or under contacts of the jack springs are not used. The sets are usually subjected to hard usage, which would soon cause such connections to become faulty.

The writer is indebted to Mr. H. E. Thompson, who is the designer of the drip pan, form board and tag box, for information he has kindly given concerning them.

NOTES ON CONDUIT WORK.

BY ARTHUR B. WEEKS.

In conduit wiring, conduit boxes, such as the one shown by Fig. 1, are ordinarily used for receptacles, electroliers, or side wall brackets, fixture studs (Fig. 2) being used for brackets and electroliers. For switch boxes and drop lights on lamp cord, fixture studs are not used. When a fixture stud is to be used, it is usually fastened in the box by means of stove bolts, through the four small holes shown in Fig. 1; the nuts are put at the back of the box. Sometimes two bolts only are used. If the box is mounted on wood, stove bolts are not required, because screws answer the double purpose of securing the stud to the box and the box to the wood. When the box is mounted on brick walls, the wall is plugged, and the stud, if used, is not screwed into place; instead, large spikes are driven through at least two of its holes.

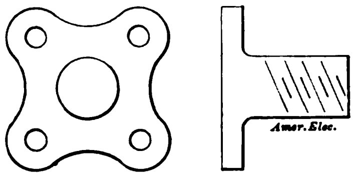

FIG. 2.

From ceiling outlets, fixture plugs must of course be used for fixtures. If the ceiling outlet box is to be also used for gas, the gas outlet is usually brought down through the center hole and the conduit enters any of the others, as is most convenient. When gas and electric light are to be used with the same fixture, an insulating joint must be used at the end of the short gas pipe which protrudes through the outlet box. Until the fixtures are ready to be installed, a cap is kept over this gas outlet.

Before putting up any boxes whatever, the exact location of all lamps must be known, the number of lamps, switches, and location of cabinets. The wireman is not bothered with these details, since they are previously marked out on the blue prints for him by the man who lays out the work. A red cross is made where outlets are to be put in, and an "S" marks the switches. Switches are easily accessible at 4 ft. 3 ins. from the floor. The right height for side wall brackets is about 6 ft. 2 ins. Lower than that, a bracket lamp does not give out much light, and is frequently in the way, causing the breaking off of the lamp socket stem. When the boxes are in place, the conduit must connect from box to box.

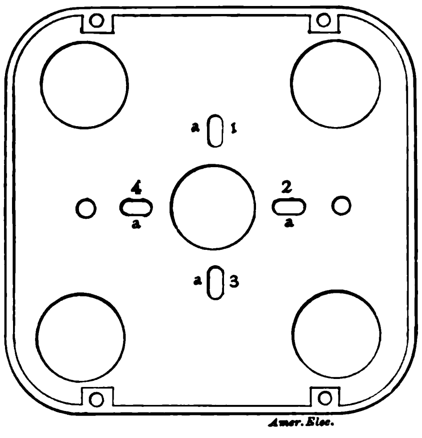

FIG. 1.

For drop cords from ceiling boxes, standard rosettes are used, to which the cords are attached. Fig. 3 shows a switch outlet box fastened to a piece of $\frac{7}{8}$-in. flooring lumber and located between adjacent studs of a wall at a convenient point near the entrance. The piece of flooring is nailed to the studding. In this illustration, it will be observed that the box cover has a rectangular opening, and that its longest measurement is vertical. This must be remembered when putting this box up for a switch, for the reason that the cover will fit only in one way. The conduit entering on the left at the bottom comes directly from the cabinet, or from another outlet. The pipe at the top in this particular case goes to a ceiling chandelier, and the switch in this box controls the lights in the chandelier. In some cases this upper pipe can make a direct run to the ceiling outlet, but again it may be necessary to go up through the floor, over, and down to the box. It is often found that conduit may be run between the joists and be fastened to the bridging by means of pipe cleats. The lower right hand conduit goes to a base-board receptacle on the farther side of the room, to be used for a portable desk light.

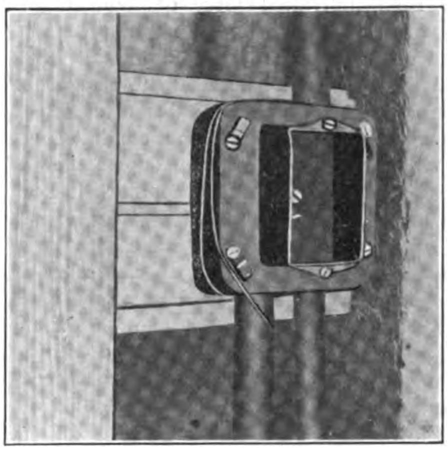

FIG. 3.

Where a rough flooring is used which is to be "furred," the conduit can be run on the floor. This is very convenient for construction work. The conduit should, however, be bent and so placed when meeting the floor line that it will not in any way interfere with the proper laying of the base-board and second or finishing floor.

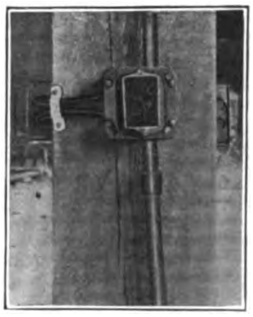

FIG. 4.

Fig. 4 shows a method of connecting outlet boxes on 10-in. posts for office use, for Zimdars & Hunt plug receptacles. Desks in the vicinity may be lighted by means of desk lamps in preference to the drop lights, if desired. Six feet above the floor is a box for a fan receptacle. The conduit comes directly from a cabinet and extends on up to the office floor above, to five outlet boxes like the one shown in this illustration. Conduit could not be used from box to box on the post, hence circular loom or alphaduct was used, fastened to the post by means of pipe cleats. The wire was pulled in each individual piece of loom before placing the final casing about the posts. In order to run vertical conduit in this manner, it is sometimes necessary to change the headers, as it is not advisable to cut them away. It is often best to run conduit down to the floor below and come up to the desired location, rather than approach it from above.

Figs. 5 and 6 show views taken in a large apartment block. In this special case, all partitions were made with 2 x 4's. It is necessary to know considerable about building construction in order to do wiring intelligently to any extent, especially conduit work. Horizontal 2 x 4's are laid directly on the floor, and the uprights placed upon them; horizontal 2 x 4's also extend across the upper ends of the uprights, along the ceiling. The conduit starts from the hall cabinet shown in the rough in Fig. 5. There are three distributing circuits from this cabinet, the feeder entering from the left. All pipes are kept between the studding and the bends at the baseboard are so made as to be concealed when the flooring and baseboard are completed. The first pipe on the left in Fig. 6 carries the feeder to the outlet box on the left; one branch is run on the rough floor to the opposite side of the room and up between the studding for a side bracket in an adjoining room. The other branch leads horizontally over to another outlet box, as shown. From this box, the conduit is continued down to the floor, crossing a vertical 2 x 4 which has been previously notched to receive it, as shown, and terminates at a baseboard receptacle in the next room at the right. The cover of this box must be flush with the strip of wood which runs above it, technically termed a "ground." From this point, conduit is run along the floor and up to a side bracket, shown in the background of Fig. 6. It will be observed that in running the conduit from the left-hand box to that at the right in the foreground, the studding is cut to receive the conduit. One or two nails, set at an angle so as to lap the pipe, secure it properly.

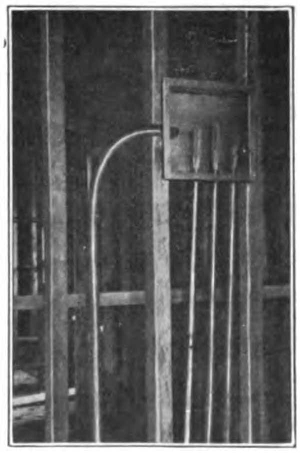

FIG. 5.

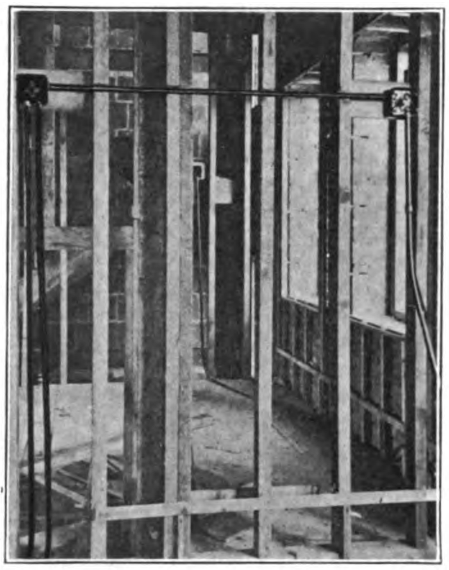

FIG. 6.

In all cases one must use ingenuity in conduit wiring to save as much pipe as possible. An unnecessary quantity can be heedlessly used by not carefully and intelligently mapping out the course of the circuits beforehand. Often expensive changes are made after the work has gotten well under way, when someone discovers a better method, or desires an outlet changed, etc. Changes in the original plan of wiring may sometimes be made necessary by alterations in the plasterers' plans; or a partition for a lavatory may be changed, or one put in so as not to include a light that was orginally included. This condition of things can be avoided by having the work under the charge of one man responsible for the whole. Changes made in this way lead to bad results, where the electric contractor is not informed of them in advance. If the building is being wired for conduit, it is of course desirable to finish all plastered work in this manner. Moulding on plastered ceilings is not very artistic, but is often made necessary, owing to a lack of foresight during wiring construction. Consulting the gas-fitter and carpenter will also save many changes to both parties. If this is not done, the electrician is liable to be compelled to change his plans at considerable expense.

Outlet boxes are sometimes placed back to back on the same board in adjoining rooms. The plugs are of course knocked out beforehand, in order that connections may be made from one to another. Sometimes a brick wall has to be cut to admit the box, and has also to be cut for the conduit, up or down as the case may require. This is not necessary when the walls are sufficiently furred, as shown in Fig. 7. The boxes are first fastened in place to plugs in the wall, and the "furring" strips are marked and cut to allow the conduit to be connected to the boxes. Lock-nuts are always required on the pipes next to the box on the outside. Insulating bushings to protect the wires on pulling in are used inside the box, over the ends of the pipes which enter the outlet boxes, for a distance of about ½ inch. Burrs are cut off the ends of all pipes by means of a reamer used in a carpenter's brace.

The first thing to be done on beginning a new contract is to erect a bench of some sort, with a pipe vise, locating the conduit bender either on the floor or on some convenient post. An improvised conduit bender can be made by screwing a 1¼-in. tee on the end of a 4-ft. piece of pipe, and fastening this pipe in the vise; almost any desired angle may be obtained. It is frequently necessary to do more or less cutting of joists in order to bring an outlet box into the right position. Accuracy in locating the outlet boxes is necessary, and in the rough work of construction this point may be overlooked. When the walls are finished and plastered, boxes located unsystematically or out of line give a very bad appearance.

To locate the ceiling fixture outlet for a room containing only one, strike a diagonal between corners both ways. The intersection will be the center for the fixture. Drill the hole, locate the outlet box, and run the conduit accordingly. If there is a "bay" in the room, it will look best not to attempt to center the fixture with relation to it.

If from the nature of the construction, the conduit is not to approach the outlet box from the floor above, but is to be reached on the same floor, a plumb bob is needed. Drop this so that the bob comes over the marked spot. Locate the place on the ceiling and secure the outlet box in the most convenient manner.

It is of course necessary to first locate the risers. These may often be best run in conduit whether the other circuits are to be run in conduit or not. If the building construction will permit, the risers can be run so as to be entirely out of the way of everything. Should the building be of iron frame construction, the conduit feeders can be run to best advantage before any wood work is done, especially should the flooring consist of 2 x 6's placed on edge. The same holds true in regard to concrete flooring. Concrete, by the way, is a hard material to

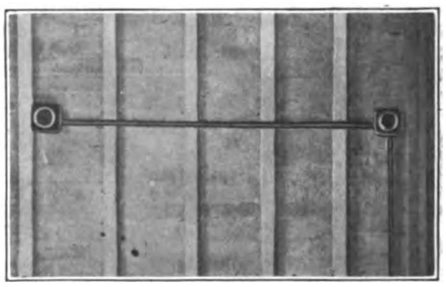

FIG. 7.

get through conveniently, to say nothing of the expense of tearing out and patching up again.

No specific rules can be laid out for all work. The accustomed plan to be followed for new work is as follows: Locate risers and cabinets first. Run to them with wire of sufficient capacity to allow for a certain drop, as previously arranged for. This will depend upon the conditions of service. If there are offices to be lighted, a small drop must be allowed, for a good light is needed for this purpose. If only mill work is to be planned for, a greater drop can be allowed. If the building is so laid out that one feeder must provide light for offices and mill combined, the wiring should be such that the offices will be first provided for.

Having located the outlets in the various rooms, start as many men to putting up boxes as can properly be provided for. Next put men at work putting in conduit. Cutting and drilling may be a part of their work also. Where bends in conduit are at right angles, the work is quite simple; but if they are to be made at different angles, the work will not progress so rapidly. When everything is well under way, the force may be conveniently increased if desired; they can then work to better advantage; before this, men would be in each other's way, and find little to do.

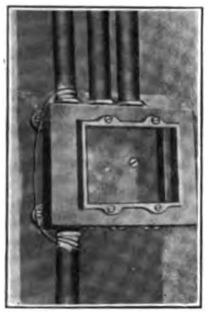

FIG. 8.

As soon as possible, pull in the feeders and risers. Run the feeders along joists in open work where necessary, to approach the conduit, using porcelain cleats even for very large wire. They are neater, and secure a better hold than tying to knobs. When the outlet boxes are all in place, put wooden plugs in the open ends of the conduits at cabinets, and stuff paper into outlet boxes to keep out plaster, etc. The covers must be put on before the plastering is done, with certain popular outlet boxes. It must be previously understood whether drop cords or fixture outlets are to be installed, and the box adapted to the class of work installed.

Provision is not always made for the location of the electric work; indeed, large buildings are often constructed without giving the matter any consideration whatever. Much valuable time is saved, however, by allowing places for electric mains and feeders. If baseboard receptacles are to be used, ascertain the location of the heaters, for they are liable to be placed directly in front of most of them. If receptacles are placed under the window frames, the cords would possibly have to drop down over hot coils of pipe, or be drawn up tight against them if pulled in back of them. Beware also of sliding doors which may cut off access also to baseboard receptacles.

All conduit should be perfectly grounded with bare copper wire before inspection. To do this, scrape the enamel off the pipe an inch back of the lock nut, on each pipe that enters an outlet box, and tie the bare wire, No. 16 or No. 14, secured around each pipe, as indicated in Fig. 8. Fig. 9 shows manner of approaching a cabinet from below. The center pipe is for the feeder, which continues up to the next floor to another cabinet. The cabinet on this floor is located in the clear space between the pipes. Part of the circuits are thus run from above and part from below.

Draw in the wire for the conduit when all plastering and other mechanical work is finished. If necessary, blow soapstone into the conduit first. A "snake" is then run through from one outlet to the next, and so on, leaving a loop as the work progresses. If there are several short bends, one will be unable to pull far, but must fish separately from box to box. The method commonly used in fishing the wire is to start at the cabinet and run in the "snake," after having bent the end into a loop with a pair of pliers if there is none on the end to be run in. (In cold weather the steel snake may snap in bending, unless the precaution is first taken to warm it slightly.) Insert this bent end into the conduit. It may meet with obstruction, but keep at it, and by examining the outlet boxes, its location will soon be found. Sometimes a change has been made in the work, but not on the blue print; as a result, the snake will not come out where it is expected. However, by examining the box to see how many pipes are connected thereto, some idea may be gained as to the change made, and where the wire should appear. Push the snake until it appears at the outlet, and fasten the wires to the other end of the snake. To do this, remove three or four inches of insulation, and secure the wire through a long flat loop at the end of the snake; tape the connection. Then pull the wire into the pipe and so continue, leaving loops as before. Use soapstone freely on the wire, to assist its going through the pipe.

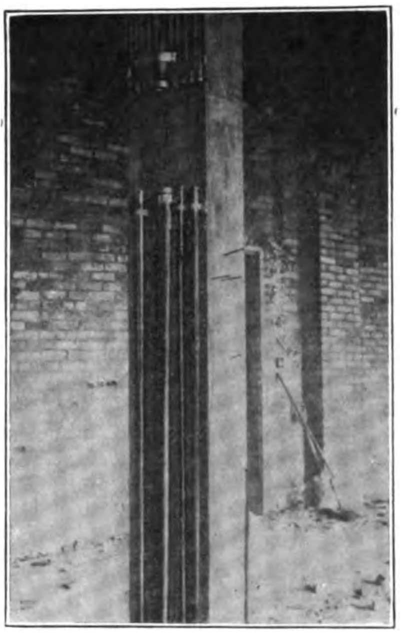

FIG. 9.

Lessons in Practical Electricity

REACTANCE. — IMPEDANCE. — ANGLE OF LAG. —PHASE DIFFERENCE.

In the December (1903) Lesson it was explained that when a current is first set up in a conductor, there occurs "self-induction" due to the "cutting" of lines of force by the conductor itself as the lines expand from the center outward; also that when the current ceases there again occurs self-induction, this time due to the collapsing of the lines of force set up by the current and therefore producing an impulse of e.m.f. of contrary sign to the impulse first produced. When a conductor is traversed by an alternating current, this phenomenon of self-induction is continuous instead of momentary, for the reason that the lines of force surrounding the conductor are constantly expanding and collapsing, under the influence of the constantly varying current. As the current rises in the positive direction, let us say, the magnetism increases in, say, the clockwise direction about the conductor; after the current passes maximum and begins to decrease, the lines of force commence to collapse, reaching zero value when the current reaches zero; then when the current rises in the negative direction, the magnetic lines expand in the counter-clockwise direction, and so on. The result is that the e.m.f. of self-induction, instead of being momentary, as when current is sent through a conductor or taken off, is always there, but varies in value like the applied e.m.f. and the current. It does not rise and fall in unison with either the applied e.m.f. or the current, however, but lags behind the current exactly a quarter of a cycle. The reason for this lagging will be apparent upon consideration of Fig. 1, where the two sine curves represent the rising and falling values of the current and the e.m.f. of self-induction or reactive e.m.f. The value of an induced e.m.f. is proportional to the rapidity with which lines of force are "cut" by the conductor, and as the lines of force vary most rapidly when passing the zero point (changing from positive to negative, or *vice versa*) the induced e.m.f. is maximum at that moment. When the current, and therefore the magnetism, is at the maximum value in either direction, its strength varies very little within a given momentary period of time, and consequently the induced e.m.f. is minimum at the moment the current and magnetism are at maximum; minimum is, of course, zero in this case.

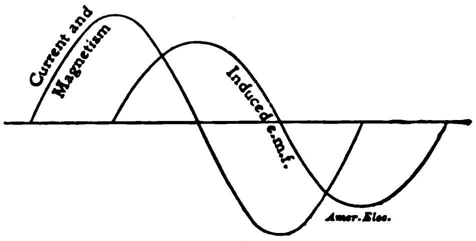

FIG. 1.

The relation between the rise and fall of the applied e.m.f. and that of the reactive e.m.f. of a circuit depends upon the relative values of the two, and also upon the resistance of the circuit. The value of the reactive e.m.f. depends upon the frequency of the current, since this determines the rapidity of cutting the magnetic lines of force, and also upon the strength of the current, since this determines the number of lines of force set up. The formula for reactive e.m.f. is

$$E_x = 2\pi f L I \ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which f = the frequency in cycles per second,

L = the inductance of the circuit (see December Lesson),

I = the current in amperes (effective, not maximum).

The quantity $2\pi f L$ is termed *reactance*, the symbol for which is X; in formula shape, $2\pi f L = X$. It will be evident from the mathematical relation between inductance and reactance that the former, which is a property of the circuit, is independent of the frequency, while the latter varies directly with the frequency. A circuit may have inductance without being active, but it has reactance only when an alternating current passes through it.

Reactance is expressed in ohms, like resistance, because it constitutes an opposition to the passage of the current. Unlike resistance, however, this opposition does not entail any loss of energy because it is due to counter pressure and is not a property analogous to friction. Its effect in practice is to make it necessary to apply a higher e.m.f. to a circuit in order to pass a given current through it than would be necessary if only the resistance of the circuit opposed the current. The combined effect of reactance and resistance is termed "impedance" and is always represented in this country by the symbol Z or z. The impedance of an alternating-current circuit is

$$Z = \sqrt{R^2 + X^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

This will be recognized by students in geometry as the equation of a right-angle triangle, if Z be assumed to represent the hypothenuse and R and X the other two sides. This is merely a mathematical coincidence, however, resulting from the use of the sine curve as the basis of alternating-current calculations. It is the custom to represent the relations between resistance, reactance and impedance by a right-angle triangle for convenience in getting at other values; Fig. 2 shows the conventional diagram.

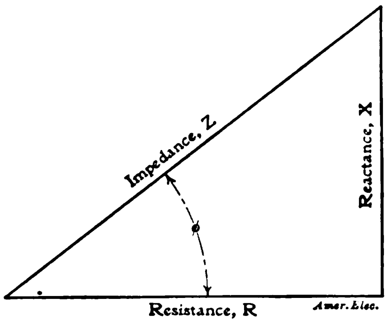

FIG. 2.

Since the impedance of a circuit is its total opposition to the passage of a current, the relation between the applied e.m.f. and the current in the circuit may be expressed by the formula

$$I = \frac{E}{Z} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

The similarity between this and Ohm's formula will be apparent.

For convenience in computation, it is assumed that in inductive alternating-current circuits there are several distinct e.m.fs., the resultant of which is the applied e.m.f. It has just been explained that there is a reactive e.m.f. produced by the self-induction of the circuit; to overcome this and allow the current to pass, a component of the applied e.m.f is used up which is equal to the reactive e.m.f. and in direct opposition to it, of course. It may be represented by V_x. Another component is required to overcome the resistance of the circuit, and is equal to IR, the drop due to resistance, it may be conveniently represented by V_r. The relations between applied e.m.f., reactive drop in volts and resistance drop in volts may be shown by means of a triangle, exactly as in the preceding case, the only difference in the values being that all three of the former values have been multiplied by the current, so that the relations are unchanged. Fig. 3 shows the triangle of voltages; since $V_x = E_x$ and $V_r = E_r$, the formula may be written either

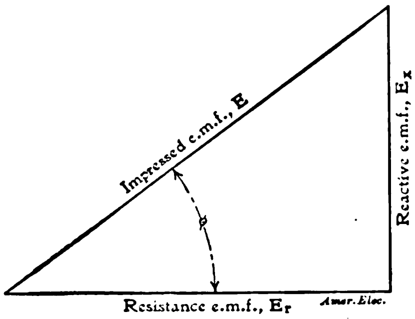

FIG. 3.

$$E = \sqrt{V_r^2 + V_x^2}$$

or

$$E = \sqrt{E_r^2 + E_x^2} \ldots\ldots\ldots (4)$$

It is usually written the latter way, and while this gives a numerically accurate result, it sometimes leads to confusion for the reason that E_r and E_x are not components of E, but are opposing e.m.fs.

It is customary to consider a cycle analogous to a circle, and to divide it into imaginary degrees; thus a quarter of a cycle is said to be 90 degrees, a half cycle to be equal to 180 degrees, and so on. This is convenient in that the lagging of the current and reactive e.m.f. may be expressed in degrees of a circle instead of parts of a cycle. Thus in Fig. 3, the angle ϕ between the lines representing impressed (applied) e.m.f. and resistance e.m.f. is said to be the "angle of lag" of the current in the circuit, the angle here being 53.13°; and the quarter of a cycle by which the reactive e.m.f. lags behind the current is referred to as "90 degrees," the line representing current and resistance making a 90° angle with the line representing reactive e.m.f. See Fig. 4. A further convenience results from this convention, namely, that trigonometry may be applied to the solution of alternating-current problems. Thus, the relation between the e.m.f. available for work and the impressed or applied e.m.f. may be expressed as follows:

$$E = E_p \cos \phi,$$

the subscript p being used to denote power. From this formula and formula (4) it will be evident that the e.m.f. available for work (or the e.m.f. to overcome resistance) is not the arithmetical difference between the counter e.m.f. of self-induction (reactive e.m.f.) and the applied or impressed e.m.f.

The proportion of a cycle by which a current lags behind an impressed e.m.f, or by which one e.m.f. lags behind another, is termed the *phase* difference; phase differences are always expressed as degrees of a circle; thus, in Fig. 3, the phase difference between the impressed e.m.f. and the resistance e.m.f. is the angle ϕ. As previously stated, this same angle is called the "angle of lag," but this term is usually employed only in speaking of the lag of a current behind the e.m.f. which is applied to the circuit; the term "phase difference," on the other hand, is generally used only in referring to two e.m.fs. or two currents which do not rise and fall in unison.

The fact that the component of the impressed e.m.f. that overcomes the reactance of a circuit and the component that overcomes the resistance are not "in phase" with each other leads to results which appear to be inconsistent to one in the habit of considering only direct-current circuits. In this latter class of circuit, the total effective resistance (corresponding to the impedance of an alternating-current circuit) is equal to the sum of all the separate resistances and counter e.m.fs., and the impressed e.m.f. is therefore equal to the sum of the e.m.fs. required to overcome these separate resistances and counter e.m.fs. individually. In an alternating-current circuit, however, this is not true, as the formulas just given clearly show. For example, if a circuit supplied at a frequency of 60 cycles contained a device the resistance of which was 10 ohms and the inductance 0.0796 henry, in series with another device of 30 ohms resistance and no inductance,

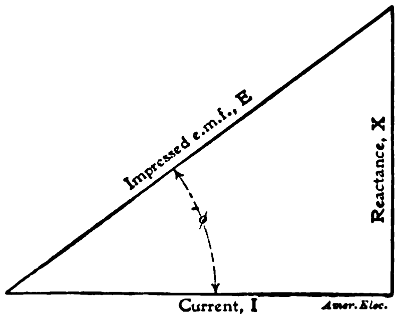

FIG. 4.

the total resistance would be 40 ohms, and the reactance would be $2\pi \times 60 \times .0796 = 30$ ohms. The impedance of the inductive device would be 31.623 ohms and the impedance of the whole would be $\sqrt{1600 + 900} = 50$ ohms; consequently, if the impressed e.m.f. were 100 volts there would flow a current of 2 amperes. Considering the two devices separately, the drop across the non-inductive device would be $2 \times 30 = 60$ volts, and the drop across the inductive device would be $2 \times 31.623 = 63\frac{1}{4}$ volts, the sum of the two drops being greater than the e.m.f. actually applied to the circuit. (See Fig. 5.) This seemingly paradoxial result is due to the two voltages being out of phase with each other, and consequently with the applied e.m.f.

Operation of Batteries and Boosters.

To the Editor, American Electrician:—

I notice in my article on Operation of Batteries and Boosters in your January issue, a slight mistake. In Fig. 8, the arrows indicate a reversed direction of currest for the combination shown. A charge applied as arrows indicate in my sketch would reverse the cells instead of charging them. The accompanying sketch shows the arrows pointing in the proper direction.

Convenient Estimate Blank.

To the Editor, American Electrician:—

Thinking that some of your readers who are engaged in the electrical construction and supply business might be interested in an estimation blank, I submit a sample of a blank form which has proved to be very helpful to both our customers and ourselves. board. Three points of attachment are pref- screws carrying the slate or marble panel When making an estimate for work or supplies, one blank is sent to the customer and a copy of it is kept on file in our office. This form of blank has proved to be very helpful in making estimates for small lighting plants and interior wiring. The actual size of the sheet is 5½ by 8½ inches.

Panel Boxes.

To the Editor, American Electrician:—

While the construction of panel boards approximates perfection panel *boxes* are, as one might say, still in the uncertain stage of existence. They linger along as a rough wooden box in various stages of incompletion through the early period of conduit installation. They must be lined with 1/16-in. iron or ⅜-in. slate, which must be ordinarily fitted, marked for the conduit and taken back to the shop to be drilled, or else hacked out on the ground in a very crude way. A casing or facing corresponding to the general trim of the building must be also made and lined with similar material. The whole operation is one of piecemeal construction at the building, at greater cost and with results far inferior to a design such as is here described.

The box proper is pressed up (or it may be lapped at the corners to save the cost of a heavy die) with full round corners from a single sheet of 1/16-in. steel. The bridges between the gutters and the panel box proper are all made by a single rectangular soft iron casting flanged at the back to facilitate riveting to the sheet steel box. The two corner lugs at the top and one in the center at the bottom are tapped for the screws carrying the slate or marble panel board. Three points of attachment are preferable so that the board cannot be sprung or strained by screwing down in case either the lugs or the board should be slightly out of true. This casting also has four arms extending sidewise as at *A*, Fig. 1, ribbed at the back for strength and furnishing points of attachment to the studding of the building. Ordinary flat-head screws may be used for securing the box, backed up with washers or a special screw by which it can be easily adjusted flush with the finished wall. Plenty of knockout holes are provided, which can be enlarged with a hand reamer for special location of mains. The whole cover of this box is cut from a single sheet of steel, the door being cut from the center piece to avoid waste. The outside, forming a cover for the gutters, is screwed on to the arms *A*, Figs. 1 and 2. Where no special finish is required this sheet metal door should be riveted to a ribbed cast frame for stiffening it and provided with hinges and spring catch. Ordinarily, however, it would simply be screwed to the back of the wooden door used for finish.

The conductors may enter the panel from the gutters through bushed holes or cast slots with well rounded edges as indicated at *B*, Fig. 1. The whole box should have at least three coats of thick enamel well baked in. This box is of standard width and is simply lengthened for greater capacity. Such a construction combines the lightness of wrought metal with the rigidity of cast metal, and requires the fewest possible number of joints and parts while affording a most convenient mode of attachment to the building. If any progressive contractor reading this will take the pains carefully to sum up the costs of the ordinary "installment-plan" box he will be surprised at the relative cheapness of this while its superiority will, I trust, be obvious.

ELMER E. WARNER.

New York.

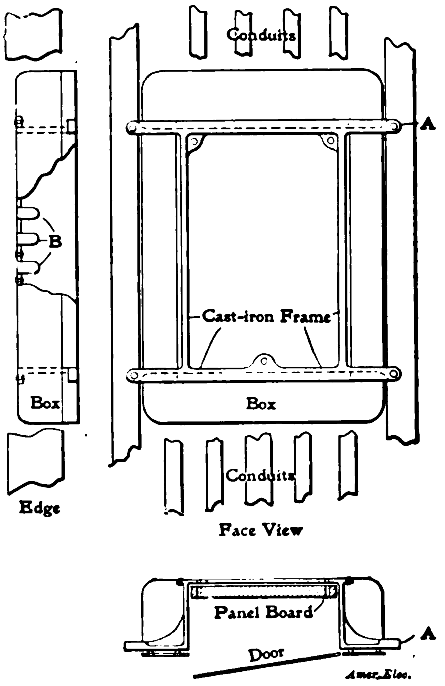

FIG. 1.—DETAILS OF PANEL BOX.

Queries and Answers

IMPORTANT.—No attention will be given to any inquiry which does not give the full name and address of the inquirer.

What should be the winding for the instrument described in the December number to make it a voltmeter indicating 20 volts at full scale?
O. S. D.

Wind the bobbin with No. 26 double silk-covered magnet wire to a depth of 1⅛ inches.

What is the difference between a gasoline motor and a gasoline engine? (2) Is gasoline ever delivered into the cylinder of an engine without first being vaporized?
K. W. E.

There is no difference. (2) We have never heard of an engine in which this is done.

An automobile battery is charged through a set of resistances from a 500-volt circuit at the rate of 8 amperes and the voltage at the terminals of the battery when fully charged is 106. For overcharging, 8 amperes is too much, but a 5-ampere rate is very effective. How much resistance will it be necessary to add to the circuit in order to reduce the rate to 5 amperes for overcharging?
G. J. P.

The additional resistance coils should have from 60 to 65 per cent of the resistance of those now used for charging. Connect the additional resistance in series with the old resistance and short-circuit it with a switch until the battery is fully charged; then open the switch for overcharging.

If the armature of a shunt-wound motor, which contains 8 turns per coil, be rewound with the same number of coils having 10 turns each, will the armature run slower or faster? (2) Will the loss in the winding be greater or less than that in the original winding? (3) What would be the difference in ampere-turns in the two windings?
C. F. K.

The armature would run slower; at no load the speed would be practically 80 per cent of the no-load speed of the original winding. (2) The loss in the winding will be 25 per cent greater than with the original winding for a given armature current. (3) The ampere-turns in the armature winding with a given load will be practically 25 per cent greater than in the original armature; consequently the tendency to sparking will be greater. The sparking tendency due to self-induction in the commutated coil will be about 25 per cent greater than in the original armature.

It is desired to install a three-phase generator having a delta-connected armature and to supply a lighting load from two collector rings only, until a motor load is obtained. What proportion of the rated output of the generator will be available for the lighting load under the condition specified? (2) If the generator is of 90% efficiency at full non-inductive load, what efficiency would be obtainable running it on the single-phase load as mentioned?
B. F. K.

If the heat losses were dissipated only by that part of the armature carrying the active winding, the available output would be 50 per cent of the rated three-phase output, but as the idle parts of the armature will undoubtedly assist in dissipating the heat the available output will be somewhat higher. (2) It is impossible to give a definite reply without knowing how the losses are distributed when the machine is operated three-phase. If one-half of the losses are in the armature winding, then the efficiency when operated single-phase, as described, would be about 86 per cent.

How can the resultant power factor at the junction of a feeder and two branch lines be ascertained if the power factor in each branch be known?
E. M.

The resultant power factor may be approximated with a sufficiently close approach to accuracy for all practical purposes by means of the formula

$$\frac{i' + i''}{\dfrac{i'}{p'} + \dfrac{i''}{p''}} = p,$$

in which i' is the current in one branch, p' the power factor in that branch, i'' the current in the other branch, p'' the power factor in that branch, and p the joint power factor at the junction. This formula is based upon the assumption that the current at the junction is the arithmetical sum of the two currents in the two branches, which is not strictly true because the two currents are not in phase with each other, and also that the actual joint resistance is the "equivalent" resistance, which is untrue; but the discrepancy is negligible in ordinary work and the error is usually in favor of the worker—it usually makes the power factor too low.

A metallic telephone line of galvanized iron wire, transposed at every second pole, runs for a distance of three miles on the same poles with a transmission line of 11,000 volts and 7 feet below the power line. Notwithstanding the transposition of the telephone lines, the induction renders conversation almost impossible. There are no transpositions on the power line. What remedy would you suggest? (2) Should a three-phase revolving-field generator make more noise in operation than a two-phase generator of the same speed and output?
E. W. B.

Two transpositions in the power line should improve the conditions; if these do not have the desired result, then the number of transpositions will have to be increased, but they should be made symmetrically so that the number of transpositions in the power line will be a sub-multiple of one less than the number of transpositions in the telephone line. Thus, if the telephone line contains N transpositions and N is an odd number (as it should be), the number of transpositions in the power line should be

$\dfrac{N-1}{x}$, x being any even number. If the number of transpositions in the telephone line is an even number, then the power line should have $N \div x$ transpositions. (2) Not necessarily. The humming of an alternator is affected by the frequency and by the shape of those iron parts of the magnetic circuit next to the air-gap.

Can four direct-current arc lamps, built to operate in multiple on a 125-volt circuit, be operated in series on a 500-volt circuit? (2) What is meant by the sparking constant of a generator or motor? (3) If two motors have power factors of 60% and 80% respectively and take 25 and 48 amperes respectively, what will be the joint power factor of the line to which the machines are connected? (4) Why does a wattmeter on a three-phase circuit give a negative indication when the power factor falls below 50%?
B. G.

Not unless the lamps are especially designed to be interchangeable between multiple and series circuits. (2) This is not a general term; it may be used by some designer to mean some numerical constant in a formula which is used as a criterion of the tendency to sparking. Different designers employ differeent sparking criteria. (3) See answer to E. M., and consider the two machines as the two branch circuits referred to there. (4) It does not necessarily do so. You will find this subject explained fully in Jackson's "Alternating Currents." Space limitations prohibit a full explanation here.

What is the working principle of the induction coil in a medical battery? (2) Why is the strength of the coil changed by changing the position of the core? (3) How can the locations for belt holes in a floor be ascertained for a belt connecting a pulley above the floor with one below it?
D. E. H.

Most medical coils are provided with only a singe winding which is energized and de-energized by the action of the vibrator. Each time the circuit is broken the self-induction of the coil produces an impulse of high e.m.f. at the terminals of the coil. (2) Because the strength of the magnetic flux, upon which depends the strength of the induced e.m.f., is changed. (3) Drop a plumb-line from the face of the upstairs pulley to the floor, holding the line at the center of the pulley-face, and bore a gimlet hole through the floor where the point of the plumb-bob strikes. Then by means of the plumb-line, manipulated from a step-ladder downstairs, locate the point on the under side of the floor which is directly over the point on the downstairs pulley-face corresponding to that on the upstairs pulley-face from which the plumb-line was first dropped; bore a gimlet hole at this point. Representing the distance from the center of the upstairs pulley to the floor by h, the distance from the floor to the center of the downstairs pulley by H (both distances being measured perpendicularly), the distance from the first gimlet hole to the second gimlet hole by D, and the distance from the first gimlet hole to the center of the belt hole by d, the belt hole may be located by means of the folowing formula:

$$\frac{D}{1 + \dfrac{H}{h}} = d.$$

This, of course, is for one side of the belt. The hole for the other side can be located in the same manner by locating gimlet holes directly beneath and above the other sides of the two pulleys.

THE AMERICAN CROSSLEY GAS ENGINE.

The type of gas engine built by the well-known English firm of Crossley Brothers is familiar to all engineers interested in gas engine work in this country and Europe and has made an excellent record wherever it has been introduced. The rights to build the Crossley engine in this country have been acquired by Power & Mining Machinery Company, New York, successor to The Loomis-Pettibone Gas Machinery Company. Although the American Crossley engine embodies the principal fundamental features of the English engine, several modifications of details have been made, notably in the valve gear. The engine is of the single-acting four-stroke-cycle type and is built in single-cylinder, double-cylinder and four-cylinder units of from 50 to 1300 horse-power rated output. The maximum ability exceeds the rated ability by about 15 per cent.

The accompanying illustrations show a double-cylinder engine of the *vis a vis* type. The crank-shaft has a center crank and the connecting rods work on one crank-pin, one rod having a single box and the other a forked end and two boxes straddling the box of the first rod. The main bearings are carried in the side frames which are two heavy castings, the ends of which are bolted to the cylinders. Between the side frames there is a steel plate crank pit bolted on, which received the waste oil and the top is surmounted by a sheet steel oil guard. The cross-head pins are pressed in the connecting rods and work in adjustable bearings in the pistons. The pistons are water-cooled and provided with adjustable slippers, an important feature too often neglected in single-acting engines. The main cylinder casting which forms the water-jacket is provided with extensions and flanges on the sides for bolting to the side frames. On the bottom the cylinder has a foot held down by foundation bolts. The working cylinder proper is an internal liner ribbed around its circumference on the end exposed to the high initial temperature and pressure, thereby having great strength combined with ample cooling surface. The cylinder head is a hollow casting and contains the admission and exhaust ports. It is of varying thickness of metal cut through in places and strengthened by staybolts in such a manner that the difference in temperature at different points does not set up any undue stress due to unequal expansion. The exhaust valve box is an independent water-cooled casting bolted to the bottom of the cylinder.

The valve gear is driven from the main shaft by means of spiral gears and the side shaft *S*. The governor is also driven in this manner, but by an individual side shaft. The operation of the valve gear and governor mechanism at each end of the engine is as follows: The air and gas enter the mixing chamber, *M*, through a proportioning valve, as indicated in Fig. 2, the air entering the mixing chamber direct and the gas entering through a gas valve, *G*, Fig. 5. From the mixing chamber the air and gas pass to a cut-off valve, *C*, and the main admission valve, *A*, Fig. 8. The admission valve, *A*, is opened by a cam on the sec-

FIG. 2.—ELEVATION OF ONE-HALF OF A DOUBLE-CYLINDER ENGINE.

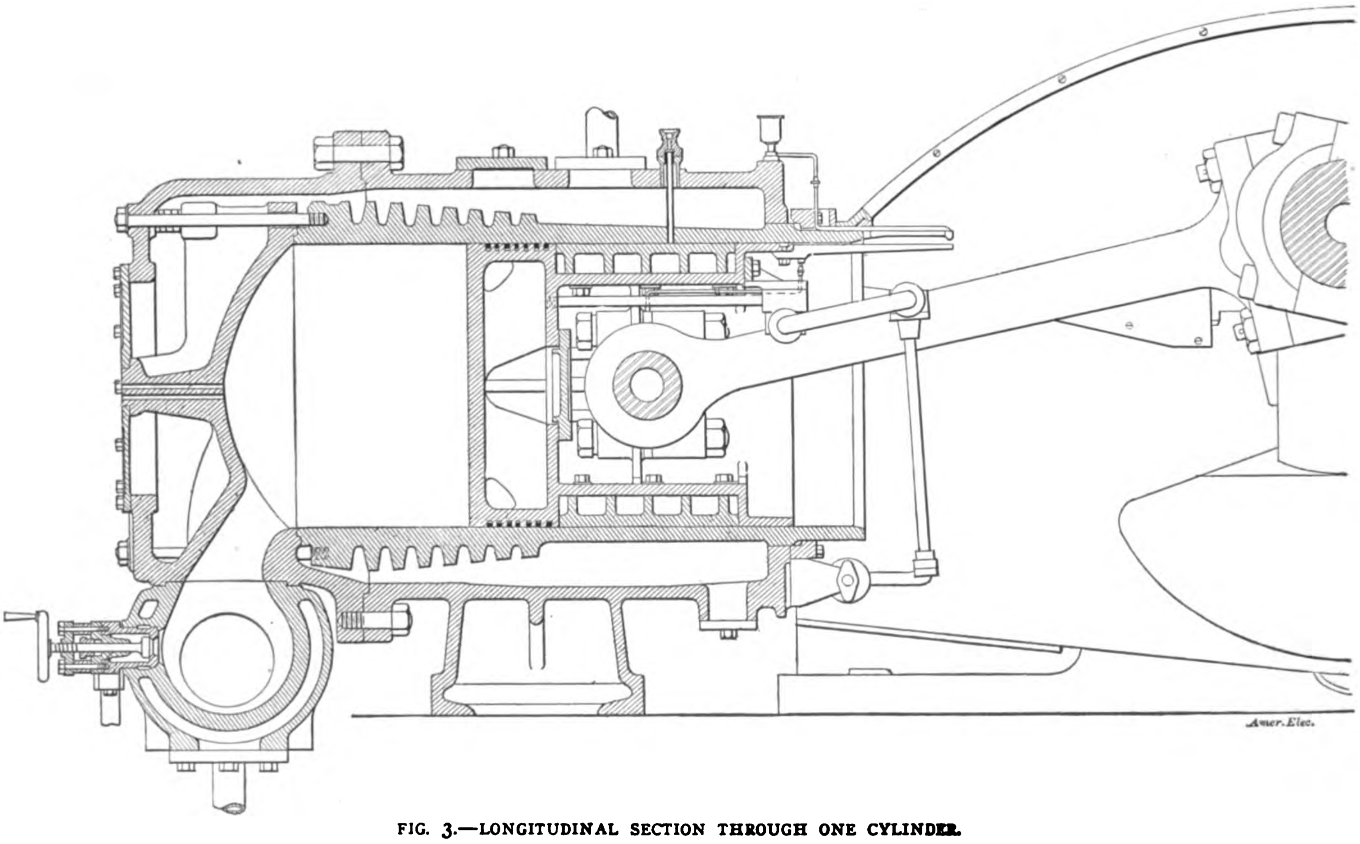

FIG. 3.—LONGITUDINAL SECTION THROUGH ONE CYLINDER.

ondary shaft, *S*, through a modified bell crank, *a*, *a'*, and is seated by the spiral spring shown in Fig. 8 surrounding the valve stem. The cut-off valve is of the multiported type and is operated independently of the admission valve by means of a rocker-arm, *c*, Fig. 5, which is fulcrumed at *f* and receives its motion, of course, from the secondary shaft. Fig. 7 shows a plan view, to a larger scale, of the admission and cut-off valves, from which the arrangement of the valve spindles will be obvious. The head of the admission valve rocker-arm, *a*, Fig. 8, works between the end of the valve spindle and the cross-head, *d*, attached to the twin valve stems of the cut-off valve.

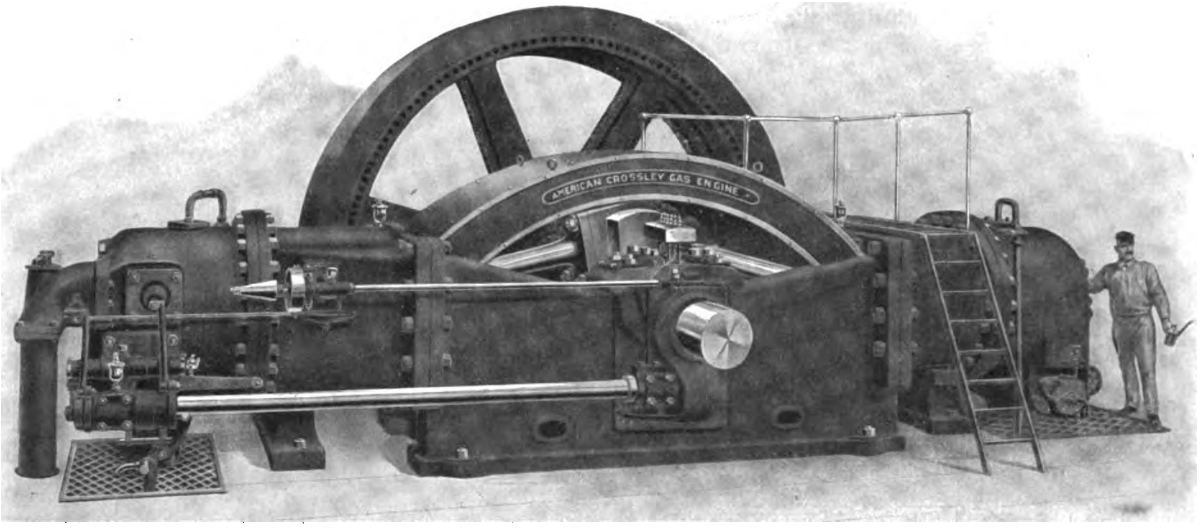

FIG. 4.—650-H.P. AMERICAN CROSSLEY GAS ENGINE.

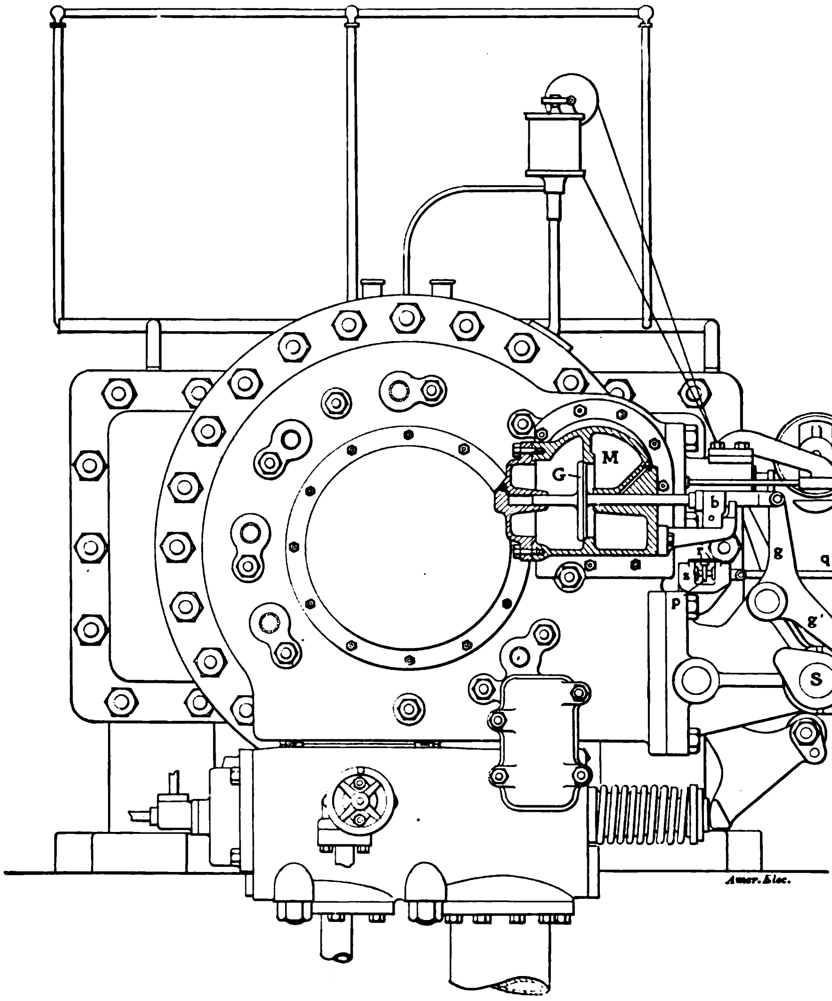

FIG. 5.

So long as the load on the engine remains constant, the cut-off valve shuts off the supply of mixture at the same point in each suction stroke. Should the load change, the altered speed of the governor will move the rod, *k*, Fig. 2, by means of the rack, *r*, and the pinion, *p*, will turn the screw, *s* (see also Fig. 6), and thereby move the rod, *q*, in or out according to the requirements of the case, changing the position of the fulcrum, *f*, Fig. 5, and altering the point of cut-off. This method of regulation controls the speed of the engine throughout the ordinary range of loads, but when the load becomes light enough to make the throttling method of regulation uneconomical the engine automatically changes over to the hit-and-miss method.

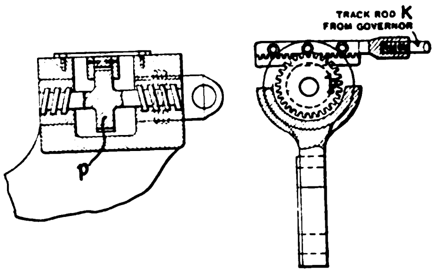

FIG. 6.

The bell crank, *g*, Figs. 1 and 5, operates the gas valve, *G*, through a block, *b*, interposed between the link pivoted to the crank arm *g* and the end of the valve stem. At a predetermined light load, the governor, by means of the reach-rod, *h*, Figs. 1 and 2, withdraws the block, *b*, from its operative position, so that the gas valve remains closed. The admission valve, however, is operated as usual, so that the cylinder is flooded with air. The point where the change is made from regulation by cut-off to hit-and-miss regulation is determined in

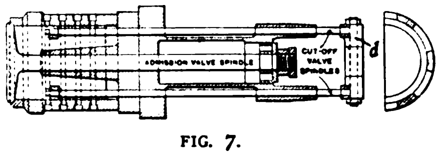

FIG. 7.

accordance with the quality of the gas and by adjusting the length of the rod, *h*.

The weight of fly-wheel necessary for good regulation at full load has been found sufficient to effect good regulation with the hit-and-miss method of governing at the smaller load which the engine is carrying when this method comes into play. The combination of the two methods of control reduces very greatly the range of variation in compression under varying loads, and therefore holds up the economy of the engine at these loads where it would otherwise drop to the rather low figure characteristic of throttling engines.

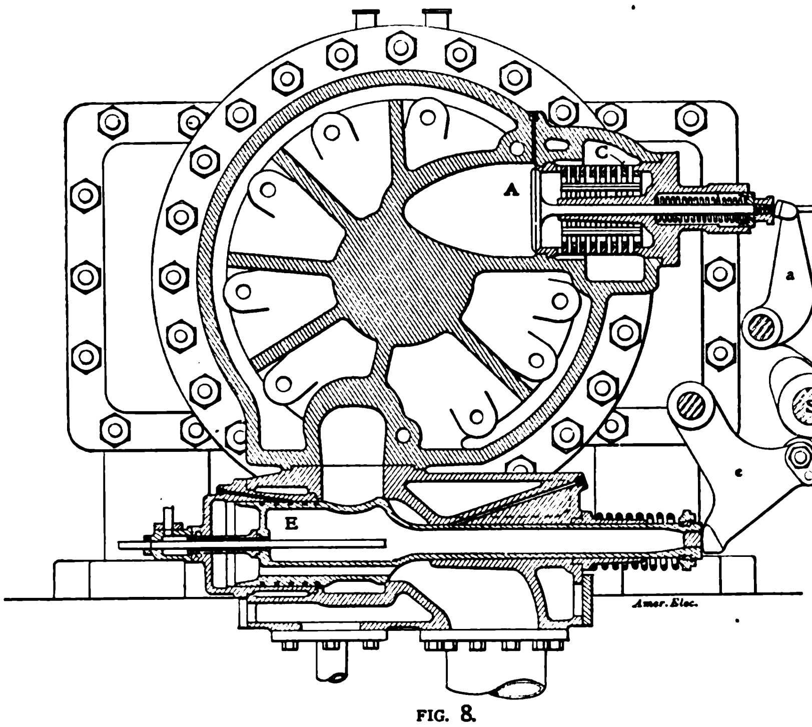

FIG. 8.

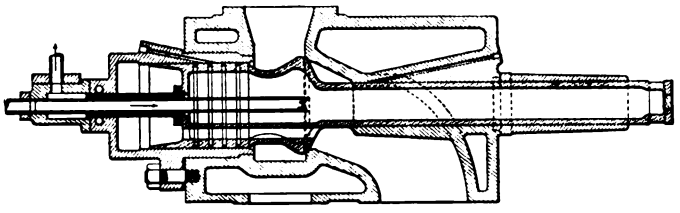

FIG. 9.

The exhaust valve, *E*, Fig. 8, is operated in the usual manner by an oscillating arm, *e*, receiving motion from the cam on the secondary shaft, *S*. This valve is shown to a larger scale by Fig. 9 and embodies the unusual feature of internal water cooling. The valve and stem are hollow, and water is delivered to the interior through the small pipe at the left, as indicated by the arrow. From the inside of the valve, it passes out again around the outside of this small pipe through the exit shown at the extreme left of the engraving. The valve is of the poppet type and the relation between the valve and its seat is the same as in the ordinary mushroom form of valve. It has the unusual advantage, however, of traveling in double guides, one on each side of the exhaust outlet, so that the pressure within the cylinder cannot throw the valve out of alignment with its seat. As Fig. 9 clearly shows, facilities are provided for lubricating both the vaalve-stem guide and the valve-shell guide. The exhaust-valve chamber is a separate casting bolted to the under side of the cylinder and can be taken off without disturbing any of the other working parts of the engine. Fig. 10 shows an indicator diagram taken from a Crossley engine fitted with the type of valve gear just described.

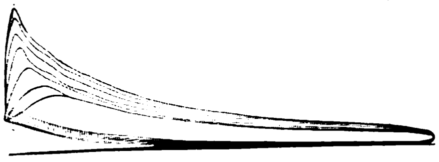

FIG. 10.

* * *

A NEW OIL-BREAK SWITCH.

The value of oil as an insulating and arc-suppressing medium in high-tension current interrupting devices used where space is a factor is universally known, and the equipment of the modern central station usually contains apparatus of this kind. The Westinghouse "Type D" oil switch is a comparatively new addition to the line of oil-immerged circuit-breaking apparatus, and is said to have original features which are not embodied in other oil switches. It is made with two, three and four poles, single and double throw, in all capacities up to and including 1000 amperes and voltages up to 3300. The ultimate breaking capacity is given at 600 kilowatts for a single-phase line, 1200 kilowatts for two phases and 1000 kilowatts for three phases.

When used on a switchboard, the switch is mounted on the back of the panel with the handle projecting through to the front. As regularly made, the switch is designed for use on marble two inches thick, but by substituting shorter bolts it can be as easily mounted upon thinner panels. The handle of the double-throw switch is locked when the switch is open. Pressing a button in the end of the handle releases it and the circuit is closed by throwing the handle up or down.

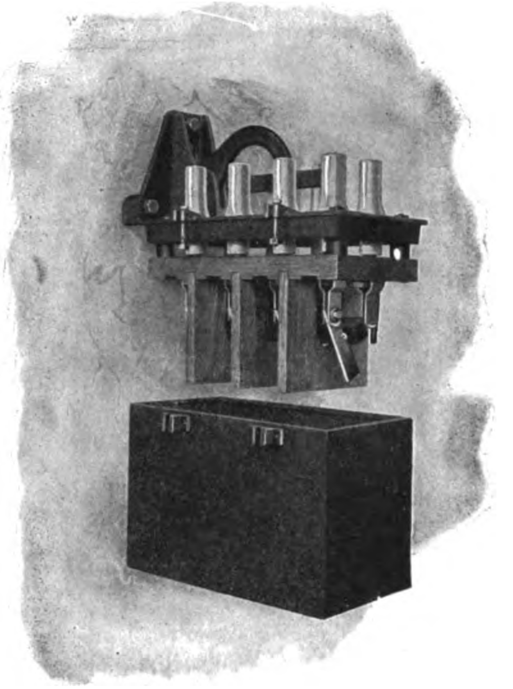

FIG. 1.—WESTINGHOUSE OIL SWITCH.

The "Type D" oil switch is very generally used with motors, mounted upon an adjacent wall or post. It is one of the smallest oil switches made, and the mechanism is said to be unusually simpe and effective. The switch is of the knife-blade and jaw type, and the final arc is taken up by an arc-

leakage distances have been carefully worked out, it is stated, and will be found to be ample. The contacts are thoroughly insulated; they are mounted on a wooden base suspended from the iron supporting frame, and are at all times immersed in the oil. Each pole is isolated by a barrier of wood which has been subjected to a treatment to give it high insulating qualities. The leads are brought out at the top, connections to the circuit being made inside the switch, and a porcelain insulator slipped over the joint; by this arrangement all conductors are kept outside the oil tank.

The tank is of sheet metal, having a suitable insulating lining and is attached to the case by bolts. The lugs through which the bolts pass are slotted, and when the nuts are loosened the bolts can be lifted out sidewise, thus facilitating removal of the tank. The form of the tank, and the interposition of the wooden barriers between the poles are said to reduce the amount of oil required and the danger of ignition during a fire. "Kilarc" oil is used; this is especially compounded for insulating purposes, and is said to have a fire test of over 400° F. It is claimed to be free from acidity and volatile matter, and therefore to have high insulating properties and a low evaporation rate, while its viscosity renders it unusually effective for extinguishing the arc.

New Apparatus and Appliances

NEW FUSELESS ROSETTE.

The rosette illustrated by Fig. 1 herewith is adapted particularly for concealed work. Ample room for the knot in the cord is provided in the dome which covers all contact pieces and the inside screws. The leading-in wires are separated by porcelain walls rendering short circuits impossible. The rosette is made by the H. T. Paiste Company of Philadelphia, Pa., and is suited for work on 250-volt circuits.

HIGH TENSION OIL FUSE.

A new oil fuse, simple in construction and especially adapted to high-tension circuits, is shown by Fig. 2 herewith. The device is made by the Anyun Lamp and Electric Company of Buffalo, N. Y., and consists of a glass tube with outwardly flanged ends, and a fibre cap at both extremities fastened to collars of similar material which are held in place by the flanges on the tube. Brass rods fastened to each cap hold the fuse wire, the latter being in the form of a link. The tube is filled with transformer oil to a point above the fuse wire, leakage of oil being prevented by disks and rubber washers, and when the fuse blows the oil fills the gap, thereby forming an effective insulation and preventing arcing. The following test which the manufacturers claim to have made in order to test the current capacity of the device is worthy of note: A piece of No. 10 copper wire was substituted for the ordinary fuse wire in the tube and the fuse short-circuited across a 2200-volt line with satisfactory results. The only part which is ordinarily destroyed is the fuse, and this can be readily replaced by another as often as the fuse blows.

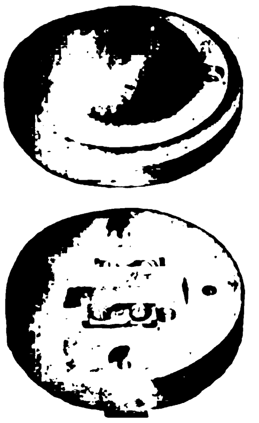

FIG. 1.—FUSELESS ROSETTE.

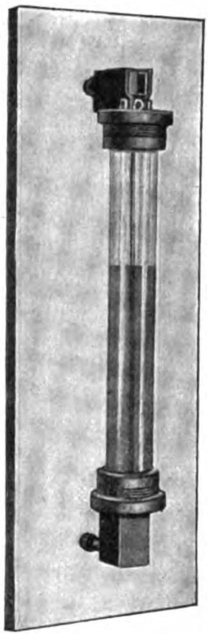

FIG. 2.—OIL FUSE.

MIL-AMPERE RULE AND CONSTANTNOMETER.

Figs. 3 and 4 herewith show the mil-ampere rule and constantnometer respectively made by Barnes Brothers, of St. Louis, Mo. Both instruments are arranged like stem-winding watches with glass-covered dials back and front, and operate somewhat after the manner of the Boucher circular slide rule. The constantnometer is used to ascertain the number of watts contained in any electrical horse-power by multiplying the number of electrical horse-power by 746. The electrical horse-power contained in any given number of amperes is obtained by moving the hand across the dial to the voltage desired and the constant will be found in the same scale. These constants are given in decimals and are said to be very accurate. Opposite them is the electrical horse-power.

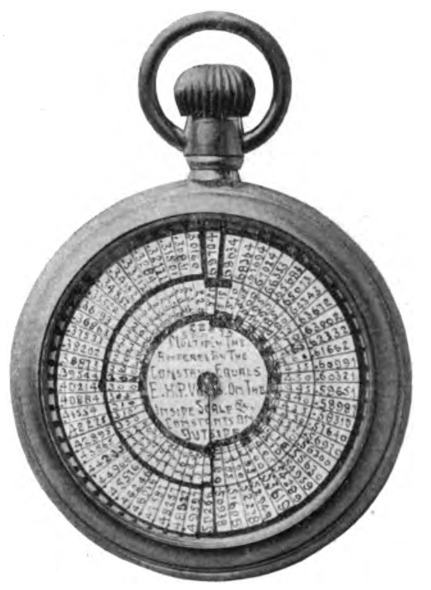

FIG. 3.—CONSTANTNOMETER.

The mil-ampere rule is said to contain all the information necessary for obtaining to carrying capacities of all sizes of conductors from 0000 to No. 22 B. & S. gauge, giving the current in amperes allowed by the National Board of Underwriters and also the circular mils of each wire. It is also said to contain the wiring rules and requirements for concealed and open-work wiring.

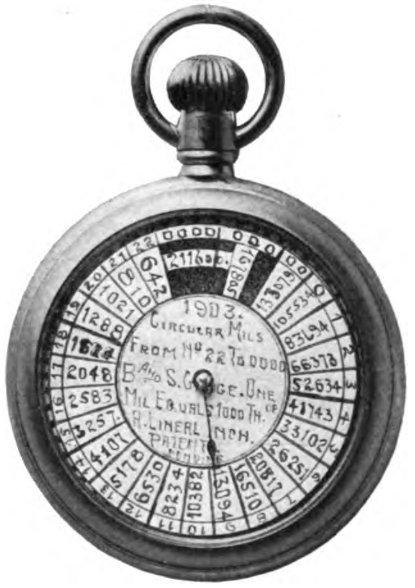

FIG. 4.—MIL-AMPERE RULE.

WATSON MOTORS.

In the line of large machines the multipolar motor with a form-wound coil armature has been standard practice for some time, but for machines of one horse-power and under this practice has not been generally followed. When the Mechanical Appliance Company, of Milwaukee, Wis., started to get out their line of motors they decided to take advantage of the benefits derived from a multipolar motor having a form-wound coil armature, and made their entire line from 1-8 horse-power up of this type. The frame of these machines is of cast-steel, the poles being cast as part of the frame and the larger sizes being provided with removable pole shoes. The bearings are of bronze with ring oilers, and are supported by cast-iron bonnets in such a manner that a good alignment is secured without the necessity of careful adjustment. The armatures are made up with a laminated slotted core, the discs making up the core being punched complete at one operation, thus making a core which requires practically no filing to finish it to receive the coils, and so maintaining the laminations intact and keeping down the core loss of the machine. The commutators are made up of segments punched from rolled strip copper, thus insuring a uniform width and density, and are insulated with mica. Before being turned the commutator is subjected to pressure, and the retaining screws drawn up while the commutator is hot, thus making the finished commutator rigid. The winding on the armature is made up of form-wound coils and insulated before being mounted on the core. After the coils are

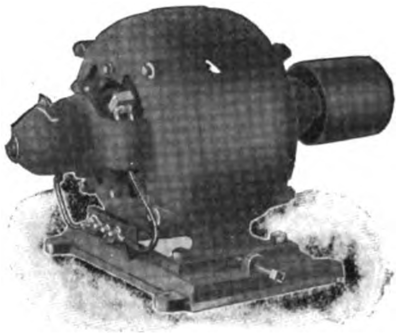

FIG. 5.—WATSON MOTOR.

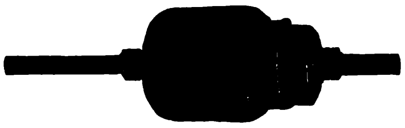

FIG. 6.—WATSON ARMATURE.

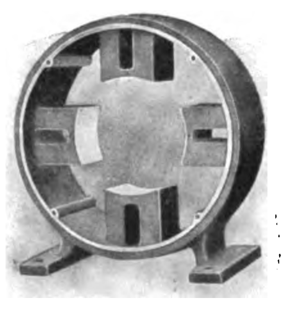

FIG. 7.—WATSON STEEL FIELD FRAME.

mounted the core and the coils are baked to dry them out thoroughly and are then treated with insulating compound and again baked for twelve hours.

THE LUNKENHEIMER METAL MELTING FURNACE.

Fig. 8 herewith illustrates the Lunkenheimer metal melting furnace, which has been found to afford a very efficient and economical method of melting metals, particularly brasses and bronzes. As shown, the furnace consists of a cylindrical sheet-steel drum, *A*, having cast-iron heads. The interior of the drum is lined with fire-proof tile, and there are two openings on opposite sides of the drum. Only one of these openings is in use, the other being closed by a fire clay filling. The object of having two openings is to increase the life of the linings of the furnace. It has been found that the furnace wears out uicker around the filling hole (which also serves as outlet for the flame) than elsewhere. An advantage claimed is that when one filling hole is worn out, this can be closed by a fire-clay filling and plate, the furnace reversed, and the other hole cut out and put in service. The oil burner is of special type, designed to give a great amount of heat with a minimum consumption of oil. Experience has shown that it is possible to secure from six to seven heats per working day of ten hours from each furnace. The weight of each heat will average about five hundred and fifty pounds, and the oil consumption, it is claimed, varies from two to two and one-half gallons of crude oil per hundred pounds of metal melted.

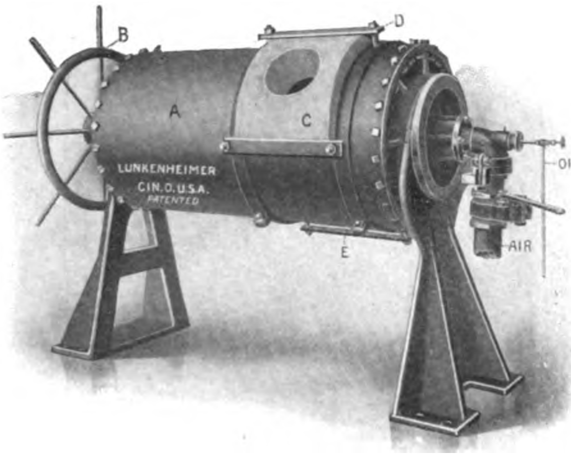

FIG. 8.—METAL MELTING FURNACE.

The life of the linings is said to be from three to four hundred heats, this varying with the kind of metal melted. The furnace is made in two sizes, one having a capacity of five hundred and fifty pounds of metal per heat, and the other having a capacity of twelve hundred pounds of metal per heat.

GENERAL ELECTRIC COMPANY'S CIRCUIT BREAKERS.

Three years ago the General Electric Company placed on the market a line of carbon break circuit breakers, which have given such satisfaction that the company has decided to extend and complete the line, by the addition of several new forms. This new line of circuit breakers is complete for all current capacities from 1 to 10,000 amperes, and for all voltages up to 650. The apparatus embodies many new ideas in circuit breaker construction, and is fully up to the high standard which characterizes all the General Electric apparatus.

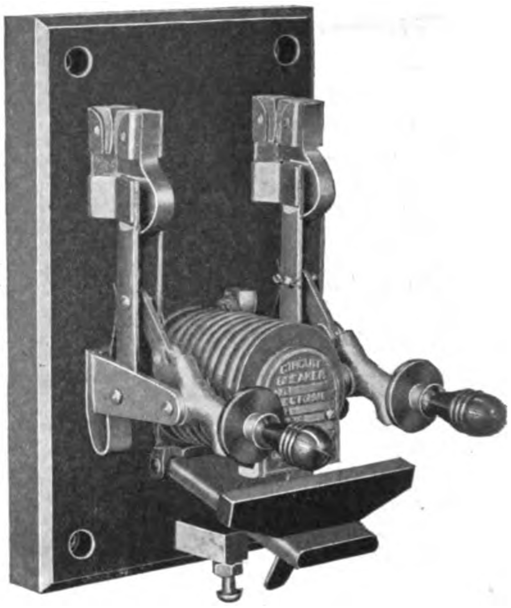

FIG. 11.—DOUBLE-POLE TYPE.

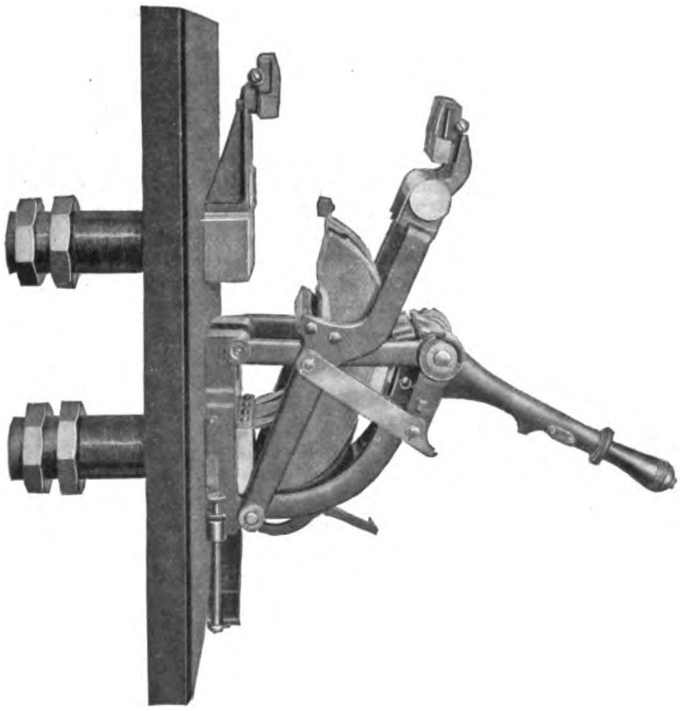

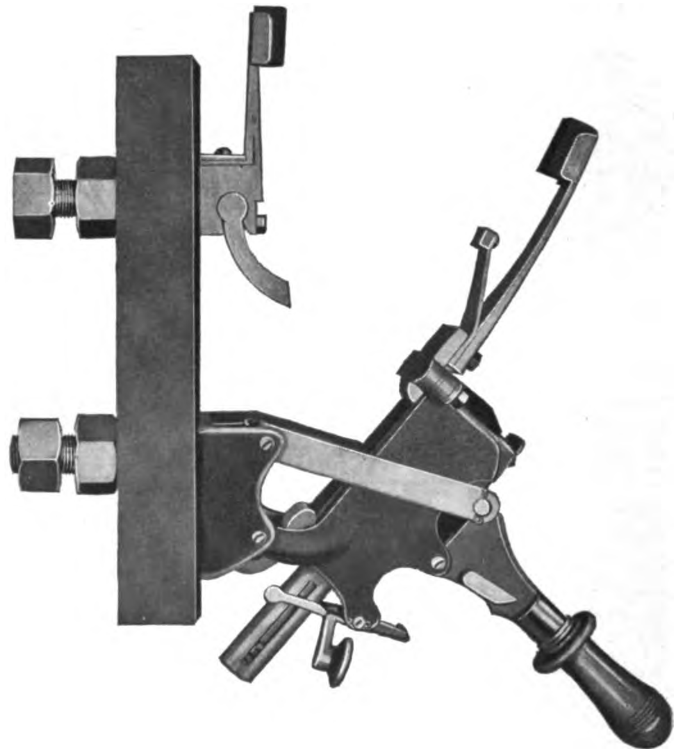

FIG. 9.—SINGLE-POLE RAILWAY CIRCUIT-BREAKERS.—FIG. 10.

The circuit-breaker illustrated in Fig. 9 is known as the Type "C," Form "K." This breaker is designed for heavy railway work, and is made in capacities from 800 to 10,000 amperes, and for voltages up to 650. It has been adopted by the Interborough Rapid Transit Company, of New York City, and other large companies for use in their power stations. These breakers are very liberally proportioned, both electrically and mechanically, having ample carrying capacity and large contract areas, and are said to be very reliable in operation.

The Type "C," Form "M" circuit breaker, which is illustrated by Fig. 10, like the Type

"C," Form "K," is intended for heavy service, but is of smaller capacity, ranging from 75 to 800 amperes. The Type "C," Form "G" circuit breaker which is shown in Fig. 11 is compact and simple, yet very reliable. It is made in various capacities up to 75 amperes, and for voltages up to 650 volts. This breaker is made in both single and double-pole types, and either pole of the latter may be operated independently.

MERIAM-ABBOTT GENERATING SET.

The Meriam-Abbott Company, Cleveland, Ohio, builders of small isolated lighting plants, are making a specialty of their 6-kw. and 8½-kw. direct-connected units. As shown in Fig. 12 these consist of a twin cylinder vertical gas engine, direct-coupled to a base type generator. Both the generator and sub-base are designed for connection to this particular engine, and a symmetry of design has been maintained throughout. In the construction of the engine the cylinders are separate, while the head is a common casting. Both the inlet and exhaust valves are located in the head and are not carried in cages. Great care has been taken to secure uniform cooling of the valve seats. The valves are operated by a cam shaft centrally located above the cylinder head. This shaft carries the cams which move positively both the inlet and exhaust valves, and at the forward end carries the make and break for the electric ignition. This shaft is driven by beveled gears from the governor shaft located at the rear and between the cylinders. The governor shaft is in turn driven by the engine shaft through beveled gears. The governor is of the simple ball type and is located on the governor shaft at the rear. It actuates a lever extending between the cylinders to the front, which in turn operates a six-ported piston valve. This valve requires less than 1/16 inch movement from no load to full load, and is very sensitive.

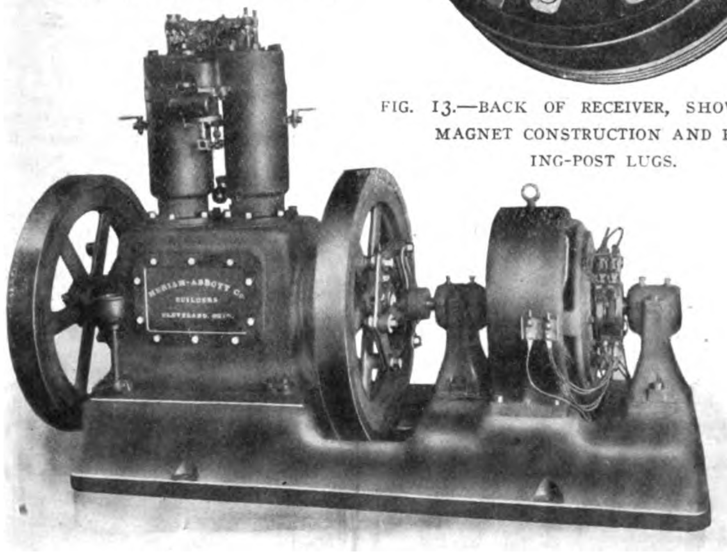

FIG. 12.—GAS ENGINE-DYNAMO OUTFIT.

Jump spark ignition is used. By this means there are no moving contacts within the cylinder and all parts are accessible. The current is supplied by three of the United States Battery Company's storage battery ignition cells.

The generator is coupled to the engine by a leather link coupling, so arranged that six links carry the load, and three links are used to take up the slack.

A NEW SOLID-FACE WATCH-CASE RECEIVER.

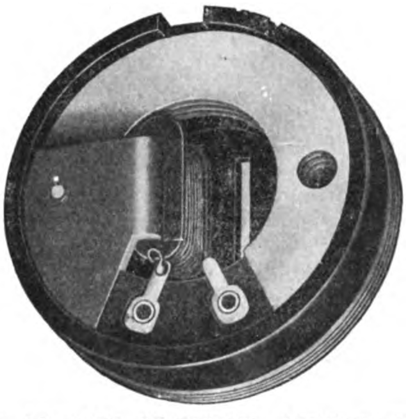

FIG. 13.—BACK OF RECEIVER, SHOWING THE MAGNET CONSTRUCTION AND BINDING-POST LUGS.

The Electric Gas Lighting Company, of Boston, Mass., has placed on the market a new solid-face watch-case receiver as a part of its line of "Samson" telephone apparatus. The case is a heavily moulded block, having a solid continuous face, with recesses in the back to contain the magnet and binding-posts. The metal back overlaps and strengthens the case, and is fastened to it by nuts. The back is insulated from the magnets and pole-pieces by the use of mica. The binding-posts are large and furnish good connection for the receiver tip. A low resonance chamber has been secured by the creation of an unbroken face, except where the pole-ends and binding-screws are brought through. This method of construction conceals and protects the magnet coil wires. The magnet is compound, having three laminations. The steel is made to carefully worked-out specifications, and is thoroughly hardened and magnetically saturated. The pole-pieces are fastened to the laminations so as to secure excellent magnetic contact.

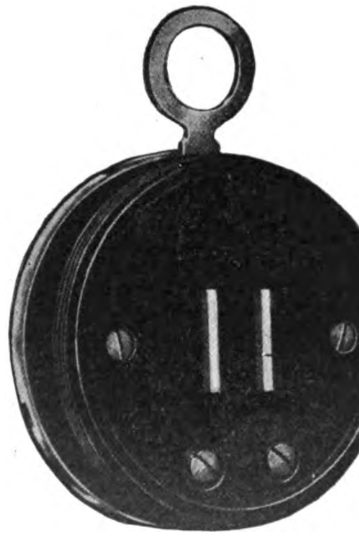

FIG. 14.—COVER REMOVED, SHOWING SHALLOW RESONANCE CHAMBER.

NEW BOOKS.

THE "MECHANICAL WORLD" POCKET DIARY AND YEAR BOOK. Manchester, England: Emmott & Co., Ltd.; 1904. Canvas; 267 text pages and 56 diary pages, 4 ins. x 6 ins.; illustrated. Price, 6d.

This is the 17th edition of this handy little pocket book, and contains a considerable quantity of new material. Weight-calculating tables have been added for steel, wrought-iron, cast-iron, gun metal, aluminum and lead, and tables giving the weights of bar copper per foot of length for a wide range of widths and thicknesses have also been added; the section on valve diagrams has been rewritten and elaborated and the new material further includes a table giving the calculated results for section moduli commonly used tables of stresses on bolts and steam and gas pipe fittings and formulas for bevel and spur gears. The gas engine section contains some interesting tables of dimensions relating to Fielding engines, and the section on oil engines contains similar tables relating to Crossley engines and some tabulated performances of Priestman, Hornsby-Ackroyd, Crossley, Premier and other oil engines.

FOWLER'S MECHANICAL ENGINEER'S POCKET BOOK. By William H. Fowler. Manchester, England; Scientific Publishing Company; 1904. Leatherette; 443 pages, 4 ins. x 6 ins.; illustrated. Price, 1s. 9d.; with leather binding and gilt edges, 2s. 9s. postpaid.

In this edition of Mr. Fowler's well-known Pocket Book the section devoted to the gas engine has been largely rewritten and considerably elaborated. Among the additions to this section may be noted a very convenient table containing constants from which one can readily ascertain the relation between compression pressure and the clearance volume. The gas engine section also contains a table giving the properties of one cubic foot of mixed coal gas and air for different proportions of gas to air, and the properties of the products of combustion of such a mixture, referred to the temperature of 32° Fah. Although no credit is given for this table, the reviewer recognizes it as having been taken from one of a series of articles written by the present editor of the AMERICAN ELECTRICIAN five years ago for *Power*. Following this section in natural sequence is a discussion of oil engines, which contains besides other useful information some data taken from a series of tests made with an 80-h.p., single-cylinder, Diesel engine, and a section on gas producers. The remainder of the book has not been greatly changed.

Fowler's Electrical Engineer's Year Book. Manchester, England; Scientific Publishing Company; 1904. Leatherette; 541 pages, 4 ins. x 6 ins.; illustrated. Price, 1s. 6d.; with leather binding and gilt edges, 2s. 9d.

This is a very complete little pocket book, and contains in addition to the material which was formerly included in the Mechanical Pocket Book also noticed in this column a large amount of other electrical information. The fundamental electrical and electromagnetic laws are of course, given, and there is the usual discussion of electric and magnetic circuits. Some of the magnetic permeability curves look as though they had been taken from Parshall's "Electric Generators," but no credit is given. The discussion of dynamo construction is unusually complete and accurate, but parts of the discussion have not been brought fully up to date, notably, the table on page 136 giving usual (?) dimensions of armature slots and the formulas on page 148 relating to sparkless collection. Incidentally, in the formula on the latter page purporting to give the limiting number of armature ampere-turns for multipolar machines the coefficient 288 should read 144 or else the symbol *P* should represent the number of pairs of poles instead of the number of poles. It is interesting to note that the chapter on storage batteries includes a brief discussion of the Edison nickel-iron element. The discussion of power measurement in alternating-current circuits might have been elaborated to advantage, and this is also true of the section on the size of conductors for polyphase transmission. The book contains, besides general fundamental data of the character mentioned, copies of the British Electric Lighting Acts of 1882 and 1888, and general particulars of the electric light and power stations and electric railways of Great Britain, which should be of value to British engineers; there are also some useful tables.

Friction and Lubrication. A Handbook for Mechanics, Superintendents and Managers. By William M. Davis. Pittsburg, Pa.: The Lubrication Publication Company, 1903. 225 pages; 60 illustrations. Price $2.00.

The book begins by stating the laws of friction as deduced by Morin, adding that these laws have been found by later investigations to apply only within a limited range of conditions. The treatment of the subject is elementary, but on the whole the statements are accurate. This cannot be said, however, of the definition of rolling friction, which is said to be "such as a journal revolving in its bearing, or a crank-pin in its brasses." There is a good deal of reliable information about lubricating apparatus for insuring the lubrication of particular machines, and also about the nature of lubricants. Under the heading of "Grease," however, the author quotes Mr. Charles F. Carpenter (who is, he says, a recognized authority on lubricants) thus: "In an oil the molecules are of a flexible spherical shape which revolve on and against each other, while in a grease they are irregular in shape, with no tendency to free movement." And all this time the rest of the human race has been fondly dreaming that the chief difference between oils and greases was that the former had lower melting points. Yet, when we think of it, we remember that some of the philosophers of ancient Greece (not grease) concluded that the bitter taste of certain substances was due to the fact that the molecules of those substances had hooks on them, and scraped the throat of the swallower as they went down. The poor overworked molecule, in addition to being absolutely rigid, as required by most molecular theories, must also, on occasion, be flexible; to say nothing of being "of a flexible spherical shape."

OBITUARY.

A. G. NICHOLS, president of the New York Safety Steam Power Company and also of the Langworthy Machine Company, died at Hope Valley, R. I., on January 13, after a short illness. Funeral services were held at Hope Valley on January 16.

HERBERT TAFT RICHARDS, late secretary of the Safety Insulated Wire & Cable Company, died in Brooklyn, N. Y., on December 26. Mr. Richards had a host of friends in the electric light and engineering fields, who will greatly mourn his loss. He was buried on December 28 from the home of his brother at Montclair, N. J.

W. O. GARRISON, president of the Columbia Incandescent Lamp Company, St. Louis, Mo., died on January 17. Although Mr. Garrison had been ailing for some time, his death was not expected and recovery seemed probable only a few weeks ago. The deceased was 42 years old, a native of St. Louis, and was officially identified with the Columbia Incandescent Lamp Company since January, 1891. He was prominent in both social and club circles. His brother, Mr. A. C. Garrison, succeeds him as president of the Columbia Company.

W. W. SKILES, president of the Shelby Electric Company, died in Shelby, Ohio, on January 9, at the age of 54 years. Mr. Skiles was one of the original promoters of the Shelby Electric Company, and was its president from the time of its inception until his death. He was also largely interested in many industrial concerns in Shelby. In addition to the business enterprises in which he was concerned, Mr. Skiles was senior member of the law firm of Skiles & Skiles, and also congressman from the Fourteenth Ohio district. He was buried on January 13. By his death The Shelby Electric Company loses a splendid adviser, who, although not actively engaged in the electric light line, had many friends among manufacturers and large consumers of lamps.

DR. FRIEDRICH VON HEFNER-ALTENECK, one of Germany's most distinguished electrical engineers, died early in January from an apoplectic stroke. Dr. Von Hefner-Alteneck was born in 1855 and was therefore 58 years of age. At the age of 22 he entered the firm of Siemens & Halske, having previously received his scientific training at the Zurich and Munich Polytechnics, and worked his way up into the position of manager of the engineering department, remaining with the firm until 1889. In 1872 he invented the drum armature, one of the most important developments in the design of dynamo electrical machinery. He also invented one of the first, if not the first, differential arc lamp, the transmission dynamometer which bears his name, and in 1883 the famous Hefner "Amyl-acetate" standard of light.

PERSONAL.

MR. R. H. MASON has been placed in temporary charge of the sales department of the Kellogg Switchboard & Supply Company, Chicago, vice Mr. A. E. Baker, resigned.

MR. J. E. WOODBRIDGE, of the railway engineering department of the General Electric Company, at Schenectady, has been transferred to the British Thomson-Houston Company, at Rugby, England.

MR. P. G. GOSSLAR, electrical engineer of the Montreal Light, Heat & Power Company, has resigned his position with that company and associated himself with the well-known engineering firm of J. G. White & Co.

MR. GEORGE W. EDGE, recently connected with Stanley & Patterson, has accepted a position with the Trumbull Electric Manufacturing Company, Plainville, Conn., as their representative in the Middle West and Eastern States.

MR. M. G. HUBBARD, for some time engineer and general superintendent of the McGuire Manufacturing Company, of Chicago, was recently elected secretary and treasurer of C. E. Hewitt & Co., engineers and contractors, of New York City.

MR. IRVING H. REYNOLDS, formerly of the Allis-Chalmers Company, and for many years identified with the design and construction of their engines, has accepted a position with the William Tod Company, of Youngstown, Ohio, as consulting engineer.

MR. SEWARD BABBITT, for a number of years sales agent for the William Tod Company, of Youngstown, Ohio, resigned his position on the first of January to accept a position with the De La Vergne Refrigerating Machinery Company, of New York City, where he will devote his time to the sale of the Koerting engine.

MR. W. J. JOHNSTON has sold to Mr. M. M. Swetland his stock interest in the Johnson Publishing Company which owns the *Engineering and Mining Journal*, and has severed his connection with that publication. Mr. Johnston will now devote his entire attention to the *Pacific Coast Miner*, which he bought over a year ago.

MR. E. STUTZ will lecture on alumino-thermics at the Massachusetts Institute of Technology, Boston, Mass., on February 25. Mr. Stütz is the American representative of the "Thermit process" controlled by the Chemical and Tin Smelting Works of Th. Goldschmidt, Essen-Ruhr, Germany, with offices at 43 Exchange Place, New York City.

MR. EDWARD N. LAKE, inventor of the Lake divided tile conduit, has accepted a position with the J. Lang Electric Company, of Chicago. Mr. Lake is well known among Chicago engineers, having been at one time chief switchboard draftsman for the Western Electric Company, and more recently on the engineering force of the Chicago Edison Company.

MR. N. S. BRADEN, formerly manager of the Westinghouse Electric & Manufacturing Company's district office at Cleveland, Ohio, has been appointed sales manager of the new Canadian Westinghouse Company, Ltd. Mr. Braden succeeds the late Mr T. C. Frenyear, whose death was announced in these columns last month. Mr. Braden will make his headquarters at Hamilton, Ontario.

DR. C. H. SHARP, engineer of the electrical testing laboratories of the Lamp Testing Bureau, of New York City, has returned from an interesting trip to Europe, where he visited all the principal electrical laboratories. Dr. Shrap gathered a mass of data and information which will enable him to fit up the new laboratories of the company, at Eightieth Street and East End Avenue, with the most complete and modern apparatus.

MR. W. S. MONTGOMERY, for many years secretary and sales manager of the Conover Condenser Manufacturing Company, of Jersey City, N. J., resigned his position with that company on the first of January to assume the management of the Payne Engineering Company, New York City, which is selling agent of the Payne Company, of Elmira, N. Y., builders of simple and compound automatic engines. Mr. Montgomery will locate in the Havemeyer Building, 26 Cortlandt St.

American Electrician.

Vol. XVI. New York, March, 1904. No. 3.

EQUIPMENT OF A LARGE FRENCH RAILWAY POWER HOUSE.

GENERATING STATION FOR THE PARIS METROPOLITAN ROAD.

BY C. DOMAR.

The plant erected in Paris to supply current for the lines of the Metropolitan underground system is one of the largest in Europe. The two sections now in operation are only a part of a great network of tunnels which will soon pierce the entire city. Work on the new sections is now in progress, and when completed, the eight sections will represent a total length of more than 40 miles of underground road.

The central station supplies current for the traction lines through a number of substations located along the road. Most of these are underground. That part of the road adjacent to the central station is supplied either by a direct current generator or from a set of rotary converters. The sub-stations are fed from the main alternators; the high-tension current of 5000 volts being converted to 600-volts direct current by a set of rotaries in each substation.

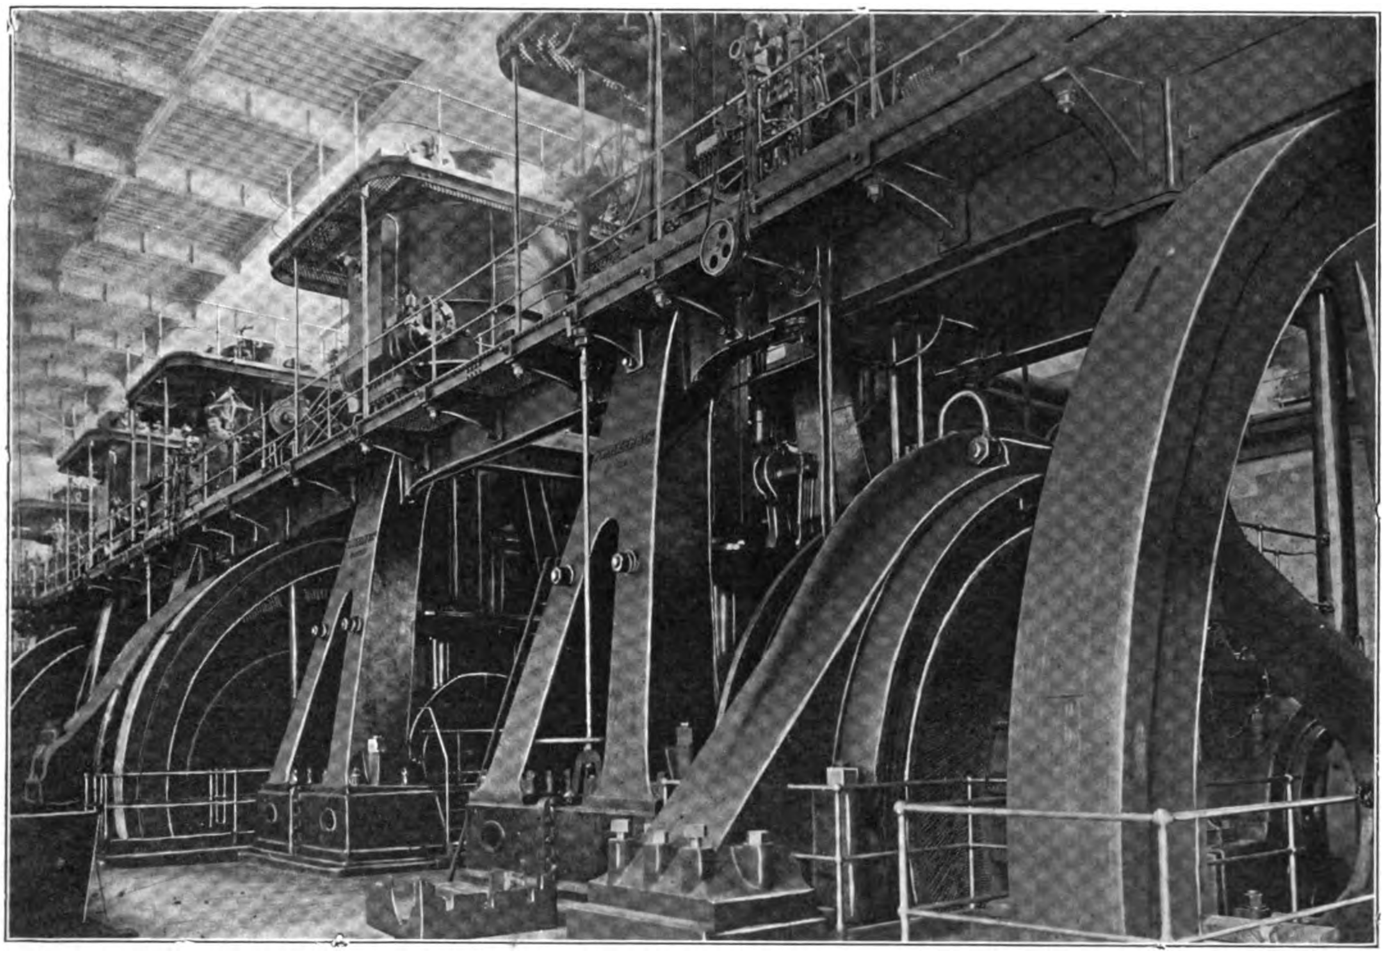

FIG. 1.—GENERAL VIEW OF MAIN GENERATING UNITS.

The plant is on the bank of the Seine at the Quai de Bercy, in the eastern part of the city, and the output is sufficient for the existing lines, but it is now being increased considerably in order to supply new branches of the road. The plant consists of a large office building fronting on the Seine, back of which is the generating station. At present the electrical equipment occupies the central building, with a boiler room on one side; but the dynamo room will shortly be extended back to the Rue de Bercy to accommodate several large generating sets. A second boiler room similar to the first will extend along the other side of the dynamo room and will supply the new equipment.

The main dynamo room at present contains four main generating sets of 1500 kilowatts each, comprising three alternators and one direct-current generator; also four rotary converter sets of 750 kilowatts, with their transformers. The exciting current is supplied by four direct-coupled units. Two booster sets work in connection with a large battery of accumulators operated in parallel on the direct-current bars. The boiler room contains five batteries of six boilers each, with a series of coal-bins having a capacity of 2500 tons. The water for the plant is taken from the Seine through two large conduits. Coal is brought into the station directly from barges on the river by a system of electrically operated conveyors.

A view in the great boiler house of the Metropolitan plant is given by Fig. 2, which shows the batteries of boilers and the system of overhead piping. On the right are the coal bins, from which the coal is fed to the boiler room floor in front of the grates. The additional boiler plant now being erected will occupy a room of about the same size on the other side of the main dynamo room. The boiler plant was constructed by Schneider & Company, of Creusot. These are of the semi-tubular pattern. Three large smokestacks are in use, two of which are placed between the batteries, with the third at the outer end. The supply pumps and feed-water heaters, with the filters, are also placed in the space available between the boiler batteries.

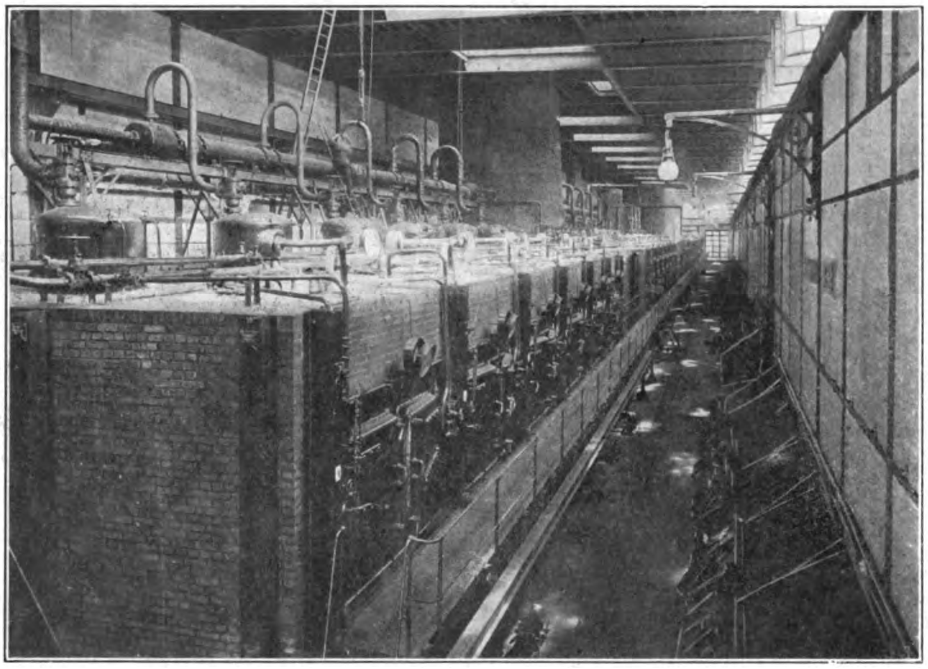

FIG. 2.—VIEW OF BOILER ROOM.

The boilers have a total heating surface of 2800 square feet. A bridge or platform which runs along the front allows the tubes to be cleaned easily. Here are also stationed the attendants who oversee the stoking of the furnaces. The feed-water for the boilers is taken from a reservoir by a set of small feed-pumps. The water passes first through a set of tubular feed-water heaters, which are heated by the steam coming from the exhaust of the pumps, then through the meters and finally to a set of large tanks from which it is sent to the boilers. A by-pass allows the water to pass directly from the tanks to the boilers in case it is necessary to remove or repair the feed-water heaters or the meters. The ash-collecting system has been installed on the most improved plan. Under each furnace is an ash-pit or conduit which runs to a long gallery extending underneath the boiler room. A series of ash-carts circulates in the gallery into which the cinders are fed from any one of the ash-pits by opening a trap. The ash-carts take the cinders along the track to a chamber in one end of the gallery, where they are dumped into the buckets of an upright conveyor which elevates them to the surface. The combination of ash-pits and coal-bins leaves the floor of the boiler room entirely free.

The extensive system of coal conveyors which is used in the Metropolitan station has been well planned, and the entire handling of the coal is carried out by mechanical devices which are practically automatic. Electric motors operate all the conveyors, so that the coal is unloaded from the boats at the wharf alongside the station and then automatically weighed and stored in the coal-bins alongside the boilers in the most efficient manner. A revolving electric crane lifts the coal from the barges and dumps it into a hopper whose mouth is flush with the wharf. The hopper feeds it into a horizontal underground conveyor which passes in a tunnel under the wharf. At the station the horizontal conveyor feeds the coal into a bucket elevator which takes it to the top floor. After being automatically weighed, the coal is taken to the bins by a third conveyor of the horizontal type.

The underground system which passes beneath the wharf is 320 feet long. It is made up of an endless metallic platform composed of a series of sheet-iron sections of channel form having a height equal to one-fourth the width. The platform thus constituted is mounted on an endless chain of the Burton type, which transmits the tractive effort from the electric motor. The sections are provided with a set of rollers which run upon an angle-iron rail attached to the sides of the tunnel. The gallery ends in an underground chamber, where the coal is poured from the conveyor by a chute into the buckets of the vertical conveyor. The latter is 80 feet high and takes the coal through a shaft to the top of the station building. Here is located the automatic weighing apparatus, and the coal is fed from the conveyor by a hopper into the scale, which weighs one ton at a time. An automatic device operates the opening and closing of the gates which feed the coal into the bin of the scale and empty it after weighing into the third conveyor. The latter is made up of a series of buckets and takes the coal in a horizontal direction over the bins. The buckets have a capacity of three cubic feet each, and are provided with rollers which run over a pair of side rails. An endless chain is attached to the buckets and is driven by an electric motor. The buckets are pivoted at the sides and are normally in an upright position throughout the whole conveyor. When in the underneath position the buckets run just over the ceiling of the large chamber which forms the coal-bins. The conveyor has a set of trip devices which can be set by the workman in charge so as to upset the buckets over any one of the openings of the coal-bins. This allows the latter to be fed automatically. The system will deliver nearly 70 tons of coal per hour, and its operation has never given any trouble. The work expended in transporting the coal over a total distance of 600 feet, including an elevation of 80 feet, is only 20 horse-power. As practically all the apparatus is motor-driven, the whole outfit requires the attention of but two men.

The main engines for the large direct-connected groups which occupy the greater part of the dynamo room were built by the Schneider Company, and are of the vertical compound condensing type. Fig. 1 shows the disposition of the direct-coupled sets which occupy a long file in the center of the station, leaving a passageway on either side. The engines have an indicated horse-power of 2600 and operate at 70 revolutions per minute. The diameter of the large cylinder is 72 inches, and that of the small cylinder 44 inches. The piston stroke is 60 inches. The diameter of the main shaft in the bearings is 20 and 22 inches. A heavy fly-wheel is used with these engines, measuring 25 feet in diameter and weighing about 70 tons.

The fly-wheel and dynamo of each group are mounted below the cylinders and the shaft is supported in a bearing at each end which is fixed in vertical columns, with a third bearing between the fly-wheel and the dynamo. The disposition of the direct-current group and the three alternate sets is quite similar. Each group is supported on a foundation 36 feet long by 34 feet wide and 40 feet deep, which is laid below the level of the main floor. On account of the proximity of the plant to the Seine, the work of sinking the foundation had to be carried out by means of compressed-air caissons.

The engines use the Corliss system of valve distribution, and as great regularity is required in running so as to allow of coupling the different alternator groups in parallel under the existing conditions of varying load and sudden shocks, the regulating devices have been made the object of special study. Each engine has two methods of regulation. One of these is a governor of the usual type which acts upon the trip mechanism of the small cylinder. The action of the second regulator is carried out by means of an auxiliary motor which exercises a special regulation on the steam inlet, so as to avoid all racing of the engine which might occur when the load is suddenly thrown off. The motors operate a series of gate-valves which are placed in the inlet of each of the cylinders.

The alternators are of the Ganz type, and have been built by Schneider & Company at the Creusot establishment. These machines have a normal capacity of 1500 kilowatts, but they can easily carry a temporary load of 2000 kilowatts without undue heating. They operate at 5000 volts and 25 cycles, and run at a speed of 70 revolutions per minute. These alternators are of the revolving field type; the field casting, which serves at the same time as a fly-wheel, is built of two simicircular parts which are bolted together. The exterior rim is connected to the hub by eight double arms. Upon the periphery of the casting is mounted a set of 42 field-poles of cast-steel.

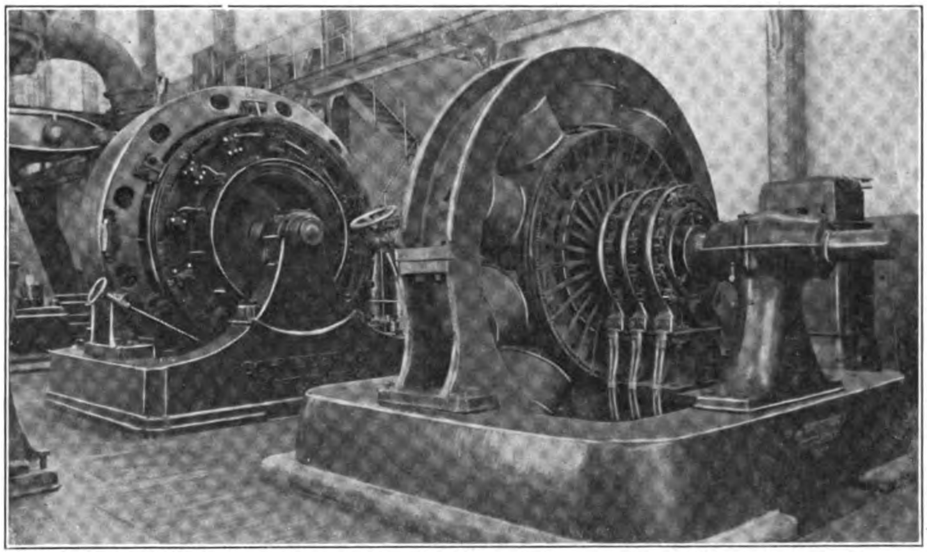

FIG. 3.—ROTARY-CONVERTER SETS.

Special care has been taken to give the field coils a solid construction, and they are forced in place at a strip winding which is forced to place at a high pressure. In this way a tangential speed of 80 feet per second can be reached in the revolving part without danger of the coils becoming loose. The field is connected with the 42 coils in series. The exciting current is brought from a two-ring collector mounted on the shaft which receives the ends of the field winding. An exciting current of 250 amperes and 100 volts is used.

The fixed armature casting which forms the outer body of the machine is built in two half-rings which are bolted together. Around the inner periphey are inserted the laminated sections which from the armature ring. This part of the machine is well ventilated by a series of air-spaces in the laminated portion which correspond to a set of holes in the outer casting. The laminated ring contains 378 slots for the winding; 18 of these are left empty in order to facilitate the removal of the winding. Copper cables are laid in the slots and the three circuits formed are connected on the star system. The active length of armature iron is 18 inches and the field bore is about 20 feet, with an air-gap of 0.3 inch. The revolving part weighs about 29 tons, while the total weight of the machine is 90 tons.

In the foreground of Fig. 1 will be observed the large direct-current generator, which has about the same external appearance as the alternators. It delivers a current of 3000 to 3500 amperes at 600 volts. This machine has been designed so that it is not necessary to shift the brushes when running under different loads, as the lead does not vary more than 5 per cent no matter what the load is. The outer field frame is built in four parts. The frame carries a series of 20 pole-pieces around the inner periphey which are cast with the field. The armature which is mounted on the engine shaft is of the slotted drum pattern. The laminated portion, which is built up on a cast-iron drum, is formed of 0.014-inch sheet iron. In the slots is laid a winding of 2160 copper bars having a section of 750 by 850 millimeters, or 63.75 square centimeters. The armature carries 540 slots, measuring 10.2 millimeters deep and 11.3 wide. The effective length of armature iron is 24 inches. On the side next the fly-wheel may be distinguished the large commutator, which is 25 inches in diameter and 16 inches long. It is built up of 1080 copper strips, insulated by mica. The commutator carries 240 brushes, which are mounted in 20 brush-holders. The total weight of the revolving part of the generator is 38.5 tons, while the whole machine weighs about 55 tons.

The exciting current for the alternators is supplied by four rotary groups, which are situated between two of the main alternators, together with the booster sets. Each of the four exciter groups is formed of two direct-current machines of the Schuckert pattern which are coupled together on the same shaft. The first machine receives direct current at 600 volts and acts as a motor to drive the second dynamo. The latter machine furnishes direct current at 130 volts for exciting the fields of the alternators. These four groups are of similar construction and operate at 650 revolutions per minute. Each exciter has a capacity of 70 kilowatts, which is sufficient to supply two of the alternators.

The station also contains two direct-current groups of 200 kilowatts each which act as boosters and are operated in connection with the large battery of accumulators in the station. These groups are stationed next the exciter sets, and consist of a direct-current motor of the Schneider pattern, direct-coupled to a specially-designed generator which has a capacity of 2000 to 3000 amperes at an e.m.f of from 50 to 100 volts. Both motor and generator are of the 8-pole type. These groups operate at a speed of 325 revolutions per minute. The armature of the generator is provided with two separate windings, which are connected in parallel and run to a commutator of large size. The fields of the motors are connected in shunt, while the fields of the generators are excited in series. These latter machines are placed in series between the direct-current bars and the storage batteries, and serve to regulate the tension of the battery charge and discharge. During the period when the main circuit is but slightly loaded, the main generators are used to charge the storage battery, and in this case the boosters, which are in series in the circuit, serve to give the added voltage which is needed to charge the batteries properly. During the times of heavy load on the direct-current generators the battery is used to help out the machines and is worked in parallel on the circuit, serving as usual to keep the voltage constant and take up the overloads. The boosters give an additional regulation of the voltage so as to secure the proper workings of the machines and batteries in parallel.

The storage battery which is used for this purpose is of large capacity, and is placed in special rooms in the basement of the office building. It is made up of 250 cells of the Tudor pattern. The battery has a capacity of 1560 ampere-hours on a one-hour discharge, but can easily stand a temporary load of 3000 amperes. The terminals of the battery circuit are connected to the direct-current bus-bars of the main switchboard. By using the battery the voltage of the direct-current circuit is kept within 5 per cent of the normal during the varying loads.

Besides the main generating groups and other auxiliary machines, the station contains four sets of transformers and rotary converters. These are designed so as to supply direct current by means of the main alternators of the station and act as a reserve which may be used instead of the large direct-current generator to supply the traction lines which are fed directly from the station when the load does not exceed 1500 kilowatts. The transformers and rotary converters are installed on the same lines as the apparatus in the sub-stations throughout the city. Fig. 3 shows the right-hand half of this plant, which is placed in the forward end of the main dynamo room, and consists of four groups of 750 kilowatts capacity each. Each of the four groups is made up of three static transformers of the 3-phase type, which lower the voltage of the main alternators from 5000 to 430 volts, together with a rotary converter which receives the alternating current at the latter voltage and converts it to 600 volts direct current.

The three-phase transformers are placed in two banks of six transformers each, one on each side of the dynamo room, with the four rotary groups between them. The transformers of one set are of the Ganz pattern, constructed by Schneider & Company, while the second set has been built by the Société des Etablissements, Postel-Vinay, of Paris. The primaries of the Ganz transformers are connected on the triangular or mesh system, while the secondaries are independent. Each of the transformers has a normal capacity of 300 kilowatts, and weighs about six tons, including the case. They are of the upright pattern and are formed of two columns of laminated iron which support the concentric primary and secondary coils. At the base they are fitted into a cast iron supporting piece. A yoke connects the columns across the top, and it is removable so as permit the removal of the coils.

In order to provide for a good ventilation, an air-space is left between the primary and secondary coils. The transformers are air cooled, being placed over an opening in the floor which connects with a horizontal air-conduit running under the bank of transformers. At the end of the conduit is a motor-driven fan. The second bank of transformers has the same general construction.

The rotary converters, whose general appearance will be observed in Fig. 3, are disposed in two pairs. The two machines in front are of the Postel-Vinay make, while the rear pair have been built by the Schneider Company. The fields of the Ganz machines are formed of a circular cast-steel frame made in two pieces bolted together. On the inner periphey it carries 12 cast-steel pole-pieces. The armature is of the drum pattern, with a winding of copper bars of large section lodged in a series of slots in the laminated ring. On the alternating current side the armature is divided into six sections, which are connected to six collector rings. Carbon brushes bearing upon the rings bring the alternating current from the transformers.

On the direct-current side of the armature the commuator of large diameter carries 12 sets of brushes. These rotary machines can be worked as high as 1000 kilowatts for a considerable time without overheating. Their speed is 250 revolutions per minute. The field bore of these machines is 81 inches and the air-gap 0.5 inch. The commuator measures nearly 50 inches in diameter, and the working surface is 12 inches wide. The total weight of these machines is about 29 tons. When working at 1000 kilowatts the rise of temperature above air is not more than 25° C. for the armature and 11° for the field. The maximum efficiency is about 95 per cent when working on full load. The rotary converters of the Postel-Vinay pattern are constructed on the same line. The alternating current is brought from the transformers by a double cable to three collector rings, which will be noticed in the foreground, as well as the special type of brush-holder which has been designed for these machines, carrying six copper brushes.

The apparatus contained in the station makes it necessary to have an extensive switchboard in order to carry out all the different operations, besides providing for the alternating and direct-current feeders. The switchboard, which contains 31 white marble panels, is located in a gallery 16 feet above the main floor, and is reached by an iron staircase. It is laid out so as to provide for the new portion of the Metropolitan plant. When the new machines have been erected there will be seven panels for the three-phase alternators and one panel for the main direct-current generator. The exciter sets require four panels, and the booster sets each one panel, with one for the storage batteries. The rotary converter groups use four panels. The high-tension feeders which lead to the sub-stations in the city require eight panels, and the station lighting and power circuits three panels. The latter are placed below the main switchboard.

The Bercy plant has been in operation for some time past, and is called upon to provide for the constantly increasing traffic on the Metropolitan lines. The successful running of the station is largely due to the efficient supervision which is given by its director, M. A. Faiveley, a prominent electrical engineer of Paris.

AUTOMATIC DAMPER REGULATORS.

BY R. T. STROHM.

To maintain a uniform working pressure in a steam boiler, which is a point for which efficient firemen strive, it is necessary to maintain a fixed ratio between the heat supplied by combustion and that taken away by the steam drawn from the boiler. The expedient of supplying more or less fuel to the furnace, as the case demands, is not a good one, when used by itself, since it is wasteful of fuel. For it gives a maximum supply of air when the fire is thinnest and a minimum when the fire is thickest, inas-

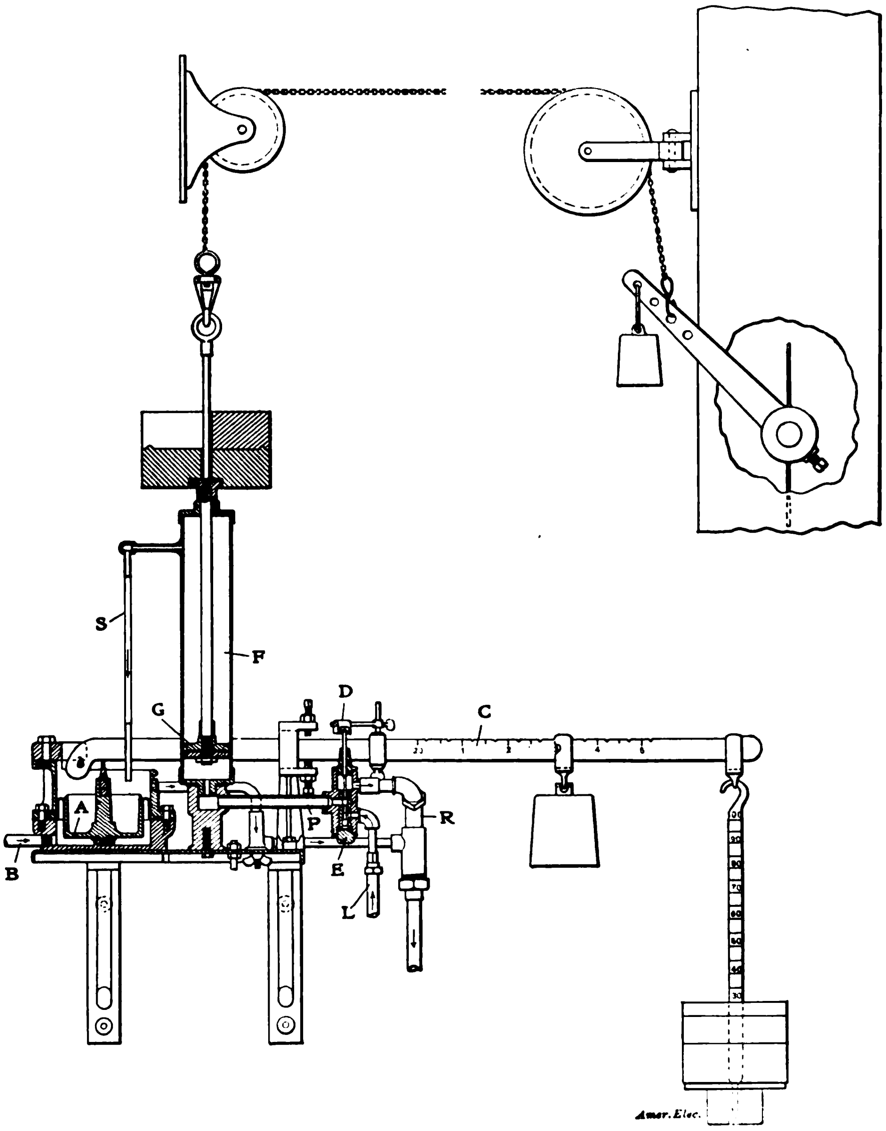

FIG. 2.

much as the resistance offered to the passage of air is less through a thin fire than through a heavy one. The reverse should be observed wherever possible. The thick fire should have the greater air supply and the thin one the smaller.

In order to secure the highest economy of combustion in the furnace, it is necessary to regulate the air supply in accordance with the rate of combustion. In plants where the demand for steam is uniform, it is not a difficult matter for the fireman to maintain a fairly constant steam pressure, since a regular rate of firing and little or no manipulation of the damper are required. But if the demand for steam is variable, so that there is a constant tendency toward fluctuation of pressure, then it will tax the energies and resources of the best fireman to keep the pointer of the steam gauge even approximately steady at the desired working pressure. For, with his numerous duties, it will be impossible for him to adjust the damper just the right amount, and at the right time, to counteract each fluctuation that the gauge may indicate. He could not do so even by devoting his undivided attention and entire time to the task.

The automatic damper regulator obviates the necessity for any such close watchfulness on the part of the fireman. It is automatic in its action, as its name implies, always sensitive to changes in the pressure, and when in proper working order it responds quickly and efficiently to all fluctuations. In doing this, it proves of value not only as a time and labor saver, but also as an economic appliance, since it gives better combustion at the varying rates employed, thereby saving fuel.

The simplest, but also the least efficient type of damper regulator, is that shown in Fig. 1. It consists of a circular diaphragm, *A*, securely fastened between the flanges of two saucer-shaped pieces forming a chamber. Beneath the diaphragm steam at boiler pressure is admitted by the pipe *B*, the upper surface of the diaphragm being subject only to atmospheric pressure. To the diaphragm is attached the rod *C*, having a pin joint connection at *D* with the lever *H*, which is fulcrumed at *F* and provided with an adjustable weight *G* at one end, the other being connected at *E* to the chain *K* controlling the damper movement. As the pressure in the boiler rises, the diaphragm *A* is bent upward at its center, carrying with it the pin *C*, which lifts the weight *G* and lowers the end *E* of the lever, this motion being transmitted by the chain *K* to the damper, closing the latter. When the pressure falls, the weight *G* forces the diaphragm downward, and a counterweight on the arm of the damper opens the latter again. This was the first crude step in automatic damper regulation, and like most first attempts, it was capable of much improvement.

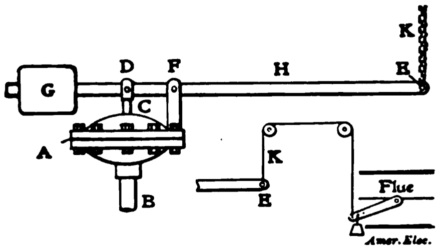

FIG. 1.

In the first place, it was necessary for the pressure to rise sufficiently to overcome the resistance of the diaphragm, the pressure due to the weight *G*, and that due to the weight on the damper arm, before the damper would begin to move. And once started, it would continue to move until the damper had completely closed the flue. In other words, the damper was either fully open or fully closed. This was not very desirable regulation, and as a consequence the successful damper regulator of to-day is a great deal superior to the one just described in all ways, excepting that of simplicity of construction.

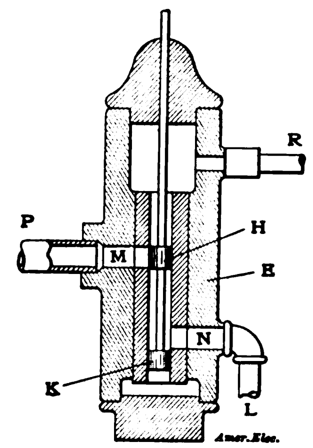

FIG. 3.

Among the many commercially successful regulators of the present day, that shown in Fig. 2 on the opposite page is an excellent representative of the class using a diaphragm and weighted lever to operate a small water valve which controls the motion of the plunger to which the damper chain is connected. Steam at boiler pressure is admitted to the chamber beneath the diaphragm *A* through the pipe *B*. Any motion of the diaphragm is at once transmitted to the lever *C*, the free end of which, owing to the method of pivoting, moves through a considerably greater distance than the diaphragm. This lever is weighted and graduated, so that the regulator may be set to act at any desired pressure by simply adjusting the weights. Rigidly attached to the lever *C* by an adjustable arm *D* is the water valve *E*, of which a larger view is shown in Fig. 3. This valve permits the flow of water, at the pressure in the main, to or from the hydraulic cylinder *F*, in which the piston *G* slides and with which the damper is connected.

When the steam pressure gets slightly above the desired working pressure, the diaphragm rises, since the weights have been so adjusted as to make the lever sensitive to very small changes of pressure. The lever *C* is thus lifted, and in turn lifts the stem of the water valve *E*. To this stem are attached the small pistons *H* and *K*, Fig. 3. The upward movement of the stem causes the piston *H* to open slightly the port *M*, and water under street pressure flows from pipe *L* through the ports *N* and *M* into the pipe *P*, and thence to the cylinder *F*, raising the piston *G* and shutting the damper. If the rise in pressure is considerable, the piston *H* uncovers port *M* fully, due to the greater rise. But at the same time the piston *K* rises an equal amount, and partly covers the port *N*, thus throttling the incoming water, and preventing the damper from being completely closed at one stroke. When the pressure falls, the lever *C* descends, forcing pistons *H* and *K* downward. The piston *H* thus uncovers the port *M* at its upper edge, and the weights on plunger *G* force it down, the water in the cylinder escaping through the port *M* to the overflow at *R*. The valve *E* is provided with a bushing which is quickly and cheaply renewable, so that the pistons *H* and *K* may always be in good condition. Any leakage of water past the plunger *G* flows out through the drain pipe *S* into the diaphragm cup and thence into the overflow by suitable pipes.

The advantages of this regulator over that shown in Fig. 1 are easily recognized. It is far more sensitive, since the diaphragm and lever are used simply to move a small valve having little friction, whereas, in the former case, the damper was controlled by the main lever. The use of water under pressure makes it possible to move heavier dampers than could be operated by the direct-acting lever.

The use of the diaphragm and weighted lever is a feature of many regulators, but the methods employed to secure a proper motion of the damper piston are varied. In Fig. 4 is shown a very ingenious mechanism. Boiler pressure is allowed to act on the under side of the diaphragm *A* through the pipe *B* and the connecting port, thus raising the lever *C*, which causes valve rod *D* to rise also, carrying with it the rod *E*, to which is attached the water valve. As the valve ascends, it opens the port *F*, allowing water under pressure to enter from *G*, and forces the piston *H* downward. This piston being attached to the wheel *J*, by a chain, causes the latter to turn. On the same shaft with *J*, but outside the casing, is another chain wheel *K*, on which the damper chain is wound. When the pressure falls, the weight on the damper lever returns the parts to their original position. The port *F* is then put

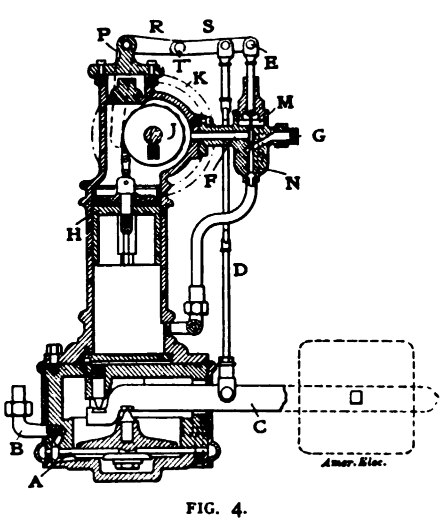

FIG. 4.

in communication with the chamber *M*, allowing the water above the piston to escape to the drip by way of the port *N*, shown dotted.

The mechanism employed to give the damper a partial stroke, so as to prevent its going completely shut at one movement, is extremely interesting. A skeleton view of this mechanism is shown in Fig. 5. A cam is attached to the shaft carrying the wheels *J* and *K*. This cam turns with the shaft, so that when the piston *H* descends and the wheel *J* revolves, it forces the end *P* of the bell-crank lever to the left, causing the other end *R* and the joint *T* to move downward. The arm *S* being jointed to the rods *D* and *E*, swings on the end of the rod *D* as a fulcrum and further raises the rod *E*, which shuts off the water and brings the damper to a standstill. This action is repeated, as the pressure rises, so that the closing of the damper is a succession of short movements, and not a continuous movement.

Still another type of hydraulic regulator is illustrated in Fig. 6. This one, however, dispenses with the diaphragm common to the foregoing regulators. The steam at boiler pressure acts on the upper side of a small piston, *A*. When the pressure rises beyond the desired limit, this piston descends, depressing the short end of the lever *B* as well as the water valve *C*. The upward movement of the longer end of the lever *B* lifts the slotted weight *D* by the chain, so that it no longer rests on the lower lever *N*. At the same time the valve *C* admits water from the inlet *H* to the water cylinder *K* through the port *J*, forcing the piston *M* downward and raising the free end of the lever *N*, to which is attached the chain leading to the damper. However, as the lever *N* rises, it picks up the weight *D*, which checks its motion somewhat, and the damper steadily closes. But, the lever *B* being thus relieved of a portion of its weight, is depressed still further by the steam pressure on *A*, and the valve *C* is completely closed. When the pressure falls to the normal point, the parts return to their former positions, the valve *C* opening the port *J* and permitting the water to be discharged through the overflow *P*. The transfer of the weight *D* from the upper to the lower lever gives the damper an intermittent, rather than a continuous motion.

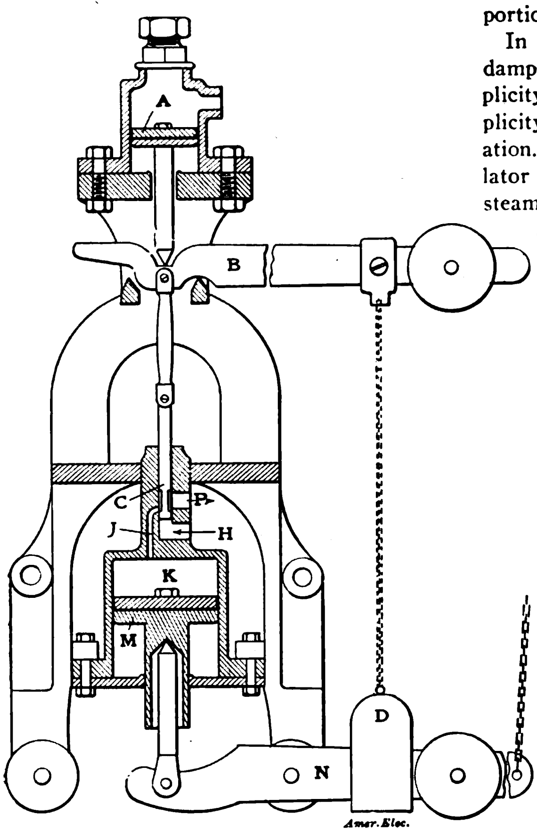

FIG. 6.

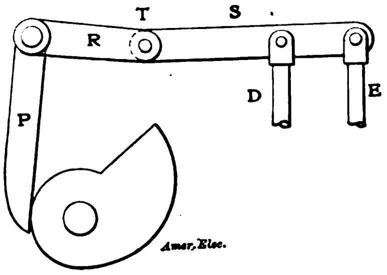

FIG. 5.

In the types thus far mentioned, the principle has been identical. That is, a piston is moved by hydraulic pressure, its motion being governed by a water valve the position of which is determined by the boiler pressure. The only marked differences in the foregoing devices have been the means of securing a movement of the damper proportional to the change in pressure.

In Fig. 7 is shown a mercurial column damper regulator, the constructional simplicity of which is parallelled by the simplicity of the principle involved in its operation. The sketch shows this type of regulator as designed for boilers carrying high steam pressures. As can be seen, it consists of two mercury columns precisely alike in construction, and joined end to end. The pipe *A* transmits the boiler pressure to a chamber *B*, in which it acts upon the surface of the mercury, forcing it up into the arm *C* and chamber *D*, partly filling the latter. The upper end of the chamber *D* and the whole of the pipe *E* are filled with water, which transmits the pressure to the second mercury chamber and column. This second column has at its upper end an open vessel, *F*, in which floats a cast-iron cylinder, *G*, to which is attached the rod by which the damper is moved. Thus, the boiler pressure plus the pressure due to the water columns in the pipes *A* and *E* just balance the sum of the pressures due to the two mercury columns. When the boiler pressure rises, the condensation in the pipe *A* transmits the pressure to the surface of the mercury in the chamber *B*, depressing it and causing the mercury column *C* to rise. The transmission of pressure continues through the second column, and the level of the mercury in the vessel *F* rises. The specific gravities of mercury and of iron being very different, the iron has been floating in the vessel *F*. As the mercury rises, the tendency is to float *G* as before, but at a higher level, and this movement of the cast-iron cylinder shifts the damper further toward its closed position.

A column of mercury 2 inches in height and one square inch in cross-section weighs approximately one pound. Hence, for every variation of one pound pressure in the boiler, the mercury level in the vessel *F* is changed 2 inches. The connection with the damper is made by a short lever, so that this amount of variation will suffice to swing the damper through its entire range. In other words, the limit of variation of pressure is one pound. Furthermore, the rise or fall of the weight *G* is directly proportional to the variation in pressure in the boiler, and the movement of the damper is simultaneous with the change of pressure since there is no intervening mechanism as in the types previously described.

When the pressure carried in the boiler is ordinary, a single column is sufficient. That is, the pipes *A* and *C* and chambers *B* and *D* may be dispensed with, and the pipe *E* connected directly to the boiler. In the case of low-pressure boilers, such as are employed for steam heating, the cylinder *G* may be made hollow, and weighted at its upper end to give the necessary sensitiveness.

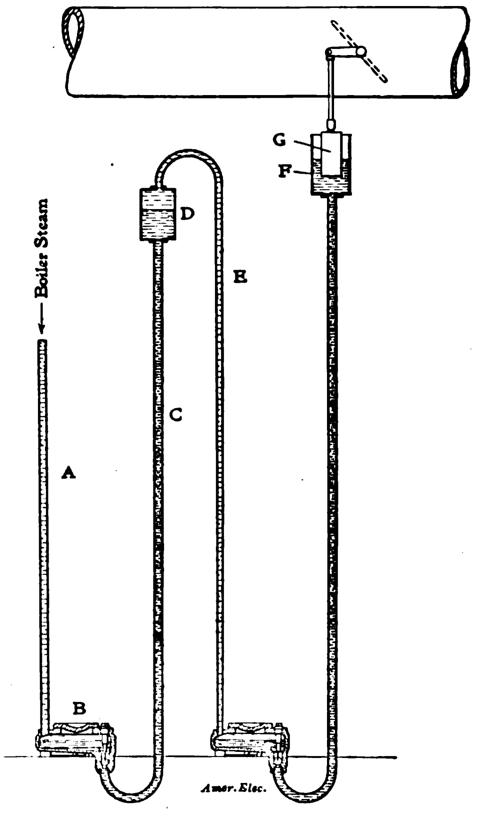

FIG. 7.

The construction of the mercury chamber *B* is shown clearly in Fig. 8. When under pressure, the mercury stands at about the level shown, thus presenting a large surface upon which the boiler pressure may act, and it requires only a slight depression of this surface to cause the level in the chamber *D* to rise considerably. At the outlet leading to the pipe *C* is a perforated plate, *H*, held to its seat by the spring *J*. Beneath this plate is a small casting consisting of four vanes recessed at their lower edges so as to form a cage for a small steel ball, *K*. The outlet is faced so as to form a seat at *M, M*, against which the ball may rest to form a tight joint. The purpose of this device is to prevent any loss of mercury due to undue increase in steam pressure, which might, if great enough, force the mercury out of the tubes. When the regulator is in proper working order, the steel ball floats in the mercury, leaving the outlet to the pipe *C* free and unobstructed. If, however, the pressure should rise abnormally and force all the mercury out of the chambet *B*, the ball *K* would then fall to its seat and close the outlet, preventing any further movement of the mercury column in the pipe *C*.

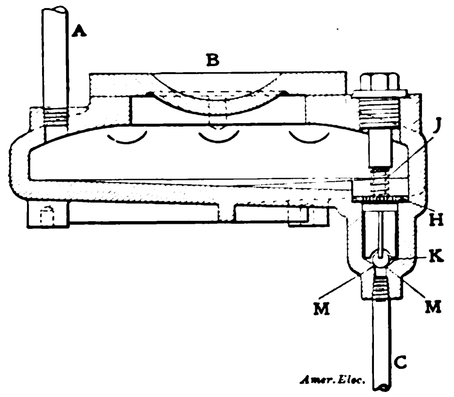

FIG. 8.

The degree of closeness with which the damper regulator will act is dependent largely upon the nature of the load to which the plant is subjected, and also, in a measure, upon the type of boiler. For example, if we consider a lighting station in which the load curve at its maximum is very nearly straight, the demand for steam will be uniform and the regulation will be an easy matter. Under these conditions, or in any other plant where the load is fairly constant, there should be no trouble in securing close regulation. But in a street railway power station things are radically different. The load on the engines is extremely variable, and this in its turn gives a varying demand for steam. Under such conditions it is impossible for the damper regulator to effect extremely close regulation, for the very reason that it requires time to accelerate the rate of combustion, or decrease it, sufficiently to affect the steam pressure. The steam engine governor acts very quickly and regulates very closely. But the damper regulator governs the steam pressure through the auxiliary process of combustion, which requires appreciable time.

The limits of variation of steam pressure as given in catalogues of damper regulator manufacturers are different, as might be expected. But the general statement is made than the variation should not exceed two pounds, between extremes. Nearly all makers state that their regulators are sensitive to changes of one pound in pressure, while some claim that a variation of a quarter of a pound, not detectable on the gauge, is sufficient to cause movement of the damper. The friction of the damper, and of the working parts of the regulator, would affect the sensitiveness to a great extent. Under very perfect conditions, it is probable that a damper could be regulated at a variation of one-fourth of a pound. But if the regulator will work continuously on a fairly steady load, allowing a variation, between extremes, of not more than two per cent, it may be considered as doing very satisfactory work. If the load is very erratic, a maximum variation less than five per cent of the working pressure may be considered as a creditable performance.

As mentioned previously, the boiler type also enters into the regulation question. The water tube boiler is a much more rapid steamer than the return tubular. The bulk of water contained in it is also considerably less than in a return tubular boiler of equal evaporative capacity. As a consequence, there is a greater liability to sudden fluctuation of pressure in the former than in the latter, and correspondingly greater difficulty in obtaining the same closeness of regulation.

In some cases, a single regulator is used to operate a large damper in the main flue or in the stack leading from a battery of boilers. In other places several individual dampers, in separate boiler flues, are connected to one shaft and operated by one regulator. Although under favorable circumstances this might do very well, it does not seem advisable to make the practice general. With a single regulator controlling the draft for a number of boilers, either by one main damper, or a number of connected individual dampers, it is essential that the fires be kept in a practically uniform condition, to avoid fuel waste. Unless this is done, one boiler will be given the greatest draft when it needs it least, perhaps, or the least draft when it requires the most. It would seem that by far the most desirable way would be to use a regulator for each boiler, thus assuring independent regulation for each unit.

The damper regulator, while being an automatic device, needs a certain amount of care and attention to keep it in proper working order. It has a certain number of moving parts which will wear, and which must be readjusted or replaced at intervals. In order to minimize the friction and the wear in regulators working by water pressure, it is usual to provide a lubricator on the pipe delivering the cold water to the motor cylinder. This lubricator consists of a small chamber in which is placed a piece of hard soap, which slowly dissolves, softening the water and lubricating the inner surfaces of the water cylinder. This chamber may also be used as a settling chamber, for the collection of sediment brought in by the water. To prevent the ingress of larger pieces of foreign matter, a strainer may be placed in the water supply pipe.

THE LAMME SINGLE-PHASE RAILWAY MOTOR.

The British patent on the Lamme single-phase railway motor has issued, and the specification contains a full description of the machine, together with a fairly complete exposition of the principles embodied in its construction. The following is a copy of the salient portions of the patent specification as printed by the London *Electrician*.

The invention has for its object the construction of an improved series-wound motor for use with single-phase alternating current. Hitherto alternating currents have been applied to operate series-wound motors, but considerable difficulties have arisen in the form of undue heating, excessive sparking of the brushes and low efficiency, together with poor regulation. The inventor states that he overcomes these defects, not by merely modifying the arrangement of parts of the ordinary series-wound motor, but by providing that certain definite proportions and relations shall subsist between such parts, together with various novel features in the construction of the motor.

Since the self-induction of the field-magnets and the counter e.m.f. set up by the armature are both dependent on the strength of field, a relation subsists between them which is proportional to the speed of rotation of the armature, the relative ampere-turns and the frequency. A higher speed, a low frequency and few turns on the field-magnets compared with those on the armature, will give a lower ratio of the field self-induction to the armature counter e.m.f. Both the field strength and the armature magnetic lines of force increase with the current supplied to the motor, and if saturation is not approached each of these will increase directly as the current, and, therefore, the torque which is produced by them jointly will increase as the square of the current, which would be a highly advantageous condition for electric traction work. Increase in strength of field, however, is accompanied by augmented self-induction which must be reckoned with. Inasmuch as the resultant of all the e.m.f.'s is equal to the applied e.m.f., increase in self-induction would result in a fall of speed, and if the self-induction of the motor becomes relatively high, the speed will fall very rapidly. Conversely, if the strength of the field be kept constant its self-induction will be constant, and, consequently, the armature speed will not fall unless its own induction be very high.

In the two cases above stated the first is that in which the strength of field is approximately proportional to the strength of the current, and in the second case the field magnetic strength is constant. As previously pointed out, the first case provides favorable conditions for electric traction, but it is limited by the fact that the maximum torque which can be developed may be insufficient for maximum requirements. In the second case the torque is not so limited, but on the other hand the general characteristics of the motor may not be suited to given conditions of working. It is therefore advantageous to proportion the motor so as to combine the two cases and thus secure conditions through a certain range of working in which the field strength is approximately proportional to the current, and have the motor capable of developing the required torque. It has been pointed out that the limitation in the torque developed when the field magnetic strength increases in proportion to the current, is due to the rapidly increasing self-induction of the field as the current is increased. It is desirable, therefore, to provide means for limiting the self-induction so that when a heavy torque is required, the self-induction shall permit a sufficient current to flow to produce the required torque. As the cross-induction of the armature through the poles acts with the self-induction of the field in limiting the flow of current, it is desirable that this should also be kept within proper limits.

The relations between the field self-induction and the armature counter e.m.f. may be expressed as follows: Self-induction of field = alternations × field turns in series × induction per pole × a constant. The counter e.m.f. of the armature = revolutions × the number of armature wires × induction per pole × a constant.

$$\frac{\textit{Field self-induction}}{\textit{Armature c.e.m.f.}} = \frac{\textit{Line alternations} \times \textit{field turns in series} \times \textit{induction per pole}}{\textit{Revolutions} \times \textit{armature wires} \times \textit{induction per pole}} \times \textit{constant};$$

since armature wires = 2 × poles × armature turns in series.

$$\frac{\textit{Field self-induction}}{\textit{Armature c.e.m.f.}} = \frac{\textit{Line alternations}}{\textit{Poles} \times \textit{revolutions}} \times \frac{\textit{field ampere-turns}}{\textit{armature ampere-turns}} \times \frac{\textit{constant}}{2}.$$

The constants are dependent upon the characteristics of the supply circuit and upon the units in which the different terms are expressed; their values are determined in any given case according to well-established laws, and the armature winding is assumed to be of the usual parallel type.

In a direct-current motor the armature alternations are equal to the product of the revolutions multiplied by the number of poles, and, since this relation may be assumed to obtain in a series alternating-current motor the foregoing formula may be further simplified by substituting the term "armature alternations" for the term "poles × revolutions." It has been pointed out that the self-induction of the motor should be relatively low as compared with the applied e.m.f., since the resultant of the self-induction of the motor and the counter e.m.f. is approximately equal to the applied e.m.f., and it follows that the self-induction should be low in proportion to the counter e.m.f. of the armature in normal working. The relation between the two is expressed in the foregoing formula.

In order that the ratio between the field self-induction and the counter e.m.f. of the armature may be low, it is clear that there must be a small number of line alternations, a large number of poles and a high speed, and a small number of ampere-turns and a relatively large number of armature ampere-turns. The ratio of field ampere-turns to armature ampere-turns has, generally, a minimum value which is fixed by the proper operation of the motor itself. If the field ampere-turns are too small as compared with the armature ampere-turns, the magnetic field will be distorted and good commutation will be difficult. The minimum ratio of field ampere-turns to armature ampere-turns is dependent upon many factors in the design, but in general it may be said that this ratio should be greater than 0.5, and may sometimes be as high as 0.75.

Therefore, when definite limits have been assigned to two of the ratios in the last equation—namely, the ratio of field self-induction to armature counter e.m.f., and the ratio of field ampere-turns to armature ampere-turns, then there is a definite relation between the alternations in the supply circuit, and the product of the number of poles of the motor and its rate of revolution. An average working value for the ratio of field ampere-turns to armature ampere-turns is approximately 0.625, and it has been found that the expression $\frac{\textit{constant}}{2}$ in the foregoing formula closely approximates the reciprocal of 0.625—*i. e.*, 1.6, so that the last two ratios of the formula cancel out, leaving only the ratios of field self-induction to armature counter e.m.f. and line alternations to armature alternations, for which definite limits are fixed, as hereinbefore pointed out. With a given number of revolutions, the number of poles must be directly proportional to the alternations in the supply circuit. Thus, for instance, if an eight-pole 700-revolution motor of a certain capacity is required for 2000 alternations per minute, 3000 alternations per minute will require a 12-pole motor at 700 r.p.m.

The forgoing considerations indicate the conditions required for securing a relatively low self-induction of the field of the motor. The field self-induction and the armature self-induction may both be limited by special construction of the pole-pieces. For instance, slots or holes may be cut in each of the field magnet poles near the pole-faces and parallel with the machine axis, the amount of iron left at the back of the slots being that which is required for the desired induction. The slots or holes may be closed, or nearly closed, at the pole faces, and usually this is preferred, as open slots increase the magnetizing power required in the field winding which, in turn, necessitates more field turns, and results in greater field self-induction. The cross-section of iron in the poles is preferably such that but little magnetizing power is absorbed in addition to that required for the air-gap until the current exceeds the normal rated amperes of the motor, when the teeth between the pole slots rapidly approach saturation. In order to secure this result, the parts in which the cross-section of the magnetic circuit is reduced should be of comparatively short length, but should, of course, be worked at a high induction. It is not necessary or desirable to subject the whole yoke to a high induction, as the desired results can be obtained by having a short length of small cross-section, whereas, if the whole yoke be subjected to a high induction, the losses due to reversals in the core will be objectionably large, and also the magnetic leakage into the surrounding frame and through the field windings will be objectionable.

The self-induction of the armature which results from a cross-induction through the poles, in which the magnetic lines enter at one edge or side of the pole and pass through the core to the opposite edge or side, is also reduced and limited by the arrangement of slots or holes described, and which would not be obtained in the same degree if the whole yoke were saturated, provided the field cores in the two cases required the same number of ampere-turns in the field for magnetizing them. The smaller the section of the pole teeth and the more highly they are saturated, the less will be the cross-induction with a given current in the armature. The magnetic reluctance of the field circuit is concentrated near the pole-face instead of being distributed through the whole yoke.

The total useful flux through the armature and field sets up no effective e.m.f. of self-induction in the armature windings, as it will add to the counter e.m.f. at one part and subtract at another part of such winding. But the e.m.f set up by the cross-induction does not neutralize itself in the same way, and thus becomes an e.m.f. of the same character as that set up in the field windings. The cross-flux from the armature may be further limited by the suitable interposition of a secondary circuit, if desired. For example, if a slot at the middle of the pole contains a conducting plate or closed coil, it will oppose the magnetic flow which would tend to cross the slot. If the ends of a conductor placed through the middle slot be connected with the outer frame of the machine at each end, or if the conductor be closed around the outside of the yoke, then the secondary circuit thus formed will oppose the flow of the cross-induction which tends to pass through the section of iron back of the slots.

The armature winding of the motor is of the closed coil type and is closed upon itself before being connected to the commutator, relatively high resistance leads being inserted between the winding and the respective commutator bars. As the magnetic field of the motor is alternating, any short-circuited turn through which the magnetic flux from a field-pole passes will have a secondary current set up to it. By the well-known laws of the transformer the ampere-turns in such short-circuited secondary will approximate the ampere-turns in the primary winding, which is, in this case, the field-magnet winding. Certain coils of the armature winding are short-circuited through the brushes when the adjacent commutator bars to which the ends of the coils are connected are bridged by the brushes, and when the latter are located in neutral positions or without lead, the short-circuited turns surround the paths of the magnetic flux and are, therefore, good secondary circuits in which relatively large secondary currents are set up by induction. This is the principal cause of the excessive sparking in series motors of ordinary construction, when it is attempted to operate them upon an alternating-current circuit. In order to obviate destructive sparking, the current in the short-circuited turns of the armature coil should be limited to an amount materially less than what would normally flow. By inserting a definite amount of resistance in each of the leads between the closed winding and the commutator bars, it is possible to so limit the secondary current due to the alternating field flux as to prevent injurious sparking. The working currents in the armature winding pass through these resistances only at the bars in contact with the brushes, because the armature winding is closed on itself inside or beyond the resistance leads.

With a given current in the motor, each armature coil which is short-circuited by a brush will tend to have the same e.m.f. set up in it irrespective of the e.m.f applied to the motor. Therefore, the resistance in the leads may be such that the short-circuited current developed will be limited in amount, and, generally speaking, with full-load current in the motor; the resistance should be such that the short-circuit current will not exceed, say, twice the value of the full-load current. The resistance in each short-circuit will include the resistance of the turn itself plus the resistance of two of the leads, plus also the resistance of the brush-holders and brushes.

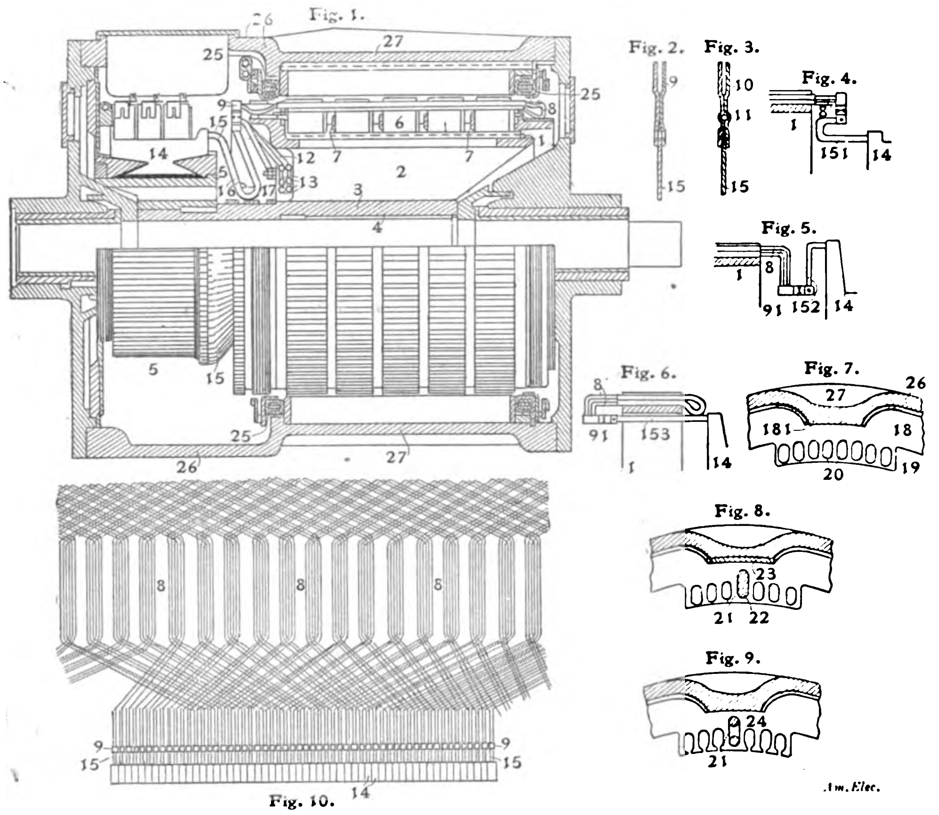
As will appear from what has already been stated, the conditions for suitably low self-induction and for a proper ratio of field ampere-turns to armature ampere-turns practically determine the number of poles the motor should have with a given rate of alternation and speed. This motor will require a relatively larger number of poles as compared with direct-current motors of corresponding size. Moreover, the conditions of good commutation are that the armature circuits of the motor be connected in parallel, and that the number of turns between consecutive armature bars be small. It follows, therefore, that the voltage of the motor is definitely limited, and it is found that the actual voltage is low relative to that for which direct-current motors may be wound—such, for example, as motors employed in ordinary electric traction. While this characteristic would be a serious limitation in connection with the distribution of energy for direct-current traction motors, it is of minor consequence in connection with alternating-current motors, since transformers may be interposed between the supply circuit and the motors, and these may be designed to receive practically any voltage from the line and to deliver any desired voltage to the motors. In service, a motor may require either a constant voltage or a variable voltage. For variable speed work the variable voltage is usually desired. A variable voltage may be obtained by the introduction of resistance or self-induction into the circuit or, preferably, by means of a transformer in which the rate of transformation is suitably changed.

The several elements which are involved are the motor, the controller, the supply circuit and the transformer. The motor, as has been pointed out, has inherent limitations as to the voltage for which it can be wound, which are independent of the transformers, the controller and the voltage of the supply circuit. The current and the voltage which can be more advantageously handled by the controller may be entirely different from those of the motor. For example, it may be advantageous to design the controller for one-third of the current and three times the voltage which are required by the motor. The line voltage may, in turn, be entirely too high to be introduced directly into the controller or the motor. It follows, therefore, that the voltage of the supply circuits and their respective currents, which may be most advantageously utilized, may be widely different. It is possible, however, by means of one or more transformers, to operate a motor adapted to any voltage by a controller adapted to any voltage from a supply circuit of any voltage. A convenient method of control consists in connecting a main transformer across the supply circuit, its secondary being included with the motor circuit, but having included in series the secondary of a series transformer, the primary of which derives current either directly or indirectly from the main circuit, and is capable of adding to or subtracting from the e.m.f. developed in the secondary of the main transformer.

This invention is applicable in cases where frequent starting is required, as, for instance, in electric traction systems. It is now the common practice in operating electric cars to have two or more electric motors upon each car, and for the purpose of securing varying speeds means are usually employed for connecting the motors either in series or in parallel, and for introducing more or less ohmic resistance into the circuits of the motors. With single-phase motors constructed according to this invention, it is possible to dispense with practically all ohmic resistances for regulating purposes, and it is not necessary to connect the motors successively in series and in parallel for the purposes of regulation, but the motors may be permanently connected either in parallel or in series and all the benefits of the usual series-parallel control as employed with direct-current motors may be obtained by varying the e.m.f. applied to the alternating-current motors. Control by means of variable ratio of transformation in the transformer provides a very much higher degree of economy in starting and at low speeds than is obtained in the usual method of operating direct-current motors where the voltage is reduced by means of rheostats, either with or without the series parallel method of control. The voltage delivered by the transformers is that required by the motor, so that there are practically no losses except those inherent in the transformers and motors, both of which are capable of being so designed as to have high efficiency. With this system, full-load torque or several times full-load torque at starting may be developed with a very small amount of energy from the supply circuit.

In the accompanying drawings, Fig. 1 is a view, partially in side elevation and partially in longitudinal section, of a motor constructed in accordance with this invention. Figs. 2 and 3 are detail sectional views of two of the combined resistance leads and connectors between the armature conductors and the commutator segments. Figs. 4, 5 and 6 are detail views illustrating modified arrangements of resistance leads for connecting the armature conductors with the commutator segments. Figs. 7, 8 and 9 are detail views of different forms of field-magnet core construction. Fig. 10 is a diagrammatic development of a portion of the armature winding and connections between the same and the commutator segments. As here shown, the armature 1 comprises a skeleton open-work frame or spider 2, the hub 3 of which is in the form of a sleeve mounted upon and suitably keyed to a shaft 4, this sleeve being extended at one end to receive a commutator cylinder, 5, which is also suitably keyed to it. The core 6 of the armature is built up in the usual manner of thin plates or laminæ, properly spaced apart at intervals by ventilating spaces 7 and provided with slots, which, in the present case, are 72 in number, in which are mounted the insulated conductors 8 constituting the coils of the armature winding. These coils or conductors, as shown, are of strap copper, the turns of which are located side by side in the slots, forming three separate coils, which span the core from the first to the ninth slot, and so on around the core. The coils are properly joined together at one end of the armature by means of suitable connectors, 9 and 10, so as to form a closed parallel winding. The connectors 10 are provided with sockets 11, in which are fastened the outer ends of suitable connecting wires or strips, 12, the inner ends of which are connected to balancing rings, 13, in a well-known manner.

For the purpose of reducing the secondary currents that are generated by the alternating magnetic field in the coils which are short-circuited at the brushes to substantially non-sparking limits, the connectors 9 and 10 are connected to the several commutator bars 14 by means of relatively high resistance leads 15, as previously described; there being in the present case 216 commutator bars and the same number of leads. These leads are strips of German silver. The commutator brushes are arranged in sets in the holders or arms, and, in the present instance, the arms or holders are eight in number. The brushes and arms may be of usual material and construction and connected in the usual manner to properly co-operate with the commutator and the supply circuit. As indicated in Fig. 1, the leads 15 are bent into substantially the form of U-shaped loops, the inner ends of which are held in place by means of a suitable winding, 16, an insulating band, 17, being interposed between the leads and the sleeve 3 of the armature spider. As illustrated in Fig. 4, the resistance leads 151 are shown as having a substantially U-shaped form, one arm of which extends beyond the other for connection to the commutator bar and the two arms of which are approximately parallel to the armature axis. In Fig. 5 the resistance leads 152 are shown as having each a main body position substantially perpendicular to the armature axis and an outer end which extends approximately at right angles to the body portion for connection to the commutator bar. In this case, the end of the armature conductors project inwardly, approximately parallel to the body portions of the leads, for connection to the connectors 91, which are also substantially at right angles to the body portions of the resistance leads. In Fig. 6 the resistance leads 153 are connected to the ends of the armature conductors, at the end opposite the commutator, and project through the spider to the commutator end, substantially parallel to the axis of the armature. Other forms and arrangements of resistance leads may, perhaps, be divided which will be adapted for the purpose. These shown are such as have been devised to most satisfactorily provide the necessary resistance and, at the same time, be economically and safely disposed in the available space in the motor.



DETAILS OF LAMME SINGLE-PHASE MOTOR.

As has already been pointed out the number of field magnet-poles of the motor must be directly proportional to the rate of current alternation in the supply circuit, and other conditions, which have been pointed out in detail, render it desirable, and, in fact, necessary, for successful operation that the rate of line alternations shall be low, and that the rate of armature alternations shall be relatively high. The motor here illustrated and described was designed for a frequency of 2000 line alternations per minute, and the motor which is adapted to this number of alternations and the other conditions has eight field-magnet poles. The field-magnet core 18 is in the form of a hollow cylinder, and is built up of thin plates or laminæ, the laminated construction being necessary by reason of the fact that the magnetic flux, due to the field-magnet winding, is alternating.

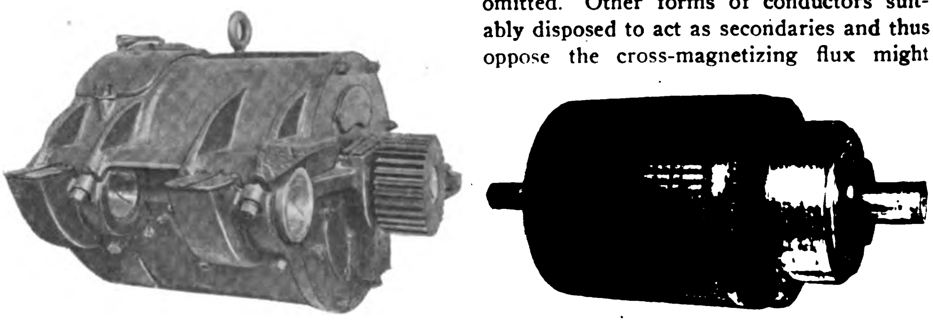


FIG. 11.—VIEW OF LAMME SINGLE-PHASE MOTOR AND ARMATURE.—FIG. 12.

The polar projections or pole-pieces 19 are provided with holes or perforations 20 extending through the same, transversely to the direction of armature rotation, and located in close proximity to the ends of the polar projections or pole-pieces, and the depth of the body portion of the core is reduced at the rear of each polar projection, as shown at 181, in Fig. 7, in order to aid in reducing the cross-magnetization and, consequently, the armature self-induction. The slots 20 are made comparatively shallow in order to keep the iron loss low and at the same time to ensure the desired saturation of the adjacent iron when the current materially exceeds the rated amperes of the motor. These slots may be entirely closed at the pole-faces, as indicated in Figs. 7 and 8, or they may have narrow openings, as shown in Fig. 9, but in every case where open slots are employed the openings should be small. As shown in Fig. 7 there are eight of the holes, 20.

In Fig. 8 are shown six holes, and at approximately the middle of the pole-piece is a hole, 21, which is of materially greater depth than the others. In this hole 21 is located a bar or plate, 22, of copper or other good conducting material, for the purpose of serving as a closed secondary circuit to reduce the armature self-induction due to the cross-magnetization. In Fig. 8 is shown a plate, 23, of copper or other good conducting material, which also acts as a secondary closed circuit to oppose any cross-magnetizing flux which tends to pass outside of the core 18 of the field-magnet. In Fig. 9 the construction is the same as that shown in Fig. 8, except that a single turn, 24, of wire constituting a closed coil is placed in the middle of slot 21, instead of the bar or plate 22, and the plate 23 is omitted. Other forms of conductors suitably disposed to act as secondaries and thus oppose the cross-magnetizing flux might be employed, if desired, those shown being set forth merely as examples that have been found well adapted for the purpose. The field magnet winding 25 is here shown as comprising eight coils of strap copper, bent edgewise and connected in series. In the present case the winding comprises 20 turns, one-half of the coils having three turns and the other half having two turns, and the coils of the two sets are alternately disposed around the core. A greater number of turns may be employed, if desired, provided they are so connected that the number of turns in series does not materially exceed that specified above.

The field magnet core and coils are mounted in a casing, 26, which is provided with extensions at its ends to enclose also the armature and commutator. As shown, this casing projects inwardly, at the backs of the pole-pieces, to constitute supports for the core 18, and is correspondingly hollowed out as regards its exterior, as indicated at 27, so as to lessen the weight of the structure.

Various methods of controlling motors, constructed in accordance with this invention, may be employed, it being preferable, as above stated, to vary the e.m.f. applied to the motors. For this purpose a transformer may be interposed between the motor and the supply mains, and the e.m.f. of the secondary may be varied by varying the number of windings of the primary or secondary, or varying their magnetic relationship in a manner well known in the art. Either a two-coil transformer or an auto-transformer may be employed. Another very convenient means consists in the employment of a three-coil transformer, the third coil of which is connected with the primary coil of a secondary transformer, the secondary coil of which is in series with the secondary coil of the main transformer, as above described. Rheostats or similar adjusting means may obviously be employed in addition to or instead of the means for varying the voltage.

The claims of Mr. Lamme's English patent are as follows:

1. A single-phase alternating-current series-wound motor, in which the ratio of the field-magnet self-induction to the armature counter e.m.f. is approximately equal to the ratio of the line alternations to armature alternations, substantially as described.

2. A single-phase alternating-current series-wound motor having a closed-coil parallel-wound armature with relatively high resistance leads connecting the armature coils with the several commutator bars, and a field-magnet the poles of which have slots transverse to the direction of rotation of the armature and with or without a closed conductor inserted in one of the slots and extending through approximately the central portion of the pole, substantially as described.

3. For use with single-phase alternating electric currents, a series-wound motor having the ratio of the number of its field poles to the number of current alternations per minute approximately as 1 to 250, and having a ratio of field ampere-turns to armature ampere-turns approximately as 20 to 27.

4. Electric motors for use with single-phase alternating currents constructed substantially as described with reference to the accompanying drawings.

TELEPHONE ENGINEERING.

Cable Splices.

BY F. J. DOMMERQUE.

In underground construction splices are required at every manhole, and these occur about every 300 or 400 feet. Splices are of great importance in cable work, because it is usually at the splice where the element of danger for the cable lies. As pointed out in an earlier article, telephone cables rely upon air and paper for insulation material between conductors; and both the air and the paper must be kept dry, or else the insulating qualities will fall below the requirements for good service and the cable will be spoiled. The lead sheath keeps moisture out. If the sheath is cut for a splice, or if two pieces of cable the ends of which are hermetically sealed are opened for splicing, an opportunity is afforded for the entrance of moisture from the surrounding atmosphere and it is remarkable how much moisture is absorbed from the air by the cable, and how quickly it is absorbed. Therefore, dry days should be chosen for making splices; in other words, summer time is the best time for cable work.

It undoubtedly pays to choose experienced men for this kind of work, as one bad splice may spoil a whole section of cable. The time for splicing should be so chosen that all splices can be finished before the work is left in the evening. It is possible in a case of emergency to cover up the end of a cable which is being spliced and boil it out the next morning and then finish the splice, but that is a risky proceeding. It has been claimed as a point against the use of 400-pair cables that splices cannot be easily made without leaving them open over night . A splicer who knows his business can make a good 400-pair splice in a day if he starts in in proper time.

The description of the making of a splice is not sufficient for actual work. A great deal of practice is required to do good work, and bad work on splices should never be tolerated. Cables are only cut for splices when a defective piece has to be cut out. Generally the two sealed ends of two cables of the same size are to be spliced, or one end of a large cable is to be joined to the ends of two or three small cables. When splicing, precaution must be taken that all wires of the same color are joined together. It is not necessary to pay any attention to the numbering of the pairs as the numbering will be taken care of when testing out. When making measurements for ordering cables, splices must be counted in. Three feet should be allowed at each end of a cable which may be used for a splice, a terminal or a pothead connection, in addition to the ends which have to be thrown away in any case.

To splice two cables of the same size, proceed as follows: Cut back the lead sheath of the cables for a length sufficient to give free conductor space on each cable and to reach over the splice; the space required depends on the size of the cables to be spliced. Mark off where the sheath is to be cut and cut around it with an ordinary knife until it is cut nearly through, then bend the cable a few times backward and forward which will cause the sheath to break. Take off the sharp edge left after the short piece of detached sheath is stripped off and remove the paper packing from the conductors, leaving about ¼ inch standing so as to prevent the sheath from cutting the insulation of the wire. Then bind the two cable ends with cotton wicking at the point where the cable emerges from the sheath, drawing the cotton tight enough to prevent the twisted pairs from shifting and to keep the end tight. Then dip the ends of the cable up to and including the cotton wrapping into boiling paraffine (the paraffine being kept boiling during the whole process of making the splice), leaving the ends immersed until no more bubbles are noticed. Then the lead sleeve which is to cover the splice after it is finished, is slipped over one end of the cable far enough back so as to be out of the way while work is being done. These sleeves are obtained from the cable manufacturer and are about ¾ inch to 1¼ inch larger in diameter than the cable, according to its size, and long enough to allow of ample space for the splice and an overlap of 1½ inch or more at each end for the wiped joint, the length increasing proportionately from 18 inches for a 10-pair cable to 40 inches for a 400-pair cable, according to gauge of cable conductor and experience of cable splicer; less experienced men need longer sleeves.

The accompanying table gives the standard size of sleeve for No. 20 B. & S. gauge lead-covered cables used by some prominent telephone companies:

TABLE I.—STANDARD SLEEVE SIZES FOR NO. 20 LEAD-COVERED CABLE.

Size of Cables.	Inside diam. of Sleeve.	Length of Sleeve.
10-pair	1 inch	18 inches
25 "	1½ "	18 "
50 "	1½ "	18 "
75 "	2 inches	18 "
100 "	2 "	18 "
150 "	2½ "	22 "
200 "	3 "	22 "
300 "	3½ "	22 "
400 "	4 "	24 "

For No. 19 B. &. S. gauge cable a size larger than that specified in the table is used.

Many construction men use a frame (like a box with sides and top removed) to hold the two cable ends in place while the splice is made. Such a frame is shown in Fig. 1. The cable ends are then laid into this frame and secured the proper distance apart, which depends upon the length of the lead sleeve. For small cables a distance three inches shorter than the length of the sleeve will be sufficient; for larger cables four inches should be allowed. Now the ends of the conductors have to be turned back so as to get them out of the way. In turning them back, do not disturb the twists in the pairs. Then begin splicing together with the innermost pair by cutting one conductor of the pair of the one cable about 4 inches, and the other conductor of the same pair about 2 inches, from the lead sheath which requires the corresponding pair to reach nearly over the whole splice. Undo the twist of each pair for about 3 inches. Slip a paper tube, from 2 to 3 inches long and soaked in boiling paraffine over one conductor of each pair; then clean each conductor for about an inch back and bend the cleaned ends of the same colored insulation at right angles from the direction of the cable and twist these ends together. Clip off any surplus and bend the twisted end back parallel to the other wires and draw the paper tube over the joint to cover it evenly.

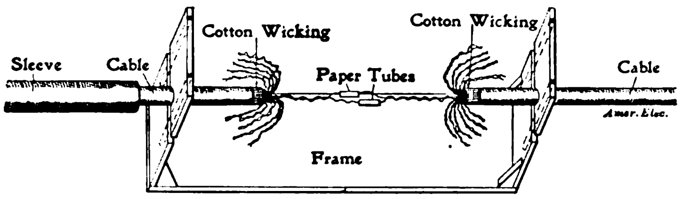

FIG. I.—FRAME FOR USE IN SPLICING CABLES.

Proceed in the same way with the two wires of the same color in the same pairs, but offset the splice enough so that the paper sleeve of one conductor, after splicing, clears the paper sleeve of the other conductor. Then take the next pair and proceed in the same way. As it will be remembered from the description of the cables, there are a number of layers of pairs grouped around a central pair. In order to avoid bunches in the splice, the pairs in each group may be all cut to the same length and spliced, offsetting the groups by about 3 inches. In this manner the joints will be well distributed over the whole splice while the grouping is not disturbed.

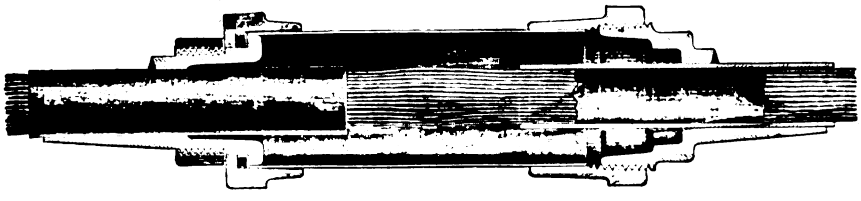

FIG. 2.—LONGITUDINAL SECTION OF CABLE CONNECTOR.

After all joints are made, boiling paraffine is ladled over the splice until all bubbling in the liquid paraffine has ceased. Then twine is wound around the splice to keep the joints in place; or some splicers prefer to wind a strip of white cotton about an inch wide around it and then boil it out again. Next the sleeve is drawn over the splice so as to overlap both ends equally, with 1½ inches of overlap at each end for the smallest size cable and 2 inches or more for larger cables. The ends of the sleeve are then hammered down with a plumber's maul until they grip the lead sheath tight; then the ends are scraped with a plumber's scraper and the process of wiping the joints can begin. First a paper ribbon is pasted around the cable one inch below the sleeve and another one around the sleeve itself. The splicer then pours with the spoon he is holding in his right hand carefully hot solder over the joint, catching what flows off with the piece of leather he holds in his left. The hot solder must be ladled back and forth on the cable and sleeve so as to get it hot enough to wipe without melting the sheath through. The leather in the left hand must retain only as much hot solder as is required to heat the joint enough from below to be able to wipe. As soon as solder and lead mix together, the splicer ceases to pour and wipes the joint, watching it carefully for cracks or blow-holes. The solder used for splicing is the so-called half and half solder, consisting of equal quantities of tin and lead. In Germany they use a solder consisting of 800 parts of lead and 400 parts of tin, by weight, which are melted in a solder pot, stirring with an iron rod. Then 5 parts of sulphur are added and as soon as the sulphur is burned, 3 parts of resin and 5 parts of tallow are mixed; when everything is melted the slag is skimmed off. All "parts" are by weight, and may be ounces, grams, or whatever unit one likes.

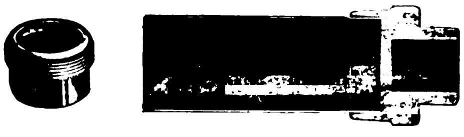

FIG. 3.—POT HEAD.

Finally the splice is to be filled with hot paraffine. For that purpose a hole is tapped into the sleeve (for large cable splices two holes are tapped, each about one-third the distance from the ends of the sleeve) and hot parffine is poured into the hole (alternately into each hole when two holes are used), or the whole splice is immersed in hot paraffine until the sleeve is entirely filled. When the sleeve is cool the holes are soldered up.

A Y-splice is used when two cables are connected to the main cable. It is not necessary that the two cables be of smaller size than the main cable, as it is often advisable to let the main cable continue in its full capacity and take a part or the whole of the conductors to some distributing point to serve a number of subscribers, having the same number of conductors also terminate at some other distributing point so as to obtain the possibility of cutting in subscribers at either point, which renders the plant more flexible and in many cases may effect a considerable saving in operation. This method is known as "multiple cabling." Although this method is frequently employed in aerial cable work, it is mostly resorted to in underground cabling. So far as the splicing is concerned, the difference consists in that in the multiple cabling two conductors are connected to one conductor in the main cable, while in the case of dividing the main cable into two branches only one conductor of one of the branch cables is connected to one conductor of the main cable.

Frequently in multiple cabling a double pothead construction is used instead of a Y-splice. The double pothead has the advantage of easier testing and of the possibility of cutting out one section without disturbing the main cable, when any trouble on that particular section should evolve. The double pothead method has its principal advantage where party lines are in use. The Y-splice of course requires also a pothead, but one only, for connection to the terminal.

A pothead is nothing less than a splice, only in this case one end of the splice is not wiped, but attached to a terminal. The cable end is treated in the same manner as the splice just described. In this case, however, no other cable is joined to the paper cable, but a rubber-covered wire is jointed to each wire in the paper cable. In potheading no paraffine is required except that the paper-covered wires after removal of the lead sheath may be doused with boiling paraffine to keep the paper from untwisting and exposing the wire. The rubber-covered wire is usually of No. 19 B. & S. gauge and the pairs are twisted, one wire being black and the other one red. The pothead sleeves vary in size according to the size of cable. Table II gives their approximate dimensions.

TABLE II.—POTHEAD DIMENSIONS.

10 pairs	Inside diam.	½ in. larger than cable	18 ins. long.
25 "	" "	¾ " " " "	20 " "
50 "	" "	¾ " " " "	20 " "
75 "	" "	1 " " " "	22 " "
100 "	" "	1 " " " "	22 " "
150 "	" "	1¼ " " " "	24 " "
200 "	" "	1½ " " " "	24 " "
250 "	" "	1½ " " " "	24 " "
300 "	" "	1¾ " " " "	26 " "
400 "	" "	2 " " " "	28 " "

The splicer as a rule knows best what dimensions he requires and generally uses his own judgment.

After the splice is made and one end wiped, the pothead must be sealed at the open end. For this purpose, a compound is used, consisting of pitch, asphalt and resin boiled together until it runs freely. In place of pitch and asphalt a prepared insulating mixture, such as "D. D." or Chatterton compound, may be used. This compound is poured into the pothead while boiling and the pouring is continued until the boiling stops and no more bubbles appear. Then a collar is put on by wrapping a piece of leather around the wires and fastening it with rubber tape. The collar is pushed down into the pothead until it is half way in and half way out. Then a little more of the compound is poured in and finally the edge of the lead sheath is trimmed down with a plumber's maul to fit closely against the leather collar; the tapping with the maul should be done lightly so that the edge of the sleeve will gradually turn over and form into a smooth curve. Then the head is fastened in the terminal box.

Lately the New Haven Novelty Machine Company has put on the market a device which it calls "Novelty Cable Connections," designed to do away with the wiped joint which is so trying to make, especially when it has to be done on a pole or on a cable car. The new device is a brass tube provided at the ends with nuts and a gravity joint. Figs. 2 to 5 illustrate some of the connectors of these makers; the following description is quoted from the company's literature:

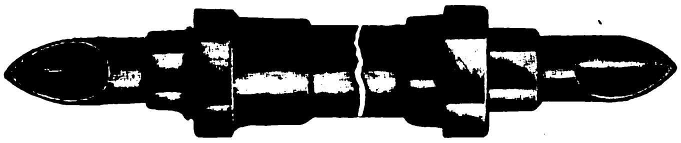

FIG. 4.—PERSPECTIVE VIEW OF CABLE CONNECTOR.

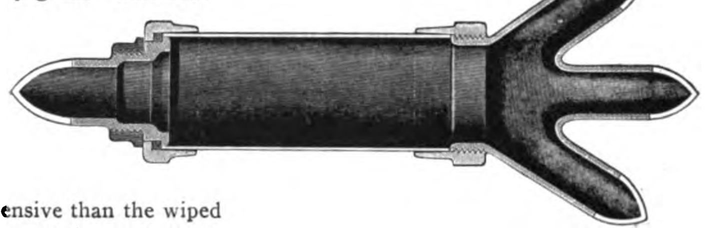

FIG. 5.—BRANCHED CABLE CONNECTOR.

The problem of making the Novelty cable connections absolutely moisture proof has been solved by means of connecting the fittings to the cable by the use of the Novelty gravity joint. The application is simply by heating the solder and allowing it to flow by gravity down the tinned inclined lip or hub, and then to pass the heated iron or blow torch underneath the lip, which causes the solder to flow. This can be done very quickly, does not require skilled labor, and, as it adheres to the cable and supports it a longer distance, is much stronger than the ordinary wiped joint. The Novelty pothead also has the advantage of the slidable sleeve, and further, should occasion require, the pothead being made of brass, it can be heated and the composition contained therein allowed to run off. The pothead further commends itself to users for the reason that it is not necessary to bend the pipe in order to wipe the joint, as at present, nor carry the molten metal up the poles. All that is required is a hot iron to cause the solder in the hub to flow. In cold weather the "compound" or paraffine oftentimes hardens, flowing into the pothead too thick, with the consequent result that it will not be properly or evenly distributed. By the Novelty system, the pothead being made of brass, a blow torch can be applied, which will heat the compound to a boiling point, and thus insure the desired result. This could not be done with the lead pothead. The ends of the sleeve are secured in different ways by the use of the lock nut and tapered screw end. Although it is not absolutely necessary to use any compound in order to make the tapered end moisture proof, the use of Dixon's Graphite Compound is recommended (it having been found by experience that this will not set) in order that the sleeve may be more easily removed at some future time. On the lock nut end it will be noticed that the shoulder of the gravity joint inside the sleeve is milled down and when the lock nut is tightened, this milled shoulder bears on a soft metal gasket, which is an integral portion of the sleeve itself. By removing the lock nut the splice may be opened at any time and as easily closed.

The makers also state that "by the old system it is impossible to open a splice for inspection or test without incurring an expense greater than the first cost of installation, to say nothing of the loss of time and impairment of service caused by the operation." It is certainly true that this Novelty splice has the advantage in testing, but as the old splice is mostly near a terminal the advantage is not so very great. This Novelty splice is more expensive than the wiped joint splice, and the latter has stood the test of time, while the Novelty splice has still to prove its merits. In small plants, however, where only a few splices and potheads are required, it may be difficult and expensive to obtain the services of an experienced cable splicer and the Novelty splice may prove economical on the whole.

◆

CHIMNEYS.

BY CHAS. L. HUBBARD.

The form and size of the chimney is a most important factor in the design of a boiler plant, and should receive careful consideration. The draft of a chimney is due to the difference in weight of the hot gases inside of the flue and of the cold air surrounding it. The draft is usually expressed in inches of water. The intensity of draft is measured by connecting one end of a U-tube containing water with the chimney flue while the other end is left open to the atmosphere; the difference in the level of the water in the two legs of the tube will show the intensity of the draft. A difference of ¼ inch indicates a moderate draft, ⅜ to ½ inch a fairly good draft, and ¾ to 1 inch a strong draft (not forced).

The required area of cross-section for a given chimney depends upon its height and the amount and kind of fuel to be burned. The conditions which affect chimney draft are so numerous and difficult to treat theoretically that it is generally considered best to use empirical formulas derived from the study of existing plants.

The formulas most commonly used are those of Kent, Christie and Gale, of which the first two are the simplest to apply. The constant used in Kent's formula is based upon the assumption that 15 pounds of coal will be burned upon each square foot of grate surface per hour under the draft produced by a chimney 80 feet high. This formula in its different forms is given below:

$$E = \frac{.3\,H}{\sqrt{h}}, = A - .6\,\sqrt{A}$$

$$H = 3.33\,E\,\sqrt{h}$$

$$S = 12\,\sqrt{E} + 4$$

$$h = \left(\frac{.3\,H}{E}\right)^2$$

in which

E = effective area in square feet,
A = actual area in square feet,
H = horse-power of boiler plant,
S = side of square in inches,
h = height of chimney in feet.

In computing the "effective" area (E) from the actual area (A) it is assumed that the gases for a depth of 2 inches next to lining have no velocity, because of friction. That is, the actual diameter of a round chimney, or the side of a square chimney, should be 4 inches greater than the diameter that corresponds to the area required to carry off the gases. Table I

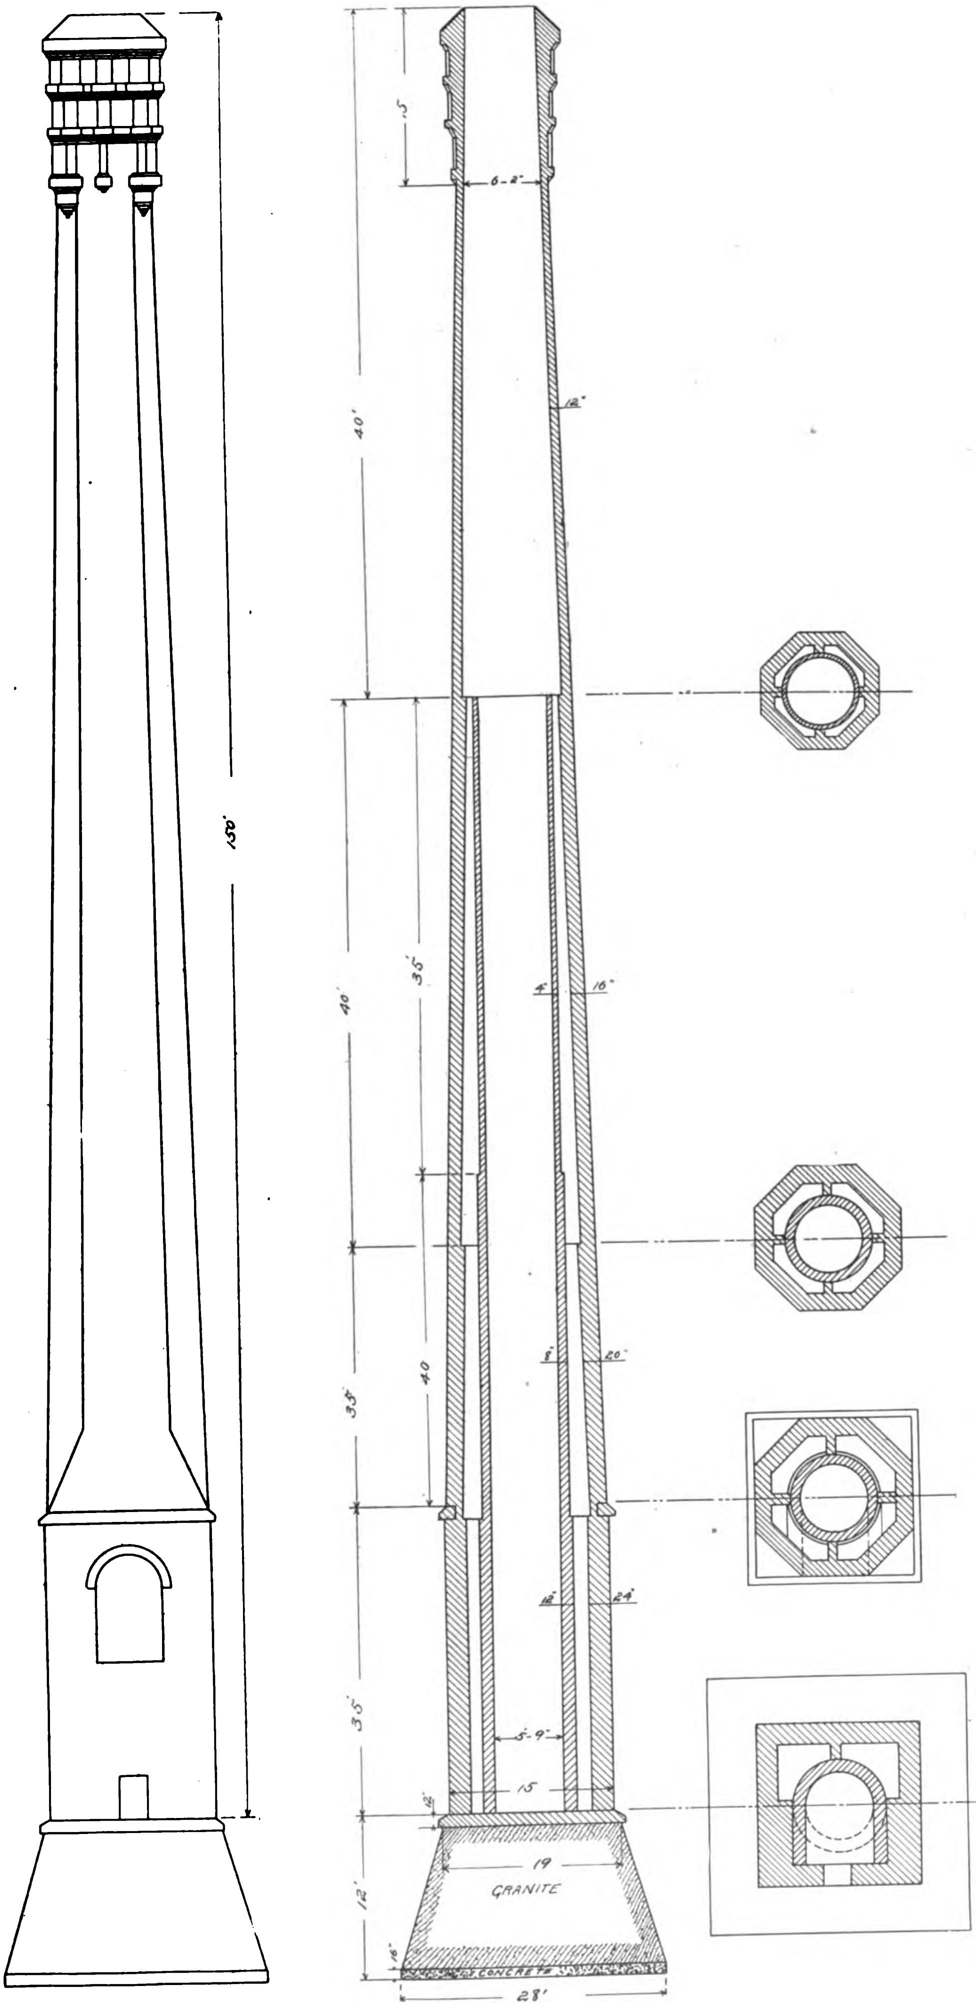

FIG. I.—ELEVATION AND SECTIONAL VIEWS OF CHIMNEY.

has been computed by this formula and will be found convenient to use. In this table it has been assumed that 5 pounds of coal will be burned per horse-power per hour. To find the number of pounds of coal that can be burned per hour by natural draft with any chimney dimensions given in the table, multiply the corresponding horse-power by 5. Only that part of the table is filled in which corresponds to ordinary proportions between area and height, and these general relations should be followed if calculations are made from the formula.

Christie's formula is

$$H.P. = 3.24\ A\ \sqrt{h},$$

it being assumed that 4 pounds of coal are burned per horse-power per hour. The notation here is the same as in Kent's formula.

In looking over the chimney plans of a number of important power plants, the heights were found to vary from 20 to 30 times the diameter of the flue, and a chimney designed with proportions within these limits should under ordinary conditions give a good efficiency, and at the same time present a good appearance.

Another method which is sometimes used is based upon the relation between the grate and chimney areas. Common practice has shown that good results may be obtained if the area of the chimney flue is made about one-eighth of the total area of all the grates connected with it. The required height of chimney to produce different rates of combustion may be obtained by the following formula:

$$\sqrt{h} = \frac{F\ w}{10\ A}$$

in which

h = height of chimney in feet,

F = area of boiler grate surface, in square feet,

A = internal area of chimney flue, in square feet,

w = pounds of coal burned per hour per square foot of grate surface.

The formula will give approximately correct results for moderately free-burning bituminous and medium to large anthracite; for free-burning bituminous coals, deduct 10 per cent from height; for slow-burning bituminous, add 10 per cent; for pea coal add 15 per cent; and for No. 3 buckwheat add 25 per cent.

Some engineers determine the height of chimney by the grade of coal to be used and then compute the required flue area by one of the methods already given. The following heights have been found to give good results in plants of moderate size, and to produce sufficient draft to force the boilers from 20 to 30 per cent above their rating:

With free-burning bituminous coal, 75 feet; with anthracite of medium and large size, 100 feet; with slow-burning bituminous coal, 120 feet; with anthracite pea coal, 130 feet; with anthracite buckwheat coal, 150 feet. For plants of 700 or 800 horse-power and over, the chimney should not be less than 150 feet high regardless of the kind of coal to be used. It will be seen that the foregoing rule gives a somewhat higher chimney than the preceding formula, and for this reason, is undoubtedly better adapted to power work, where it is frequently desired to force the boilers or to change the grade of fuel. For heating purposes, or where the requirements are likely to remain more nearly constant, the formula may be used with suitable corrections for the grade of coal to be burned, as already stated.

It will be found for a given area that a round chimney will have a greater capacity and also present less resistance to the wind, but in ordinary building construction the flue is usually of rectangular outline, especially in the case of smaller plants, although iron or steel stacks of circular section are often used. In the construction of brick chimneys it is better to make the inside walls entirely separate from the outside, both in order to permit expansion of the inner wall and also to secure the advantage of the poor heat-conducting air space between the inside and outside walls. Such construction is common for the chimneys of power plant stations, but is not ordinarily applied to those in other buildings nor in plants for heating purposes only.

The foundation of a large chimney is of great importance and should be laid out under the direction of an experienced engineer. The base of the foundation should be of such size that the pressure per square foot will not be over 1 ton for a soft clay bed nor over 2 tons for stiff clay, well-packed sand or loam. These loads are often exceeded in building foundations, but should not be in the case of chimneys. Where the soil is of low bearing power, pile foundations should be used, especially for large chimneys. The piles should be driven on 2 to 2½-foot centers and the tops cut off below the level of the surface water. A layer of concrete 2 or 3 feet in thickness should be laid over the piles, allowing their tops to extend well up into it, and on top of this should be placed the regular foundation of brick or stone.

In computing the weight of a chimney, the following figures may be taken as a guide. Granite masonry weighs from 150 to 175 pounds per cubic foot, and brick work from 120 to 130 pounds. The external diameter or breadth of a chimney at the base should be at least one-tenth the height, unless it is supported by some other structure. The taper should be from ⅛ to ¼ inch per foot in height on each side.

Regarding the outer shell, the following approximate method may be used for determining the thickness of walls. If the inside diameter at the top is less than 3 feet the walls may be 4 inches thick for the first 10 feet, and increased 4 inches for each 25 feet downward. If the inside diameter is more than 3 feet and less than 5 feet, begin with a wall 8 inches thick, increasing 4 inches for each 25 feet downward. If the diameter is over 5 feet, begin with a 12-inch wall, increasing below the first 10 feet as before. The lining or core may be 4 inches thick for the first 20 feet from the top, 8 inches for the next 30 feet, 12 inches for the next 40 feet, 16 inches for the next 50 feet, and 20 inches for the next 50 feet. Using this method for an outer wall 200 feet high and assuming a cubic foot of brick work to weigh 130 pounds, it gives a maximum pressure of 8.2 tons per square foot of section at the base; while a lining 190 feet high would have a maximum pressure of 8.6 tons per square foot. The safe load for brickwork may be taken at from 8 to 10 tons per square foot, although the strength of best pressed brick will run much higher.

When the thickness of walls is determined as above, it is well to take sections of the chimney at different elevations and compute the weight of brickwork above, and see what the pressure per square foot of section is at these points. The lining of a chimney carries its weight only, while the outer shell must be made stable against wind pressure also. Power to withstand the overturning force of the wind requires a certain relation between the height, breadth, weight and form of chimney. This is expressed in the formula

$$W \geqq \frac{C\,d\,h}{f},$$

in which

$$C = \begin{cases} 56 \text{ for square chimneys,} \\ 35 \text{ for octagon chimneys,} \\ 28 \text{ for round chimneys,} \end{cases}$$

f = breadth or diameter at base, in feet;
d = average breadth or diameter, in feet;
h = height in feet;
W = weight of chimney in pounds.

The external form of the top is a matter of appearance and may be designed to suit the taste; it should, however, be protected with a covering of tile or cast-iron plates to shed the rain and keep water from penetrating the brickwork. Iron ladders, either inside or outside the flue, and lightning rods are accessories which should be added to tall chimneys.

The inner core or lining is usually built of fire brick for a portion of its height, and it may be from two-thirds to three-fourths of the total height of the chimney, although some engineers prefer to carry it up the full height. In any case, it should be entirely separate from the outer wall. Openings must be left near the base for smoke pipe and clean-out. These may be either arch over the tops or provided with iron bearing bars. Fig. 1 will be found useful as a guide in the design of new chimneys.

Iron stacks of boiler plate are quite commonly used at the present time. These are of two kinds; the first is designed simply to carry its own weight, and is supported against wind pressure by guying it. The second kind is made stable by heavy foundations and anchor bolts. Only the first will be discussed here. Iron stacks are made up in sections like the shell of a boiler, the end of one section being slipped into the next and the joint riveted. Sometimes the sections are butted together and a covering ring placed over the joint and riveted to each piece. The stack usually rests upon a cast-iron ring or plate from 1 to 2 inches in thickness, which in turn is supported upon a foundation of stone or concrete. When the side of the stack is cut away for connecting the smoke pipe, suitable means should be taken to strengthen the shell at this point. This may be done by riveting angle or tie bars to the plates at the sides of the opening, extending them for some distance above and below it. Stiffening pieces are sometimes placed across the top and bottom of the opening, with a supporting piece placed vertically across its center. The following table gives usual and safe dimensions for supported stacks.

TABLE II.

Diam. of chimney in ins.	Height in feet.	Thickness of shell for first half of height, in ins.	Thickness of shell for sec. half of height, in ins.	Diam. of rivets, in ins.	Pitch of rivets, in ins.	Total weight of stack, in lbs.

48	120	⅜	5/16	¾	3	21,450

◆◆◆

Areas of Safety Valves for Steam Boilers.—The size of safety valves required on boilers is usually determined by the area of the grate surface. The United States Government law for marine boilers is, generally speaking, accepted as the standard. That rule is, "one square inch of safety-valve area to every two square feet of grate surface," and "where a spring-loaded or pop-valve is used, one square inch of safety-valve area to every three square feet of grate surface." With the various types of boilers in use, no doubt exists that this rule gives good results. But there are cases where the rule does not apply. In a puddle mill, for instance, the boiler has no grates, being operated solely by the waste heat from the puddle furnace. Boilers at blast furnaces also use waste gases for the stoves, and the grate surface is very small indeed, due to very little coal being used, and that only when the gas is not available. In the sections where natural gas is found and used, it is customary to cover up the grate with sheet iron and brickwork while using gas. With the use of oil it is the same. Weighing all these facts, it is clear that, at least where these fuels are used, the safety-valve area must be determined from the heating surface, as the grate surface, if not entirely absent, is absolutely of no value. We may dispense with grates, but we cannot dispense with safety-valves, as the United States Government rule inferentially suggests. Accepting, then, the basis of heating surface for determining the safety-valve area, and assuming that pop-valves are used, it is probable that in order to afford sufficient release, the ratio of heating surface to safety-valve area should be about 100 feet of the former to 1¼ square inches of valve area, which would call for a 4-inch pop-valve in a boiler with 1000 feet of heating surface. With larger boilers, it would be best to have two valves rather than increase the size of valve above 4 inches, one being set to blow off at a steam pressure slightly under the other.—*Exchange.*

Fan Motors for 1904

Except for the development of the swinging or oscillating fan-motor, the number of improvements in the design and construction of these little machines grows steadily less and less each year, which is, of course, a perfectly natural result of the serious engineering skill bestowed upon the problem of producing reasonably efficient apparatus which shall be inexpensive and at the same time require no attention for months in succession. The General Electric Company has brought out this year a convertible type of machine which may be changed from a desk fan-motor to a bracket motor by the use of a small "adapter."

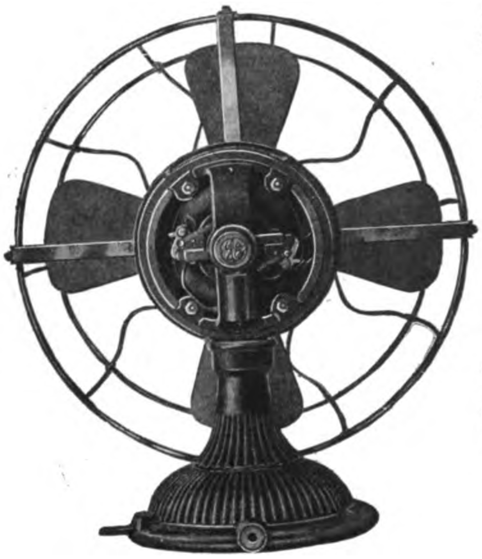

FIG. I.—MOTOR WITH CAP REMOVED.

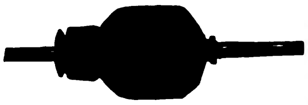

FIG 2.—G. E. DIRECT-CURRENT ARMATURE.

The general construction of the G. E. machines is similar to that of last year's designs. The direct-current motors have bipolar laminated field magnets, enclosed dust-proof frames, swivel and trunnion mounting, etc., as before. The armature discs are twisted on the shaft to prevent disturbance of the magnetic field and humming. The brushes and holders are easily accessible by removing a shield on the back of the motor frame, leaving the machine in running condition, as indicated by Fig. 1. Fig. 2 illustrates the armature construction just mentioned. The brushes are of unusually large size and are fed through brass boxes by means of spring-actuated brass fingers pivoted so that the tips of the fingers describe a rather flat arc, to the center of which the axis of the brush is tangential.

Three running speeds are made available by means of a rheostat and switch mounted within the pedestal base. Fig. 4 shows the under side of the porcelain disc on which is mounted the regulating switch. These motors are built with 12-inch and 16-inch fans. The speeds of the 12-inch fans are 900, 1200 and 1600 r.p.m., and the power required is 32 watts, 41 watts and 51 watts, at the respective speeds named. The 16-inch fan runs at 800, 1100 and 1500 r.p.m, and requires 60, 80 and 100 watts, respectively, at these speeds. Both sizes are wound for 115 and 230 volts.

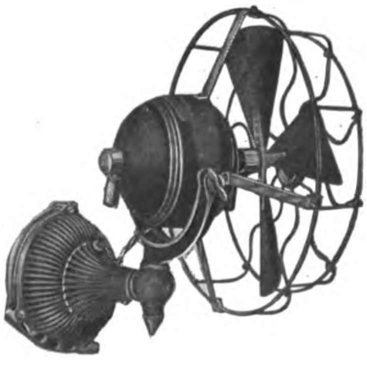

FIG. 3.—G. E. BRACKET MOTOR.

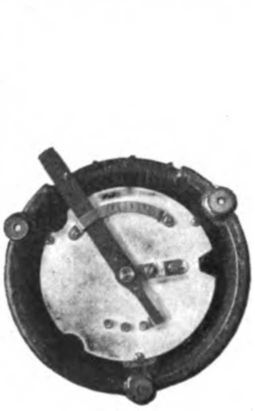

FIG. 4.—G.E. SWITCH

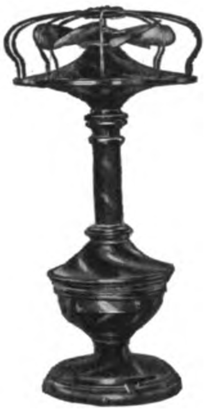

FIG. 5.—G.E. RADIAL FAN

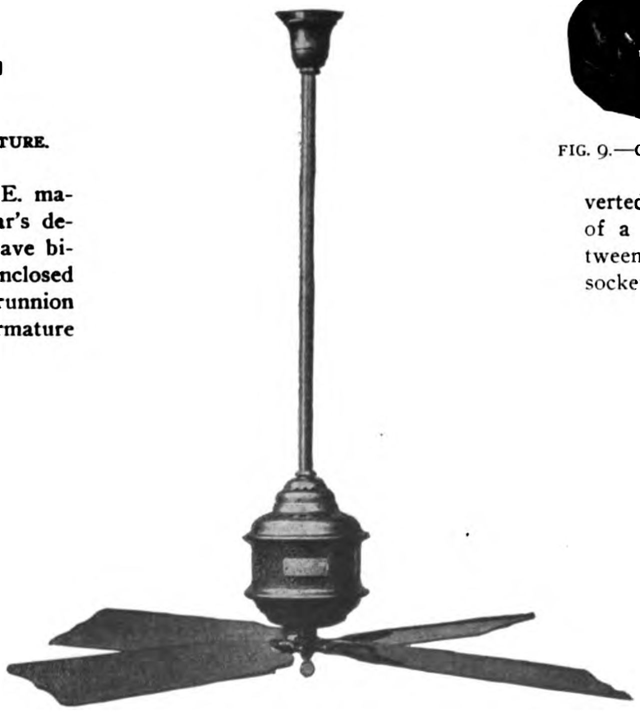

FIG. 6.—G. E. DIRECT-CURRENT CEILING FAN MOTOR.

Fig. 5 illustrates a special form of fan motor, recently brought out and known as the "radial" fan, the distribution of the air being substantially radial to the axis of the machine. This distribution is accomplished by means of the curved deflecting plate shown immediately beneath the fan blades; the fan revolves so as to throw the air downward against the deflecting plate. The motor, of course, is mounted in the semi-spherical casing near the base of the standard. The maximum speed is 2000 r.p.m. and the machine is wound only for 115 volts. It is intended chiefly for use at banquets and similar service.

The General Electric alternating-current fan motors are of the squirrel-cage induction type. The regulating device is mounted in the pedestal base instead of in the back of the motor casing as formerly, and is connected to the motor by means of a flexible cord, as indicated in Fig. 7. This illustration shows the exterior appearance of the 12-inch swivel and trunnion motor, and Fig. 8 shows the same motor converted into the bracket type by the addition of a compact universal joint inserted between the shank of the trunnion and the socket in the top of the pedestal. The stator is of the usual laminated construction, with four polar projections; these are wound as usual in direct-current machines, and also have shading coils to enable the motor to start up from rest. Fig. 9 shows

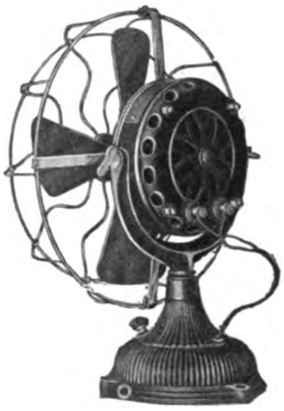

FIG. 7.—G. E. ALTERNATING-CURRENT MOTOR.

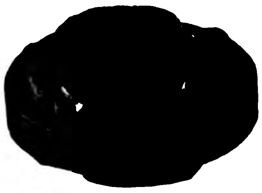

FIG. 9.—G. E. FIELD MAGNET.

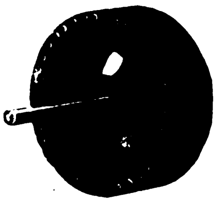

FIG. 10.—G. E. ROTOR.

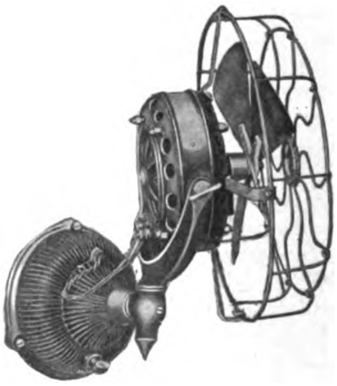

FIG. 8.—G. E ALTERNATING-CURRENT BRACKET MOTOR.

the magnet and coils complete, and Fig. 10 shows the squirrel-cage rotor. The rotor conductors are not insulated from the core. These machines are built for the standard frequencies and voltages and with 12-inch and 16-inch fans. The normal running speeds are 900 and 1550 r.p.m. for the 12-inch size and 900 and 1400 r.p.m. for the larger machine. They require respectively 75 and 180 watts at full speed.

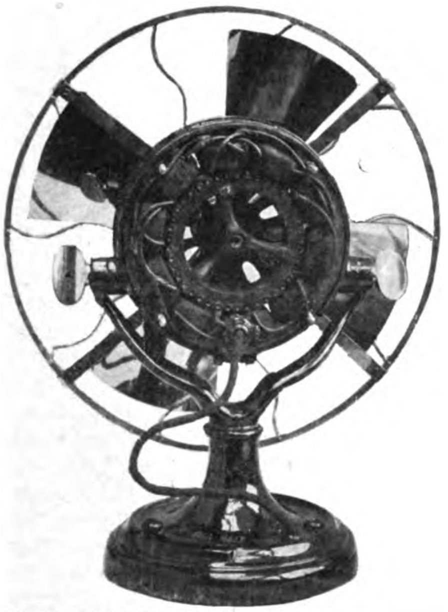

FIG. 11.—WESTINGHOUSE TEN-POLE DESK FAN-MOTOR.

The General Electric ceiling fan-motor is illustrated by Fig. 6. The blades have a sweep of 58 inches, and the machine may be operated at any one of three speeds. The motors built for 115 and 230 volts run at 125, 160 and 200 r.p.m., and the 500-volt machine runs at 140, 170 and 200 r.p.m. All these motors take 108 watts at full speed.

The Westinghouse & Electric Manufacturing Company has brought out a new line of direct-current fan-motors this year, but they are unfortunately not ready for description as we go to press with this issue. The Westinghouse alternating-current fan-motors are similar to those of last year.

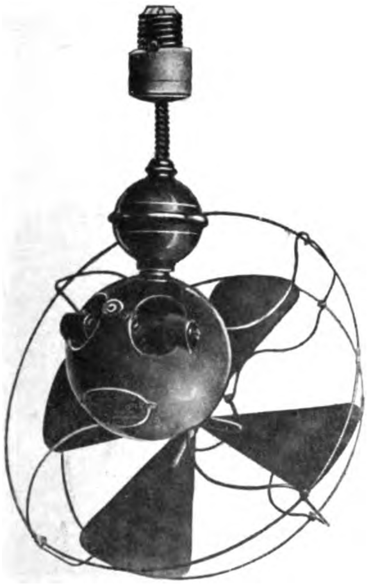

FIG. 14.—FT. WAYNE REVOLVING MOTOR.

The machine is an induction motor embodying no special features except the use of a rotor of unusually large diameter. Fig. 11 shows a 133-cycle machine, which, on account of the high frequency, has a large number of poles: ten. The field magnet or stator consists of a laminated yoke ring with integral poles mounted in a light cast-iron casing and wound with a sectional winding which is connected to the regulating switch so that the sections may be cut in or out of circuit to obtain different speeds. The rotor, Fig. 12, is obviously of the squirel-cage type. The rotor conductors are bare copper rods, with their ends soldered into heavy rings at the ends of the core. There is only one bearing, which is located between the rotor core and the fan, and this is lubricated by means of felt wicking in an oil reservoir beneath the journal.

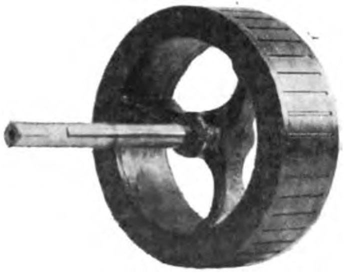

FIG. 12.—WESTINGHOUSE ROTOR.

These machines are built with 12-inch and 16-inch fans, and for 100-120 volts at each of the standard frequencies. The 12-inch 60-cycle fan requires 60 watts at low speed (which is 1000 r.p.m.) and 85 watts at full speed (1550); the 12-inch 133-cycle fan runs at 1200 r.p.m. on 50 watts and at 1350 r.p.m. on 65 watts. The speeds and power requirements of the 16-inch 60-cycle fans are 1000 and 1550 r.p.m. and 145 and 180 watts, respectively; the 133-cycle fans of this size run at 1200 r.p.m. on 87 watts and 1450 r.p.m. on 103 watts. The two speeds are secured by cutting in or out part of the field magnet winding, as previously mentioned, a switch for this purpose being located in the base of the pedestal.

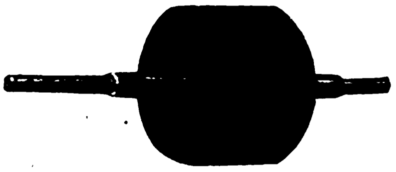

FIG. 17.—FT. WAYNE ROTOR.

FIG. 16.—HIGH-FREQUENCY FIELD MAGNET.

"Wood" fan-motors manufactured by the Fort Wayne Electric Works are made in three styles, for use in different locations, and in three voltages, one for direct current at 115 volts and another for 52 and 104 volts alternating current, or 60 and 140 cycles. The first style of fan-motor produced was a small stationary desk-fan as shown in Fig. 15. This fan-motor is exceedingly light for its output and makes a very neat appearance without taking up much room. The motor drives an 8-inch four-blade fan at 2200 r.p.m.; the 140-cycle alternating-current machine requires 40 watts and the direct-current and 60-cycle alternating-current machines each require 20 watts. The direct and alternating-current motors are exactly alike in appearance, and very similar in internal construction, excepting the high-frequency motor, which is of the squirrel-cage induction type. The 60-cycle and the direct-current motors have bipolar laminated field magnets with tapered pole-tips, and drum-wound slotted-core armatures, as illustrated by Figs. 18 and 18-a respectively. The high-frequency alternating-current motor has a four-pole laminated field magnet equipped with shading coils to assist in starting, as shown by Fig. 16. The rotor is of the usual squirrel-cage construction, except that the discs are twisted on the shaft so as to spiral the slots and reduce humming; see Fig. 17.

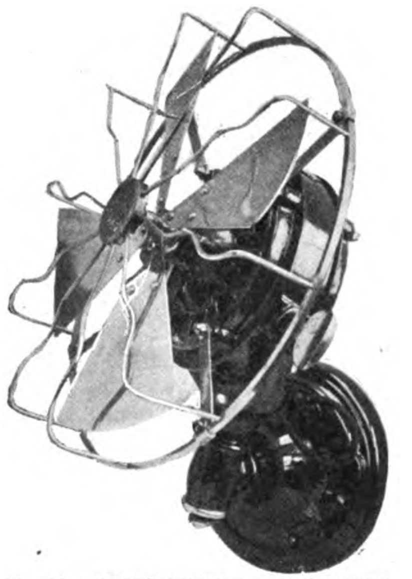

FIG. 13.—WESTINGHOUSE ALTERNATING-CURRENT BRACKET MOTOR.

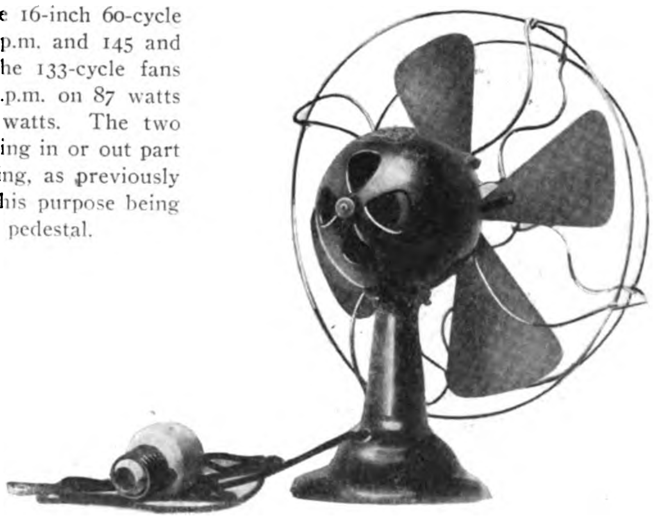

FIG. 15.—FT. WAYNE DIRECT AND ALTERNATING-CURRENT MOTOR.

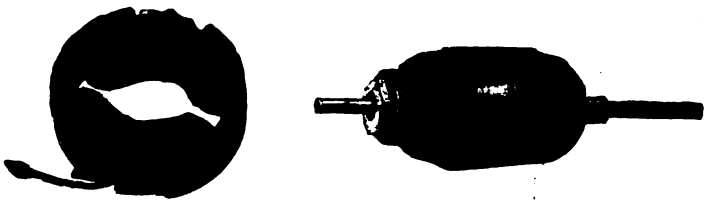
The field laminations are individually japanned before being assembled and are



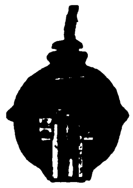


FIG. 18.—FT. WAYNE DIRECT-CURRENT AND 60-CYCLE FIELD MAGNET AND ARMATURE, FIG. 18-a.

FIG. 19.

riveted together with German silver to reduce eddy currents to a minimum. The magnet poles have projecting tips and the coils when pulled into place and bent into shape shown in the engraving are drawn into recesses above the pole tips. The coils are form-wound with silk-covered wire and after construction are shellacked, baked and taped. The armature coils of the commutator-type motors are form-wound, taped, shellacked and baked before assembling on the core, and the complete armature is baked. The core-slots are lined with an insulating fabric and the coils are held by a wedge in the upper part of each slot. The commutator is separate from the armature and assembled complete with its insulation and thoroughly baked and tested before the final assembling on the armature shaft. The brushes are rectangular in cross section and located in square brass tubes in which they are fed toward the commutator by means of helical springs. Adjustment of the spring tension is provided for in a screw set into the upper end of each brush tube. Contact between the brushes and brush box is obtained by a small sliding pressure spring on one side of the box which also prevents chattering by the brushes.

Fig. 14 illustrates a style of mounting employed by the Fort Wayne Electric Works which has met with general appreciation. The motor of this outfit is exactly the same as in the desk type, except as to the position of the point of support for the motor casing. In the suspended revolving type the motor is attached to a bearing within the lower hemisphere of the hollow suspension shell in such a way that the shaft makes an angle of 45 degrees with the horizontal and, of course, the same angle with the vertical axis of suspension. This brings the upper fan-blades further away from the axis of suspension than the lower blades at any instant. This, together with the fact that the backward pressure exerted by the fan tends to raise the motor, causes the whole motor to rotate about the axis of suspension due to the action of gravity acting in opposition to the repulsion of the blades which tends to raise the motor.

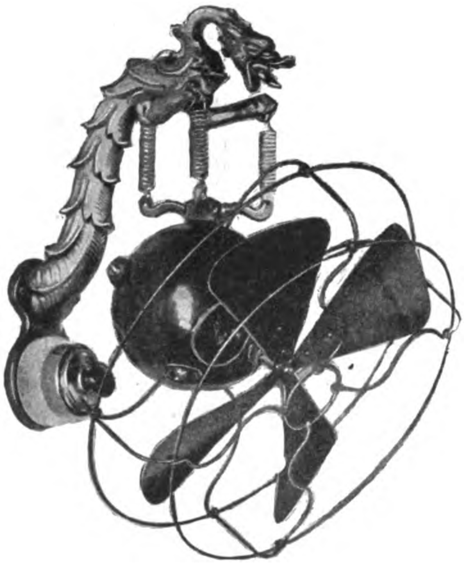

FIG. 20.—FT. WAYNE SUSPENDED MOTOR.

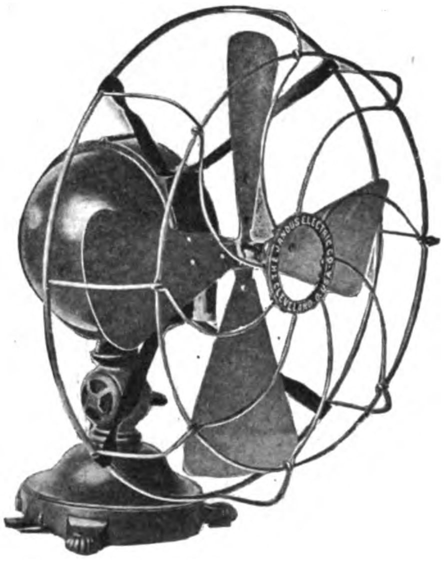

FIG. 21.—JANDUS DIRECT-CURRENT MOTOR.

The rate of rotation about the vertical axis varies, of course, with the speed of the fan and the angle of the blades. At a speed of 2200 r.p.m. the motor rotates about the vertical axis from 25 to 50 times per minute, depending upon the angle of the blades, which can be varied at will by bending them slightly.

The spherical case above the motor contains frictionless ball bearings on which the motor turns about the vertical axis. Current is delivered to the motor through brushes bearing on small collectors mounted on the upper end of the suspension bearing within the small spherical case, as shown in Fig. 19.

The fact that the motor is suspended while in operation necessitates making it as light as possible. This is accomplished by constructing the enclosing shell of the motor and the suspension sphere of aluminum alloy, which is amply strong enough for all strains and results in an exceedingly light motor. The revolving type is built for the same circuits and is attached to the lamp socket in the same manner as the attachment plug for the desk type motor. It may be suspended from any convenient electric light socket on a chandelier, wall bracket, etc.

The "Wood" fan-motors are also mounted as illustrated in Fig. 20. This type is intended for mounting directly on a wall or partition where silent running is essential. The motor is attached to a three-arm spider which replaces the suspension bearing used with the revolving type. This spider is suspended from three points of support through tempered spiral springs adjusted to take up all vibration of the fan. The special purpose for which this motor was designed was for use in telephone booths where noisy operation is prohibitive. It may be swung about a vertical axis and clamped in any position by a small set screw in the suspension spider. The wall bracket is hollow and encloses the wires leading from the motor to the switch in the base of the bracket. This motor can be used in series with a 16-c.p. 110-volt incandescent lamp on a 110-volt or 115-volt direct-current circuit. When so used the lamp and motor are connected to the line through a door switch arranged so as to light the lamp and start the motor when the cabinet door is closed. The speed of the motor is suitably lowered for use in this service and the candle-power of the lamp is also slightly reduced from its standard rate. For example, connecting the motor and lamp in series on a 110-volt direct-current circuit will result in a speed of 1100 r.p.m. by the motor and 12 candle-power is obtained from the lamp. The power used by the motor in this way is, of course, negligible, since the light is necessary anyway.

The Jandus Electric Company, Cleveland, Ohio, also builds a compact and graceful motor of the spherical type, as illustrated by Fig. 21. Fig. 22 shows the machine with the protecting caps removed, and Fig. 23 is a sectional view on a plane parallel with the shaft. The field magnet is bipolar and is built up of soft sheet steel stampings. The magnet coils are form wound, taped and varnished, and are connected in series with the armature, as usual in this class of machine. The armature is of the usual slotted type, but the coils are form wound and are insulated before being put in the slots. The brushes and brush-holders are of the cartridge type, but the brush cross-section is rectangular. The speed-regulating rheostat consists of resistance wire wound

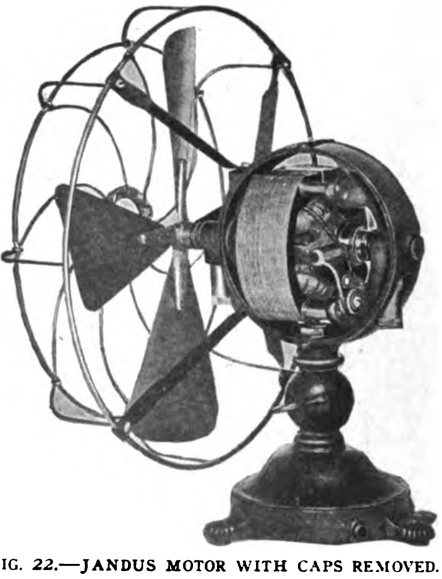

FIG. 22.—JANDUS MOTOR WITH CAPS REMOVED.

on an enameled tube and mounted in the pedestal base. The bearings are of the wick-oiling type, as shown in the sectional view, Fig. 23. These motors are wound for 100-120 and 200-250 volts, and have three speeds. The 12-inch fan runs at 900, 1200 and 1600 r.p.m. and takes 44 watts at maximum speed; the 15-inch fan runs at 900, 1150 and 1525 r.p.m. and requires 65 watts at full speed; the 16-inch fan runs at 800, 1050 and 1400 r.p.m. and takes 75 watts at full speed.

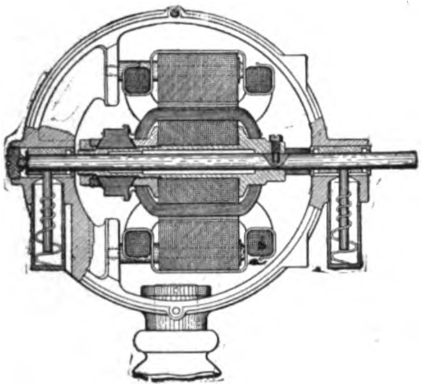

FIG. 23.—SECTION OF JANDUS MOTOR.

The Jandus Company also builds an alternating-current fan motor very similar in construction and appearance to the direct-current machine. It is built for 60 and 133 cycles and for 104 to 110 volts. Speed regulation is secured in this motor by means of a switch in the base which connects the field magnet coils in series or parallel, according to the speed desired. The fan diameters are the same as those of the direct-current machines. Both classes are provided with the swivel and trunnion mounting, shown in Fig. 24, which enables the user to change the motor pedestal from desk to bracket form by merely turning the base up through an angle of 90 degrees and screwing it to the wall or other vertical support.

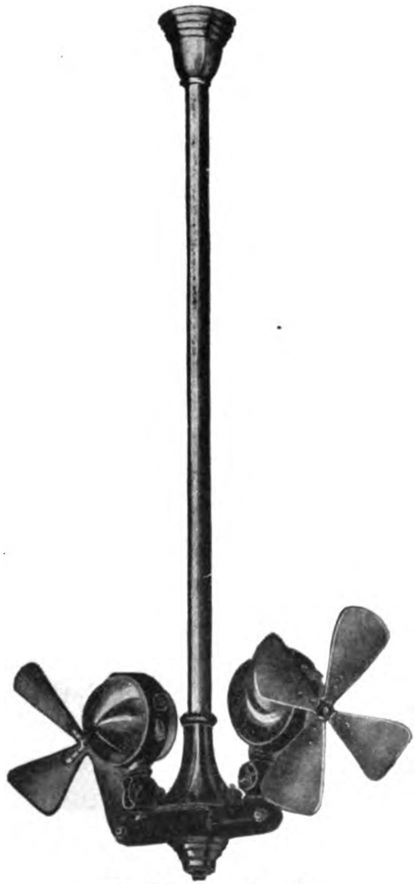

FIG. 25.—"GYROFAN."

Fig. 25 shows a method of mounting that the Jandus Company brought out last year. Two desk fans are seated on a bracket which is adapted to revolve about the axis of the hanger stem, and the motors are set at such an angle that the reactive effort of the fans causes the whole to revolve. The bracket may also be locked in any position and the fans adjusted to throw air continuously in any direction.

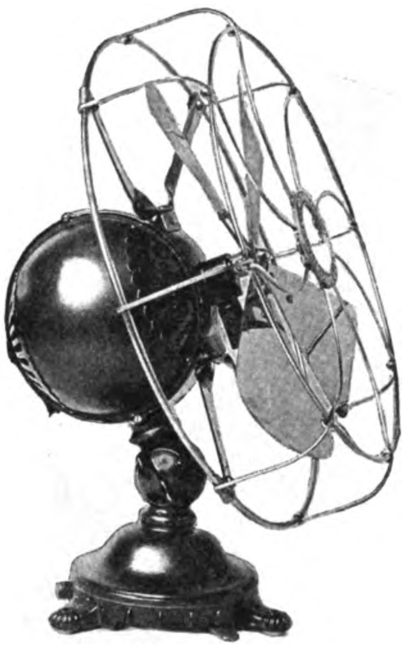

FIG. 24.—JANDUS ALTERNATING-CURRENT MOTOR.

This arrangement is designated the "Gyrofan"; it is also furnished with an ornamental electrolier beneath the revolving bracket when desired.

Another spherical fan motor is that built by the Colonial Electric Company, Ravenna, Ohio, and illustrated by Figs. 26 and 27, showing respectively the swivel and trunnion desk machine with a 12-inch fan, and the bracket mounting of the same machine in the 16-inch size. The Colonial motor is bipolar, with shell and magnet poles cast integral. The magnet coils are form-wound, taped, varnished and baked. The armature is slotted and drum wound. The slots are insulated with oiled linen and the coils are machine-wound directly into the slots. The machines are provided with the usual form of speed-regulating switch and rheostat mounted in the base. The normal running speed of the 12-inch fan is 1650 r.p.m., and the power required is 55 watts. The 16-inch fans run at 1350 r.p.m., with an input of 77 watts. The bearings are of phosphor bronze, self-aligning, and provided with wick-feed lubrication. These fans are also built with rigid mounting.

The Colonial ceiling fan motor is illustrated by Fig. 28, which shows the Type R machine. The brush-holders and brushes are of the cartridge and carbon-pencil type. The bearings are of phosphor bronze, self-oiling and self-aligning, and of such construction that the working parts are constantly immersed in oil. The sweep is 60 inches, and the speeds are 110 to 200 r.p.m. with four blades, or 130 and 220 r.p.m. with two blades; a two-blade switch being provided with each Type R fan. These machines are wound for 110, 170, 220, 250 and 500 volts, and the current required at these voltages is 1 ampere, 0.7 ampere, 0.55 ampere, 0.45 ampere and 0.23 ampere.

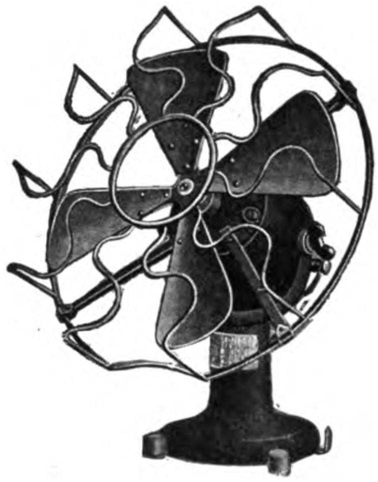

FIG. 26.—COLONIAL MOTOR.

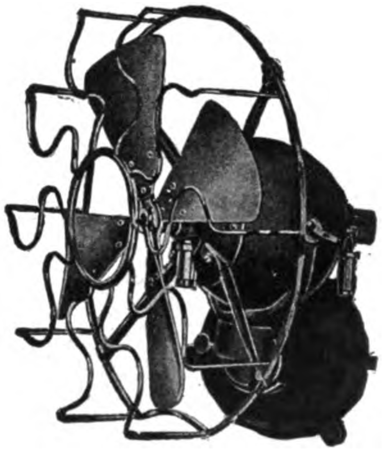

FIG. 27.—COLONIAL BRACKET MOTOR.

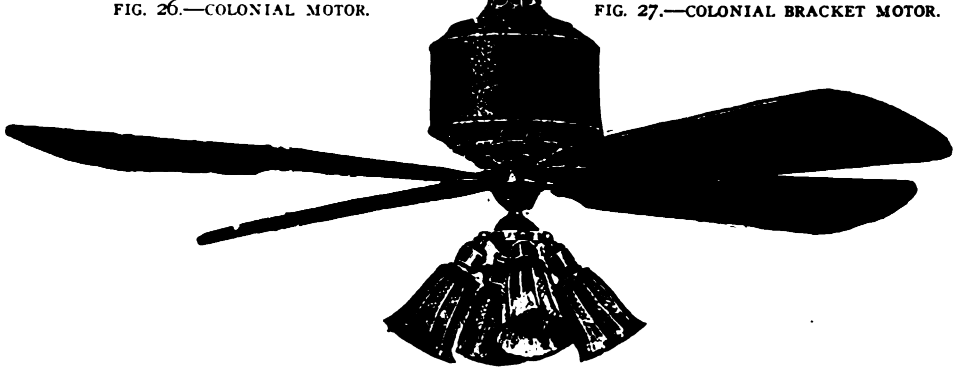

FIG. 28.—COLONIAL CEILING FAN MOTOR.

Fig. 29 illustrates the new Universal fan motor of the Eck Dynamo & Motor Works, Belleville, N. J., which was put on the market for the first time last summer and was brought out too late to be described in our fan-motor article last year. Like the three motors last described, this is of the globular bipolar type, but the internal construction is entirely different from the Wood and Jandus machines. The field-magnet is a one-piece casting of soft steel, and the coils are form-wound and hand insulated. The armature is of the usual slotted-drum machine-wound type. The field-magnet shell is provided with an oblong slot at the rear, through which the field coils are inserted and removed, this slot and the circular opening in the opposite side of the shell being closed by the journal brackets. As the engraving clearly shows, the fan is of the oscillating type. The oscillating device consists of a worm on an extension of the armature shaft, a worm-wheel mounted just beneath the rear journal, a crank disc, and a pitman extending from an adjustable crank-pin on the disc to a stationary pivot on the frame below the magnet shell. The shell is pivoted to the part of the frame just mentioned, and the revolution of the worm-wheel causes the entire motor to tilt forward and back on its pivot. The frame and shank on which the motor is mounted are supported on the pedestal by means of a ball and socket joint which permits the shank to be tilted at any angle with respect to the base. The motor therefore combines in a single structure both the universal adjustment on the pedestal and the oscillating feature. In order to convert it into a bracket machine, it is only necessary to turn the pedestal up through an angle of 90° and fasten the base against the wall instead of allowing it to set on a horizontal surface.

The brushes are rectangular carbon pencils held in a special form of holder which presses the brushes against the commutator in the same manner as the ordinary cartridge type of holder, but in addition, permits the removal of the brushes from the holders without dismantling the parts in any way. The bearings are lubricated by means of grease cups and automatic feeding pins. These machines are built for 115 and 230 volts, with 12-inch and 16-inch fan blades. The oscillating mechanism on the 16-inch fan motor is considerably heavier and stronger than that on the 12-inch machine, and even since the preparation of this data the Eck fans have been considerably improved in minor details, but the general features remain the same.

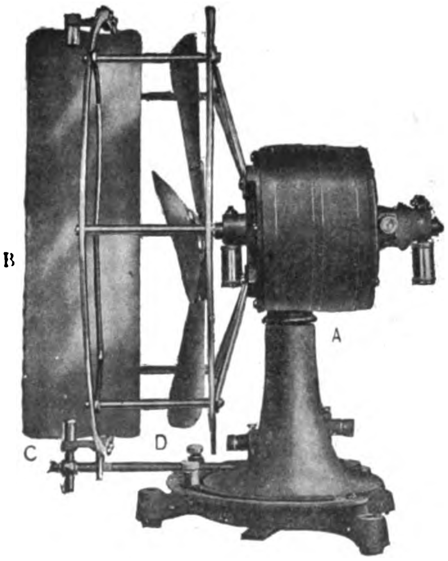

FIG. 30.—COMFORT OSCILLATING FAN MOTOR.

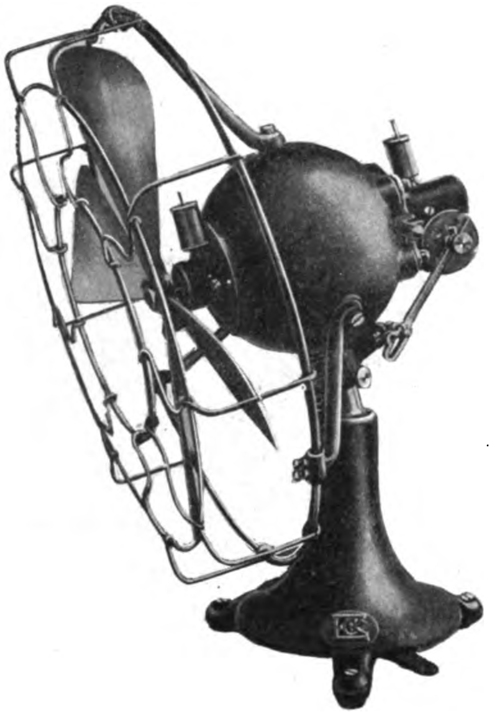

FIG. 29.—ECK UNIVERSAL FAN MOTOR.

The Eck Dynamo & Motor Works also builds a very compact exhaust fan outfit consisting of the standard fan motor mounted on a tripod and provided with a 16-inch fan, which is driven at 1600 r.p.m. Like the desk fan, this machine is wound for 115 and 230 volts. It requires 100 watts when running at rated speed.

The Comfort oscillating fan motor, shown by Fig. 30, turns about a vertical axis, instead of a horizontal one as in the previous case. The motor is of the bipolar type, with a one-piece field-magnet casting. The magnet coils are machine-wound and hand-insulated. The armature is of the usual slotted-drum type, but embodies the somewhat unusual feature in machines of this size of having the armature discs keyed to the shaft. The armature winding is of silk-covered wire heavily insulated from the core. The brushes and holders are of the familiar pencil and cartridge type and the brushes are of graphite. The bearings are self-aligning and oiled by means of wick-feed oil cups, as the engraving clearly indicates. The motor is mounted on a ball-bearing at the top of the pedestal, so that it is free to turn from side to side. Connections between the terminal posts at the base and the motor itself are made by means of small collector rings and brushes, in order to obviate the nuisance of flexible cords subjected to tortion stresses by twisting and untwisting as the motor oscillates. The oscillation is caused by the single vane, *B*, pivoted to the front of the fan-guard. A finger, *D*, is attached to the spindle at the lower end of the vane and projects over the base, on which two stops are mounted. When the motor swings in one direction this finger comes in contact with one of the stops and the vane is turned so that the reaction of the stream of air against it swings the motor back in the opposite direction until the finger comes in contact with the stop at that end of the travel. The stops are adjustable in a circular slot in the base so that the range of oscillation may be made anything up to 180°. The machine is built with either 12-inch or 16-inch fan blades and provided with a speed regulator which enables the motor to be operated at either 1400 or 1800 r.p.m. for the 12-inch size, and 1200 or 1500 r.p.m. for the 16-inch size. The power required by the 12-in fan is about 43 watts and the 16-inch fan requires about 90 watts at full speed. An unusual feature of detail construction is the rheostat conductor, which consists of a composition block about ½ inch square and 2¼ inches long. This is mounted flat on a porcelain base, and when included in the circuit with the fan, reduces the speed to the lower limits just stated. At full speed the resistance block is, of course, cut out. The machines are made by the Shedd Electric & Manufacturing Company, New York, and wound for the actual direct-current voltages. The fan-guard is made of brass and held together rigidly with screws.

The Emerson Electric Manufacturing Company has brought out this year a new line of alternating-current desk, bracket and ceiling fan motors known as the Trojan line. These machines are built to meet a demand for a slightly less expensive line than the standard Emerson machines. The difference between the two lines is confined chiefly to refinements. The Emerson standard fans have Parker fan blades, hardened steel shafts and a specially efficient self-starting winding. The Trojan machines have fan blades of the ordinary type, as indicated by Fig. 31 herewith, which shows the swivel and trunnion desk fan for 60 and 133 cycles. This machine is also self-starting, of course, and has two running speeds. The construction of the gearing is clearly shown by Fig. 32. The shaft is of

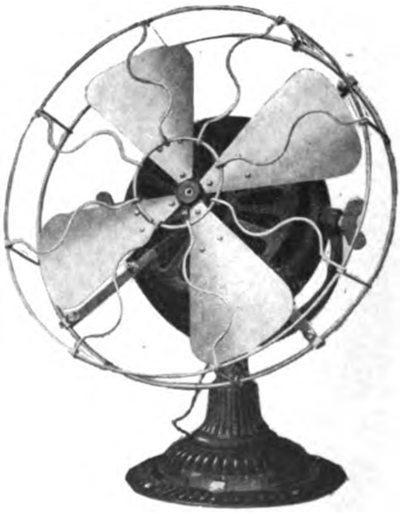

FIG. 31.—TROJAN ALTERNATING-CURRENT FAN MOTOR.

tool steel, ground to size, and revolves in the double bronze bearings shown in the engraving. Between the two bearings is a cavity which is filled with cotton wicking completely surrounding the shaft; oil is fed to the wicking from the oil cup in the cover hub, and felt washers at each end of the bearing prevent leakage of oil. The Trojan machines are built with 12-inch and 16-inch fans and for the usual alternating-current voltages. The 12-inch machine runs at 1600 r.p.m. at full speed and 1300 r.p.m. at slow speed, on either 60 or 133 cycles. The power required is 75 watts at full speed and 55 watts at slow speed. The 16-inch machine runs at the same speeds and requires 130 watts at full speed and 100 watts at slow speed. The machines are also built with bracket mounting, of course. Fig. 33 illustrates the Trojan ceiling fan motor, which is built only for 60-cycle current and one speed, namely, 225 r.p.m. The sweep of the blades is 52 inches and the motor requires 135 watts at full speed. This machine is also furnished with two blades of 56 inches sweep, and with this equipment requires 130 watts at full speed and runs at 225 r.p.m.

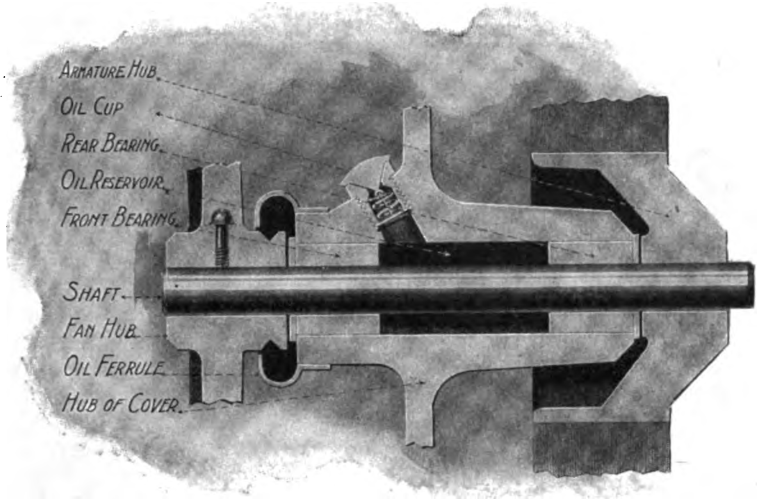

FIG 32.—SHAFT AND BEARING OF TROJAN MOTOR.

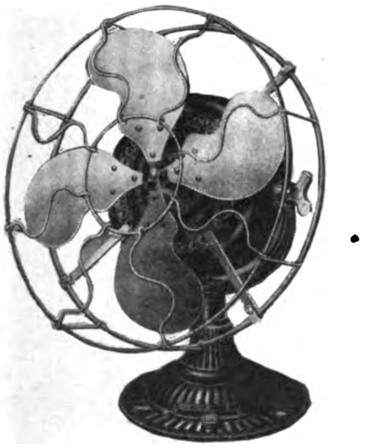

FIG. 34.—EMERSON 133-CYCLE MOTOR.

The Emerson standard line of fan motors is practically the same as last year. Fig. 34 shows the two-speed desk fan motor for 133-cycle circuits and with the swivel and trunnion mounting. The running speeds are 1400 r.p.m. and 1700 r.p.m., and the current consumption is 60 watts at the slow speed and 75 watts at full speed for the 12-inch size; 90 watts at slow speed, and 100 watts at full speed for the 15-inch size. These machines are wound for all of the standard alternating-current secondary voltages. This type of machine is also built in bracket form, as illustrated in Fig. 35, which shows the 60-cycle fan motor with this style of mounting, the only difference being the form of mounting. The 60-cycle motors are furnished with 12-inch and 16-inch fans, and require respectively 55 and 100 watts at full speed; the speeds are 1300 and 1650 r.p.m. for both sizes. Fig. 36 illustrates the field-magnet and rotor construction of the standard Emerson motor. The construction of the stator is similar to that of large induction motors, and it is provided with starting coils located midway between the regular working coils; these starting coils are cut out of circuit after the motor has attained normal speed. The rotor is of the ordinary squirrel-cage type.

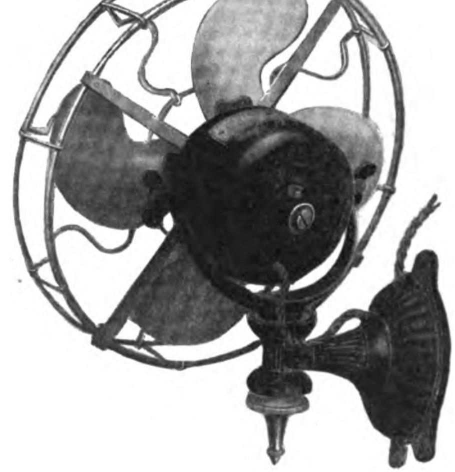

FIG. 35.—EMERSON 60-CYCLE BRACKET MOTOR.

Fig. 37 illustrates the method of lubricating the rotor bearings. There is no shaft, the rotor core being mounted on a drum provided with extensions, *F* and *F*, at each end, which fit around a stationary hollow spindle, *M*, and constitute bearings. The fan is provided with a hollow hub, *J*, screwed on the projection at one end of the rotor core-drum, so as to completely enclose the bearings at that end. The outer end of the bearing at the other end of the rotor is enclosed by a rawhide washer, *E*, mounted on a portion of the frame, *B*. Lubrication is provided through the oil cup, *A*, the lubricating oil being delivered to the interior of the hollow spindle, *M*, and finding its way through holes, *L* and *L*, to the bearings, *F* and *F*; the hollow fan hub, *J*, catches the oil at that end of the armature, and it is prevented from leaking out at the other end by the rawhide washer mentioned above. A cavity, *N*, within the armature spider, is provided for the retention of a reserve lubricant.

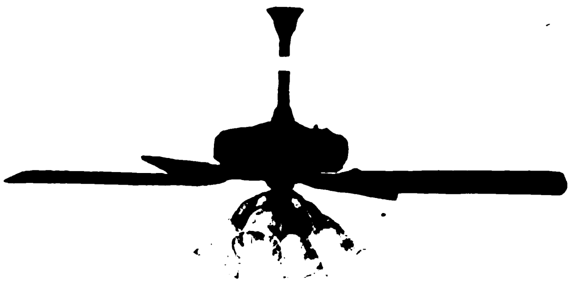

FIG. 33.—TROJAN CEILING MOTOR.

Fig. 38 illustrates the Emerson "residence type" of fan motor. It is similar in general construction to the machine just described, differing from it only in the speeds, which are 900 and 1100 r.p.m., and in the number of fan blades—6. The 12-inch fan-motor of this type requires 40 watts at slow speed and 50 watts at full speed; the 16-inch ma-

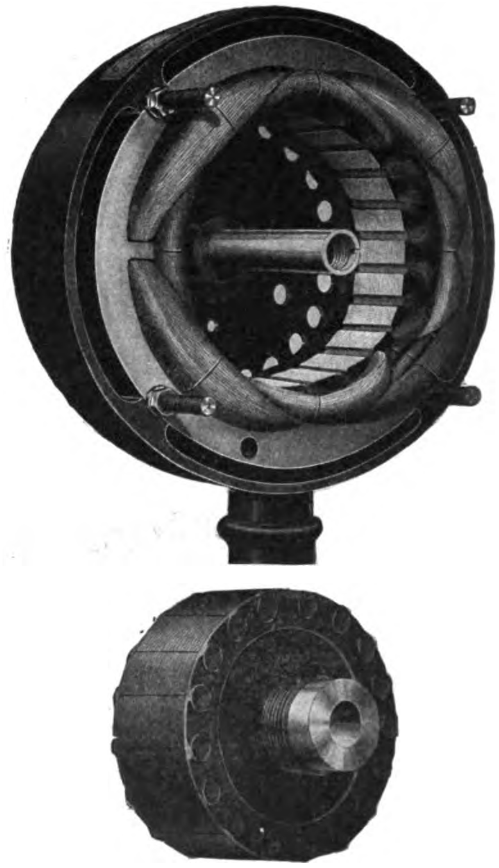

FIG. 36.—EMERSON FIELD MAGNET AND ROTOR.

chine requires 80 watts at slow speed and 90 watts at full speed.

The Emerson ceiling fan motor is a 60-cycle induction motor, somewhat similar in design to the desk type of machine. The stator has 28 poles, so that the full running speed is 225 r.p.m. There are two windings, disposed like the windings of a two-phase induction motor, and the windings are of different inductances so as to produce a rotating field at starting. Only 14 of the magnet poles are wound, and these are slotted up the center to take the extra "phasing" winding. Unlike the desk motors, this extra winding remains in circuit during the operation of the motor.

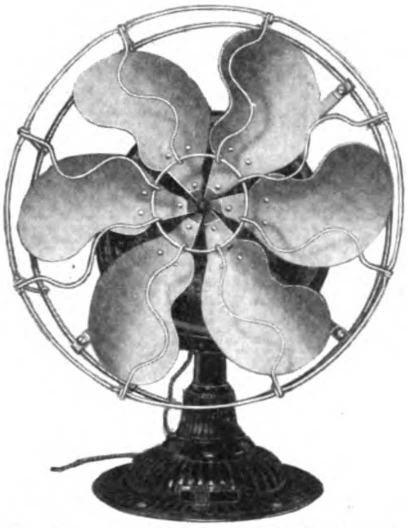

FIG. 38.—EMERSON "RESIDENCE" TYPE MOTOR.

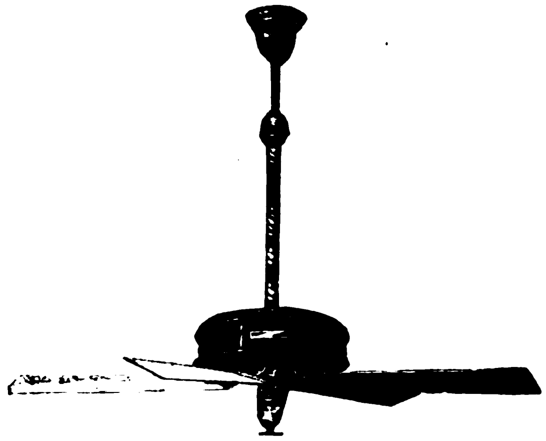

FIG. 39.—EMERSON 60-CYCLE CEILING MOTOR.

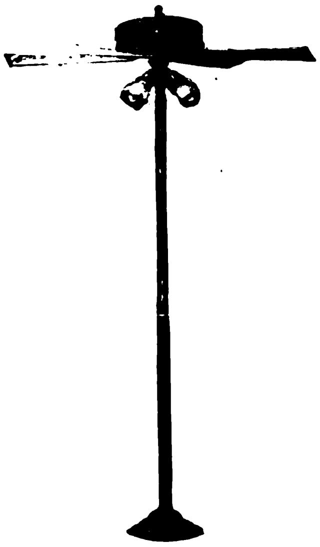

FIG. 41.—EMERSON COLUMN FAN MOTOR.

Fig. 40 illustrates the construction of the machines, from which it will be evident that the oiling arrangement peculiar to Emerson ceiling motors in past years has been retained. This consists of a spiral groove in the hollow armature shaft, which raises oil to the top of the shaft, whence it trickles down again and in doing so lubricates the bearing. Fig. 39 shows the exterior appearance of the four-blade fan, which has a sweep of 52 inches and requires 130 watts at full speed. It may be also operated at 180 r.p.m., when it requires 110 watts. These motors are also furnished with two blades of 56 inches sweep; the speeds are the same, and the power required is 125 watts at full speed and 100 watts at slow speed. The column fan, Fig. 41, is identical in construction with the ceiling fan-motor, except that only one speed (225 r.p.m.) is provided, and there is consequently no switch.

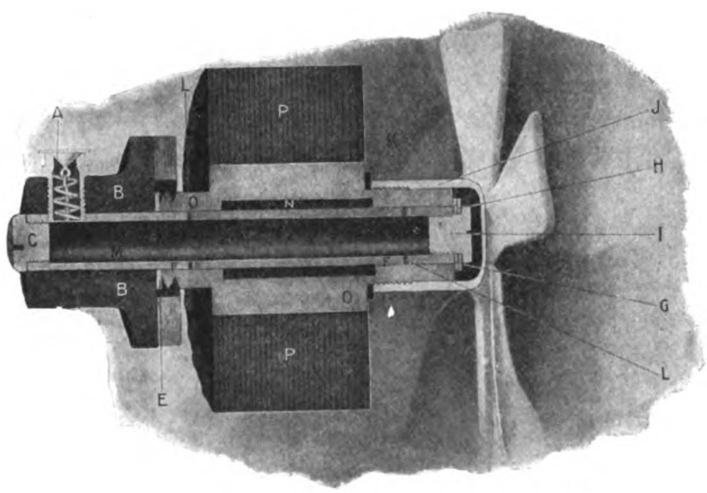

FIG. 37.—BEARING OF EMERSON DESK MOTOR.

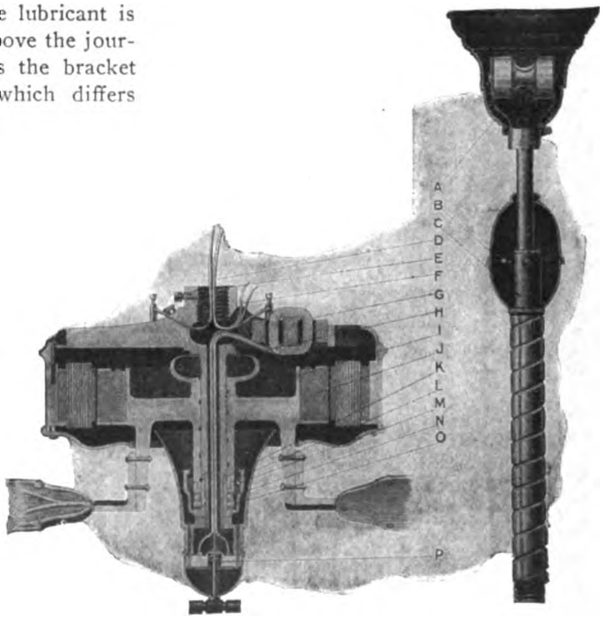

FIG. 40.—SECTION OF EMERSON CEILING MOTOR.

Fig. 42 illustrates the swivel and trunnion desk fan motor of the Pennsylvania Electric Company, Marietta, Pa. The motor is of the bipolar type and the field magnet is built up of soft sheet-steel laminations bolted to a cast-iron casing. The field-magnet coils are form-wound and hand-insulated. The armature is of the usual slotted-drum type, and the coils form-wound, insulated and baked before being put on the core. The commutator is unusually heavy for this style of machine and is insulated with the best grade of mica. The brushes are of rectangular cross-section and are set obliquely on the commutator, so as to prevent them from twisting and squeaking. The brush-holders are of the cartridge type, feeding the brushes to the commutator by means of helical springs. They are mounted in the rear cap of the frame and are removable without dismantling the motor. The bearings are self-aligning and the sleeves are turned up from solid phosphor-bronze stock. Grease is used for lubrication and the lubricant is contained in large chambers above the journal boxes. Fig. 43 illustrates the bracket mounting of this machine, which differs from the desk type only in the form of swivel employed. The machines are supplied with 12-inch and 16-inch fans and are wound for 110, 220 and 500 volts. The 500-volt motors have only one running speed, but the others have three. The 12-inch fan may be operated at 1800, 1500 or 1100 r.p.m. and requires 55 watts at full speed. The 16-inch fan runs at 1650, 1200 or 900 r.p.m. and requires 75 watts at full speed. These machines are also built with solid frames for desk service. With exception of swivel and trunnion mounting, the specifications are exactly the same as for the machines just described.

The ceiling fan motors of the Pennsylvania Electric Company are furnished with electroliers or without them; in the latter case the appearance of the fan is as shown in Fig. 44. The motor is bipolar, with a single-piece cast-iron field magnet, and the armature is of the slotted-drum type. Both the field magnet and armature coils are form-wound, hand-insulated and baked. The commuator is of the usual barrel type with heavy segments and first-grade mica insulation throughout. The brush-holders and brushes are of the same type as those on the desk and bracket fans. The armature revolves on a single long bearing, which is constantly flooded with oil from a chamber at the bottom of the fan, which holds a supply sufficient for a complete season's run. The standard ceiling fan motors have only one running speed, namely, 225 r.p.m., and require 97 watts. They are also supplied, however, with speed regulators, giving two or three speeds when desired. The three-speed fans run at 225, 185 and 140 r.p.m., and the two-speed fans at 225 and 175 r.p.m. The blades are of polished hardwood, 7 inches wide at the tips and with a sweep of 60 inches. Four blades are usually supplied.

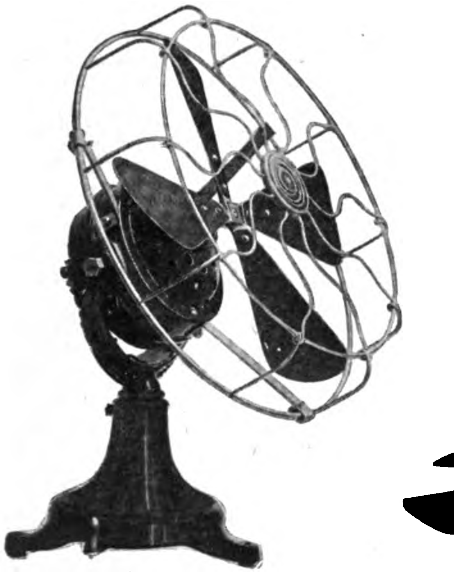

FIG. 42.—PENNSYLVANIA DESK MOTOR.

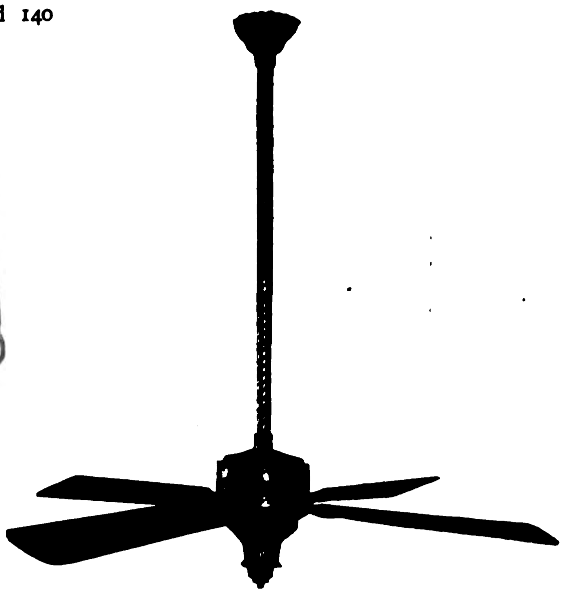

FIG. 44.—PENNSYLVANIA CEILING MOTOR.

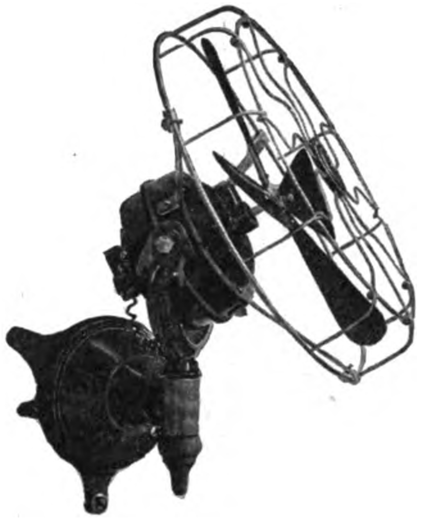

FIG. 43.—PENNSYLVANIA BRACKET MOTOR.

The Pennsylvania Company states that arrangements have been made with the owners of such patents as cover fundamental features of ceiling fans, so that the users of their apparatus are immune from interference on this score. Every machine sent out is first tested thoroughly.

The Paragon fan motors, built by the General Incandescent Arc Light Company, New York, remain fundamentally unchanged; the machines have been improved in minor details, but the general design is the same. The field-magnet is a single-piece casting of soft iron, with the front journal box integral; the rear bearing is contained in a removable cap, as indicated by Fig. 46, the removal of which leaves an aperture large enough to withdraw the armature and field coils. The field-magnet coils are machine-wound, covered with two layers of linen tape, dipped in insulating varnish and thoroughly baked. The armature is of the slotted-drum type, hand-wound; the complete armature is dipped and baked. As shown by Fig. 46, the brush-holders are mounted in the removable journal cap; the brushes are rectangular carbons fed by helical springs in the usual manner. The bearings are self-aligning, have phosphor-bronze sleeves, and are lubricated by under-fed wick oilers in the standard machine. The company also builds what is known as the "Paragon Black" fan motor, which differs from the standard machine only in point of finish and in the use of grease instead of oil cups for lubrication. The standard motor is finished in dark green enamel with gilt stripes and the brass work is polished and lacquered, while the "Black" motor is finished in plain black enamel, with dipped and lacquered brass work and an enameled iron fan guard instead of the polished brass guard used on the standard Paragon motor.

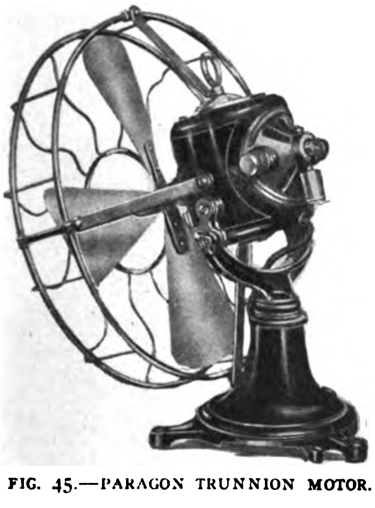

FIG. 45.—PARAGON TRUNNION MOTOR.

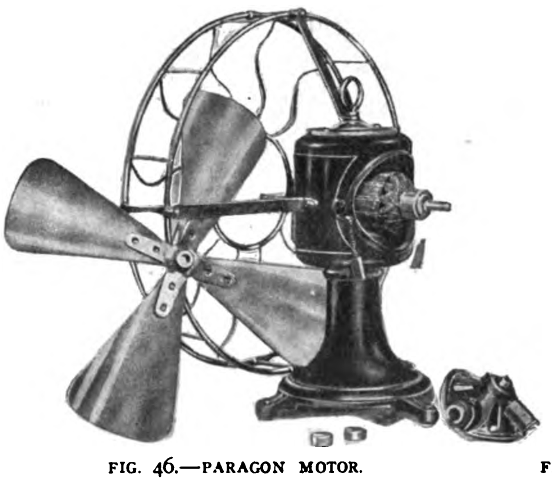

FIG. 46.—PARAGON MOTOR.

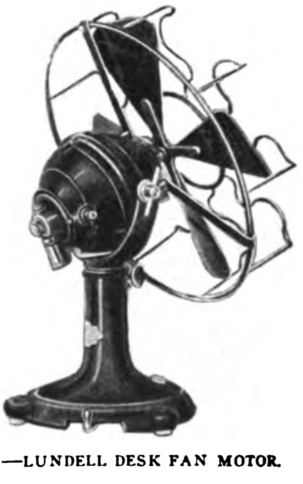

FIG. 47.—LUNDELL DESK FAN MOTOR.

Fig. 45 illustrates the Paragon swivel and trunnion form of mounting, from which it will be seen that the trunnion adjustment is limited by a stud projecting through a slot in the trunnion arm and the motor is held in position by a thumb nut on this stud. The machines are also built with bracket form of mounting. All of them are built with 12-inch and 16-inch fans and wound for the usual direct-current voltages up to 250 volts. They are provided with enamel insulated resistances and regulating switches which give three running speeds, the resistance being mounted within the pedestal. The 12-inch machines run at 1700 r.m.p. and require from 35 to 45 watts, according to the voltage; the 16-inch fan motors run at 1500 r.p.m. and require from 60 to 70 watts, according to voltage. This data applies to both the standard and the Black Paragon fans.

The Lundell fan motors built by the Sprague Electric Company, New York, are illustrated by Figs. 47 and 48. These machines are of the well-known concentric field coil type which has been employed in small Lundell motors for many years past. They are equipped with form-wound hand-taped field windings which are varnished and baked; the armature is of the usual slotted-drum type. The brushes and brush-holders are of the pencil and cartridge type and the oil cups are the under-feed wick type originated by Mr. Lundell several years ago. The machines are built this year only in 12-inch and 16-inch sizes, the 15-inch and 18-inch sizes having been discontinued. They are provided with either rigid mounting or the swivel and trunnion mountings here illustrated and are equipped with three-speeds rheostats and switches. The 12-inch fans run at 800, 1350 and 1900 r.p.m. and require from 52 to 57 watts at full speed, according to the voltage; the 16-inch fans run at 800, 1150 and 1450 r.p.m. and require 103 watts at full speed regardless of voltage.

The Diehl Manufacturing Company, Elizabethport, N. J., has brought out an entirely new line of direct-current desk and bracket fan motors this year. Fig. 49 illustrates the 12-inch desk fan motor. The field-magnet is a single-piece casting with two poles and the ends are closed by the journal caps. The field-magnet coils are form-wound of silk-covered wire, heavily taped, dipped and baked before going on the machine. The armature is of the usual slotted drum-wound type; the winding is of double silk-covered wire and is wound directly into the insulated slots by machine. The commutator is built up of hard-drawn copper bars and insulated throughout with mica. The brushes and brush-holders are of the pencil and cartridge type, but the brushes have rectangular cross-sections. The brush-holder caps are of fibre and are held in place by a pin which is readily withdrawn, the use of screw threads being avoided on account of the liability to damage the cap in removing or replacing it hastily. The machines are all equipped with three-speed rheostats consisting of high-resistance wire wound on a mica plate. The fan guard is also new this year. The outer ring of the guard is made of square stock, and the braces which hold it to the fan body are made of similar stock; the outer ends of these braces are bent so as to hug tightly the outer ring and one of the curved arms, as may be seen by close inspection of Fig. 50, thus rendering solder and screws unnecessary. The bearings are of the usual type, lubricated by means of under-feed wick oilers. The mounting is of the trunnion and swivel form and the trunnion is attached to the pedestal by a ball and socket joint so that the desk fan motor may be converted into a bracket fan motor by loosening a small screw in the head of the pedestal, swinging the latter up through an angle of 90 degrees and resetting the screw in place. See Fig. 50. The motors equipped with 12-inch fans are wound for 110 and 220 volts and require 36 watts at full speed; the speeds are 1750, 1400 and 1100 r.p.m. The motors having 16-inch fans are wound for all three direct-current voltages and require 80 watts at full speed; the speeds are 1450, 1100 and 800 r.p.m.

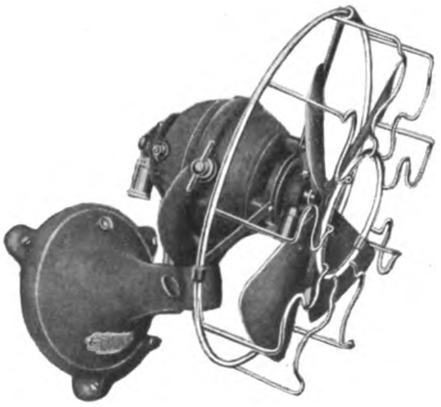

FIG. 48.—LUNDELL BRACKET MOTOR.

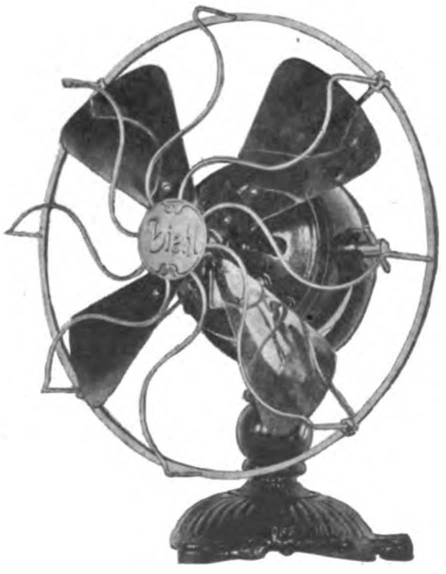

FIG. 49.—DIEHL DESK MOTOR.

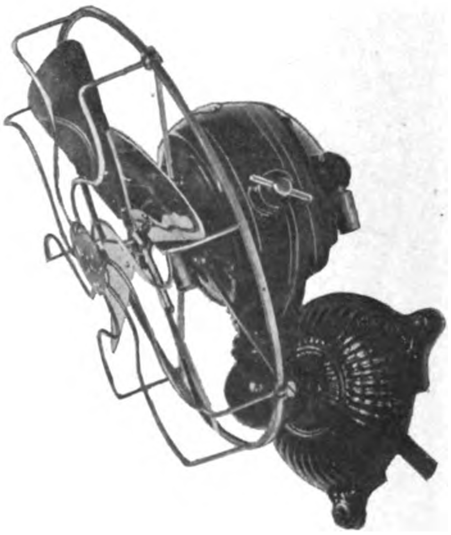

FIG. 50.—DIEHL BRACKET MOTOR.

The Diehl ceiling fan motors remain practically unchanged, so far as constructional features are concerned. The insulation of the machines has been considerably improved, however, the windings being subjected to extra dipping and baking as compared with the previous practice. Fig. 51 illustrates the standard machine, the motor of which is bipolar with a laminated internal field magnet, the armature being of the Gramme-ring external type. As the engraving shows, a part of the case is attached directly to the armature and revolves with it, and the blades are mounted in sockets on this part of the casing. The Diehl internal drum armature ceiling fan motor is illustrated by Fig. 52. The field-magnet is of cast iron in a single piece and is equipped with machine-wound coils which are heavily taped, dipped and baked before being put in place. The armature is of the slotted drum type; in fact, the whole design of the machine is somewhat similar to that of the desk motor. The coil slots in the armature core are insulated with micanite troughs and the coils are machine-wound directly into the slots.

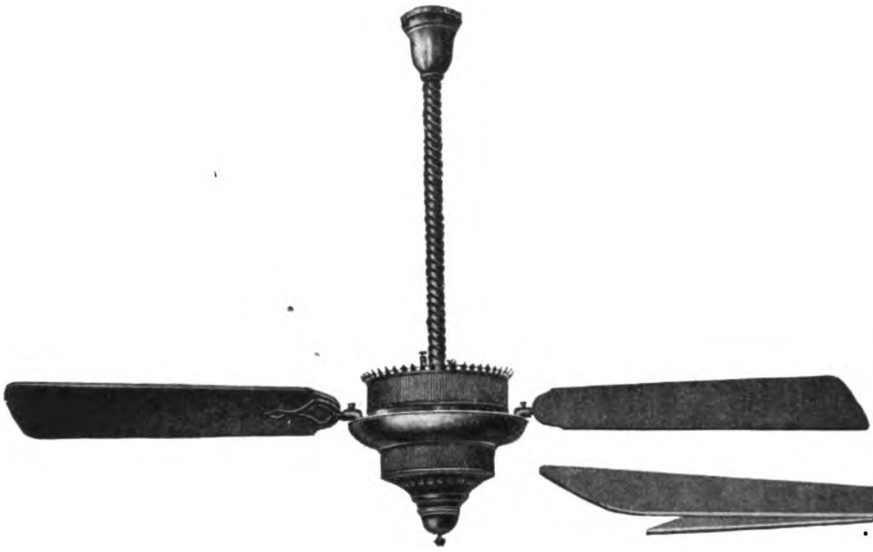

FIG. 51.—STANDARD DIEHL CEILING MOTOR.

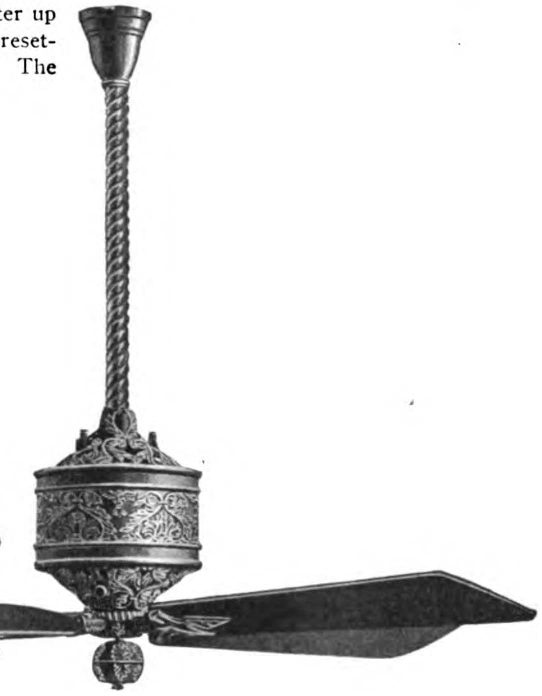

FIG. 52.—DIEHL INTERNAL-DRUM-ARMATURE CEILING MOTOR.

Fig. 53 illustrates the direct-current bracket fan motor of The Peerless Electric Company, Warren, Ohio. The desk machine is exactly similar except in the manner of attaching the swivel to the pedestal. The motor is bipolar, with the yoke-ring and magnet poles cast integral, and has the usual slotted-drum type of armature. The field-magnet coils are heavily insulated and taped; cotton-covered wire is used for low voltages and silk-covered wire for high-voltage machines. This is also true of the armature windings, and the winding is insulated from the armature core by oiled linen; after being connected to the commutator it is tested for break-down between the individual coils and between the coils and the core, 500 volts being applied to the 110 and 220-volt armatures and 1000 volts to the 250 and 500-volt armatures. The brushes are of the carbon pencil type, fed in cartridge brush-holders by helical springs. The commutator is built up of hard-drawn Lake Superior copper, machined to size and insulated with the best grade of mica. Mica is also used to insulate the ends of the segments from the clamping rings. The bearings are lubricated by under-feed wick oilers; the manufacturers recommend the use of heavy cylinder oil in the reservoirs. The bearings are self-aligning with sleeves of gun metal. The fans are provided with three-speed rheostats consisting of a German silver conductor wound on a porcelain spool and the usual form of swivel switch mounted on a porcelain plate in the base of the pedestal.

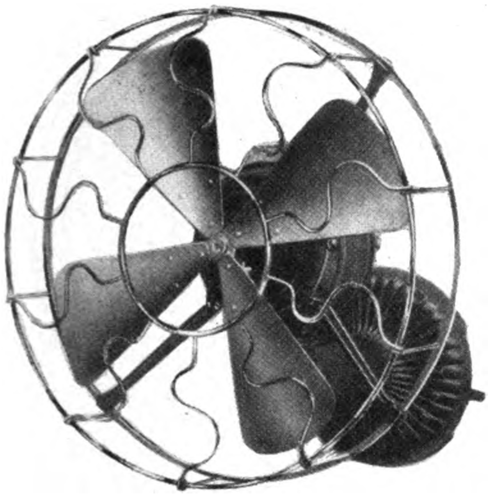

FIG. 53.—PEERLESS DIRECT-CURRENT BRACKET MOTOR.

The Peerless alternating-current desk fan motor is illustrated by Fig. 54. This is a simple single-phase induction machine and is provided with an ingenious starting switch which is so constructed that it gives the rotor a strong impetus when the switch handle is thrown to connect the machine to the circuit. The rotor is of the squirrel-cage pattern, with a shaft of drawn steel. The bearing of the shaft is long and is composed of a seamless drawn tube of phosphor bronze forced into position in the fan motor case, being reamed to accurate size after it is placed in position in order to avoid the liability of a poor fit on the motor shaft. The base of the starting device and switch is made of vulcanized rubber, and the contact blades and points are of phosphor bronze. The mounting is of the swivel and trunnion type. The motors are made with three speeds and are of two sizes: 12-inch and 16-inch, wound for any voltage and frequency up to 250 volts and 140 cycles.

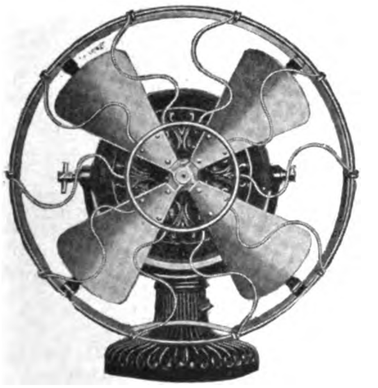

FIG. 54.—PEERLESS ALTERNATING-CURRENT DESK FAN-MOTOR.

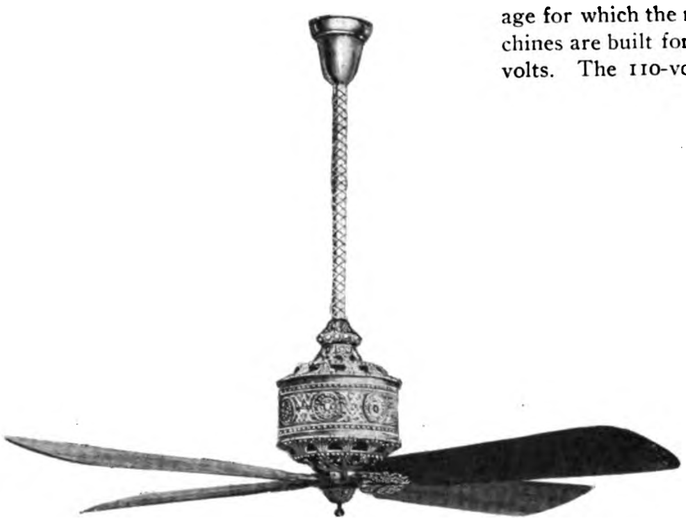

FIG. 55.—PEERLESS CEILING FAN MOTOR.

Fig. 55 illustrates the Peerless Type H-1 ceiling fan motor, which is built for all of the standard direct-current voltages. Fig. 56 is a vertical sectional view of the motor. The machine is bipolar, with form-wound field-magnet and armature coils. The insulation and other features are the same as in the direct-current desk fan motor, except the arrangement of the bearings and the method of lubrication. The bearings are submerged in two oil baths, as the illustration clearly shows; the sleeves are of gun metal and self-aligning. The cartridge-type brush-holders are mounted in the lower part of the casing so as to be accessible without disturbing the casing. The machine is furnished with either four blades, as shown in the illustration, or two, the sweep being 60 inches in both cases. The full speed with four blades is 200 r.p.m. and 220 r.p.m. with two blades. The power required ranges from 110 to 115 watts, according to the voltage for which the motor is wound. The machines are built for 110, 170, 220, 250 and 500 volts. The 110-volt and 220-volt machines are provided with two-speed switches, as shown in Fig. 56, the switch being located at the top of the frame work and operated by means of a spindle through the hollow armature shaft and terminating in a button at the bottom; the slow speed is 110 r.p.m. for the four-blade fans and 130 r.p.m. for the two-blade machines. The motors for the other three voltages specified operate at one speed only.

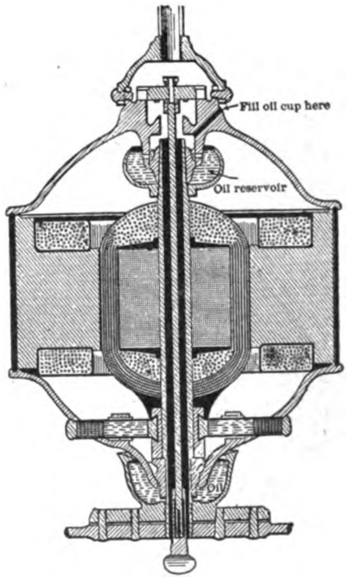

FIG. 56.—SECTIONAL ELEVATION OF PEERLESS CEILING FAN MOTOR.

The Eclipse fan motors, illustrated by Figs. 57 to 64, are built by the Fidelity Electric Company, Lancaster, Pa., successor to the Geo. C. Towle Mfg. Company. The construction of the field magnet is clearly indicated by Fig. 58. The field-magnet coils are form-wound to a rectangular outline and drawn into the slots on each side of the polar extensions after being insulated by hand, varnished and baked. The armature is of the familiar slotted-drum type, with the coils wound directly into the slots. The illustration shows rigid pedestal mounting, but the machines are also built with swivel and trunnion mounting, as shown by Fig. 61, which represents the bracket form of motor. They are built in 12-inch and 16-inch sizes, and furnished with three-speed rheostats and switches. The 12-inch fan runs at 1000, 1600 or 2000 r.p.m., and the

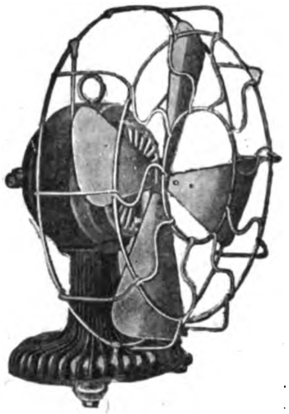

FIG. 57.—ECLIPSE MOTOR.

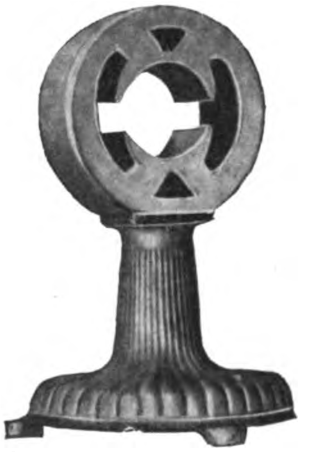

FIG. 58.—ECLIPSE FIELD-MAGNET FRAME.

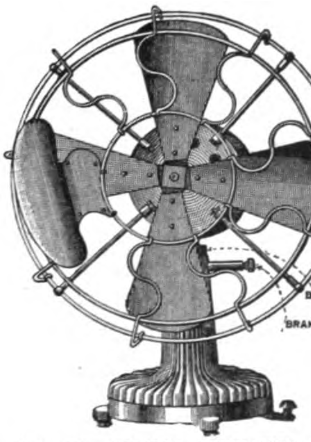
16-inch fan at 600, 1000 or 1650 r.p.m. Fig. 60 shows the duplex fan motor of this company, consisting of a rigidly-mounted desk machine with two fans and guards. These are wound for 110, 170, 220 and 250 volts, and are furnished with rheostats and switches giving 1000, 1400 and 1800 r.p.m. This form of machine is also built with the standard type of motor used in the desk fan motor described above.



BALL BEARING.
BRAKE SCREW.

FIG. 59.—ECLIPSE REVOLVING MOTOR.

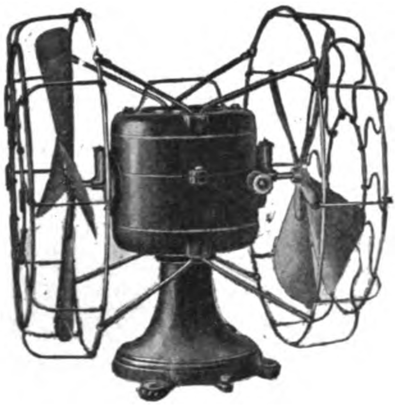


FIG. 60.—ECLIPSE DUPLEX MOTOR.

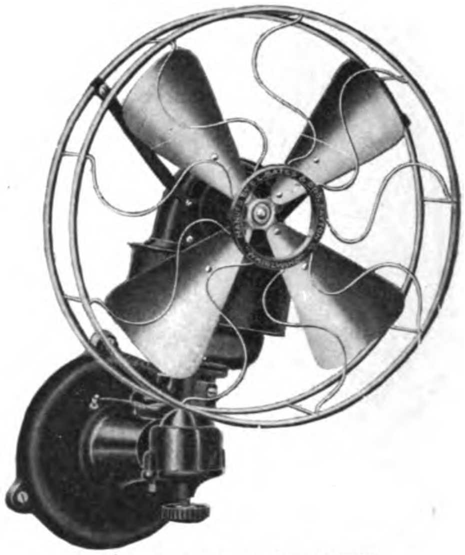

FIG. 65.—BATES BRACKET MOTOR.

Fig. 59 shows the revolving desk fan motor of the Fidelity Company, brought out last year. The motor is mounted on a ball-bearing at the top of the pedestal and is caused to revolve about its vertical axis by the reaction of the air blast on the deflector shown attached to the fan guard. Connections are made between the motor and the terminals on the base by means of small collector rings mounted on the shank of the motor frame and brushes mounted on a porcelain plate in the pedestal base. The fan is provided with a two-speed rheostat and switch in the pedestal base. The rate at which the motor revolves about its vertical axis is adjustable by means of the brake screw shown at the top of the pedestal in the illustration. The Fidelity ceiling fan motor is of essentially the same design as the motor of the desk and bracket machine, except that the motor has four field-magnet poles and the armature coils are form-wound and insulated before being put on the core. These machines are furnished without the electrolier shown in Fig. 62 unless it is specially ordered. Either two or four blades are furnished, and the speed is 180 to 200 r.p.m. The motors are wound for the standard direct-current voltages and also for 170 volts to operate three in series on a 500-volt circuit.

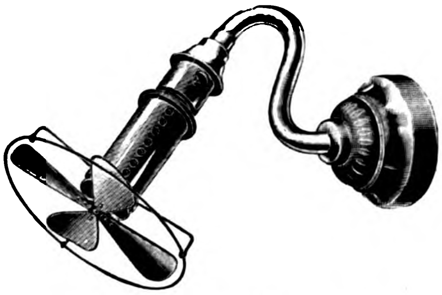

FIG. 63.—ECLIPSE SOCKET MOTOR.

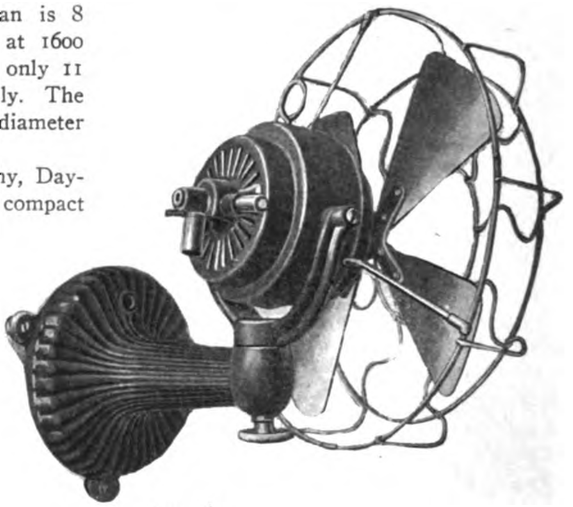

FIG. 61.—ECLIPSE BRACKET MOTOR.

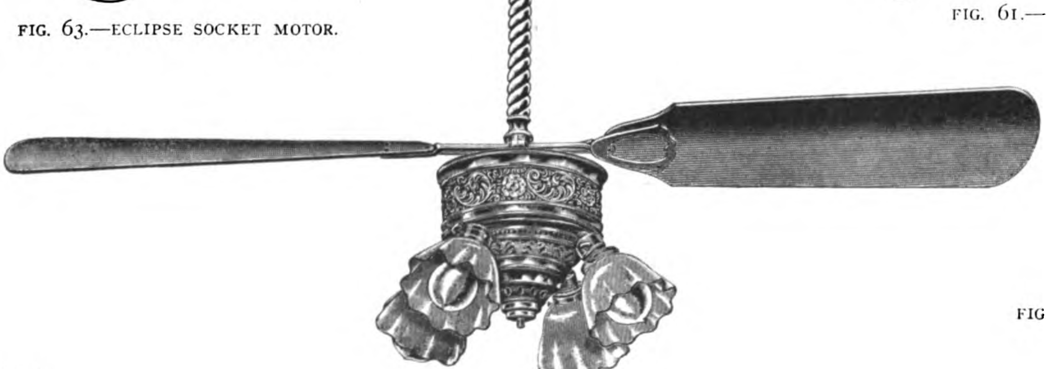

FIG. 62.—ECLIPSE CEILING MOTOR.

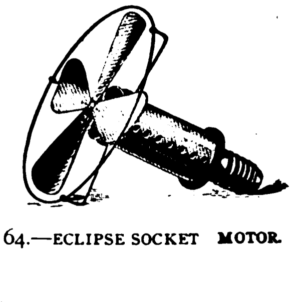

FIG. 64.—ECLIPSE SOCKET MOTOR.

Fig. 64 shows an ingenious little socket fan motor brought out this year by the Fidelity Company, and Fig. 63 shows the motor in position for operation. The field-magnet is bipolar, with a single coil, and the motor is completely enclosed in a ventilated brass casing, which terminates at the rear end in a screw plug to fit the standard Edison lamp socket. The fan is 8 inches in diameter and is driven at 1600 r.p.m. with an electrical intake of only 11 watts; it is wound for 110 volts only. The motor casing is only 1¾ inches in diameter and 4½ inches long over all.

The D. L. Bates & Bro. Company, Dayton, Ohio, continues to build the compact type of bipolar fan motor illustrated by Figs. 65 and 66. The magnet cores are of forged steel, and the armature is of the usual slotted-drum type. The armature is protected by enclosing caps applied to the magnet poles and containing the journal boxes. These machines are built for 110, 220 and 500-volt circuits. The bracket motor (Fig. 65) is provided with a universal socket adjustment and the desk motors are built with either a swivel and trunnion base shown in Fig. 66, or a solid base. The power consumption of the machines at full speeds is as follows: 12-inch fan at 110 volts, 31 watts; at 220 volts, 44 watts; 16-inch fan at 110 volts, 60 watts; 220 volts, 83 watts, and at 500 volts, 125 watts. All of the fans are provided with three-speed switches, giving speeds of 1500, 1700 and 1900 r.p.m. in the 12-inch size; 1200, 1350 and 1600 r.p.m. in the 16-inch 110-volt machine; 1400, 1500 and 1600 in the 16-inch 220-volt machine, and 1300, 1400 and 1500 in the 16-inch 500-volt machine.

The Bates "Style E" ceiling fan motor with electrolier attachment is illustrated by Fig. 67; the construction of the motor itself is shown by the sectional elevation, Fig. 68. The machine has a six-pole field magnet with the yoke-ring and poles cast integral. The magnet coils are wound on fibre spools and heavily insulated. The armature core is a slotted-drum of large diameter and the coils are form-wound and hand insulated before being put in place. The commutator bars are of hard-drawn copper and are assembled under hydraulic pressure. The brush-holders and brushes are of the cartridge and pencil type, with helical springs for feeding the brushes. The holders project through openings in the lower part of the motor casing, so that the brushes may be renewed without disturbing any other part of the machine. The brushes are of rectangular cross-section, ¼ x ⅜ inch in size. The motors are furnished with or without the switch shown in the sectional view; the switch proper is indicated by *S* and the speed-regulating rheostat by *R*. The machine is also supplied with the switch alone for convenience in starting and stopping the fan. When furnished with four blades the sweep is 54 inches; two blades of 59 inches sweep are supplied when desired. These machines are wound for 110, 167, 220, 250 and 500 volts. The 110-volt machine requires 85 watts at full speed.

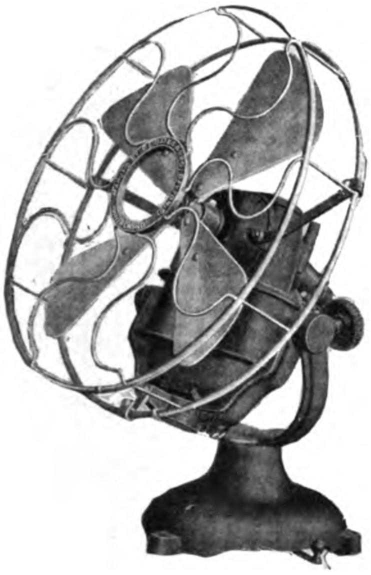

FIG. 66.—BATES DESK MOTOR.

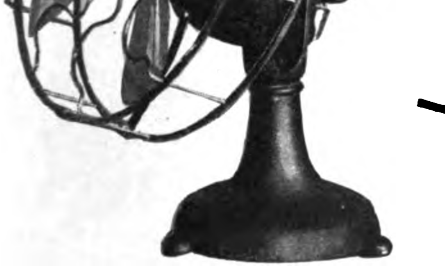

FIG. 69.—DAYTON DESK MOTOR.

Fig. 69 illustrates the direct-current desk fan motor built by the Dayton Fan & Motor Company, Dayton, Ohio. This machine is bipolar and equipped with the usual form of slot-wound drum armature, cartridge and pencil brush-holders and brushes, under-feed self-oiling bearings, and three-speed rheostat. The motor is built in three styles of mounting: the swivel and trunnion pedestal mounting, shown in the engraving, the same style of mounting in bracket form, and a rigid pedestal mounting. The motor is wound for 110, 220 or 500 volts. The speeds are 1800, 1300 and 800 r.p.m., and the power consumption for the 12-inch fan is 44 watts at full speed. The construction is very similar to that of the Dayton Junior ceiling fan motor illustrated by Fig. 72, so far as the field-magnet and armature are concerned; the bearings are of course different, being of the usual type for horizontal shafts. In the Dayton Junior ceiling fan motor the usual form of armature shaft is employed. The case is stationary, being mounted solidly on the field-magnet frame. The lower bearing is lubricated from the reservoir in that part of the casing marked *B*. Fig. 72, the oil being caught in the cup formed in the upper part of the fan-blade hub; the upper bearing is oiled from the reservoir, *J*, the oil that trickles through being caught in the cup, *I*, mounted on the armature shaft. The commutator of this machine is of the usual type, and the brush-holders of the cartridge type, provided with adjusting screws. The Dayton Junior fan is usually provided with four blades, and runs at 225 r.p.m.

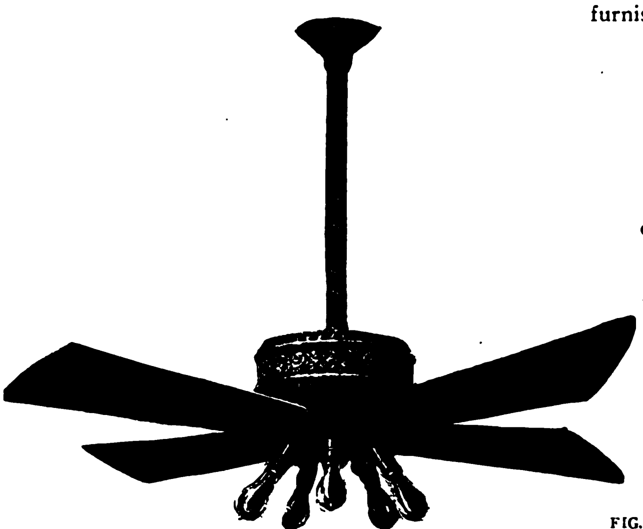

FIG. 67.—BATES CEILING FAN MOTOR.

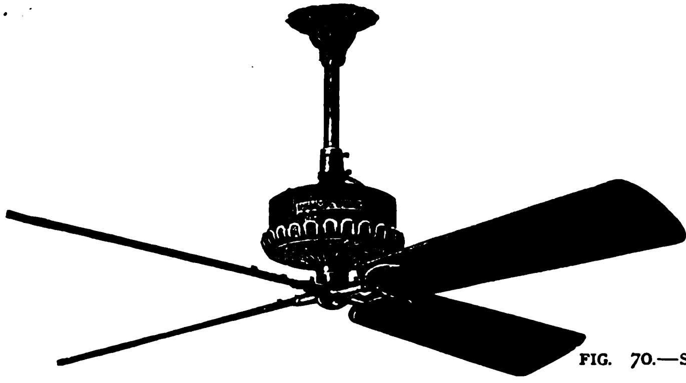

FIG. 71.—DAYTON CEILING FAN.

Fig. 71 illustrates the Dayton Fan & Motor Company's standard ceiling fan motor, this engraving showing the style that is furnished for operation at 500 volts; Fig. 70 is a cross-section through the motor of this machine. It will be evident from an inspection of the latter engraving that the field magnet is bipolar and has channeled pole-pieces which embrace three sides of the armature cross-section. The armature winding is necessarily of the Gramme ring type, and the arrangement of the air-gap obviously results in a very low magnetic reluctance in this part of the circuit. The field-magnet coil is divided into two sections, in order to leave the center of the core free for the passage of the axle about which the armature rotates. The armature is secured by means of the screws directly to the ornamental casing, *B*, which closes the motor in on the under side, and this casing also carries the commutator, *C*, which is of the disc type. The casing, *A*,

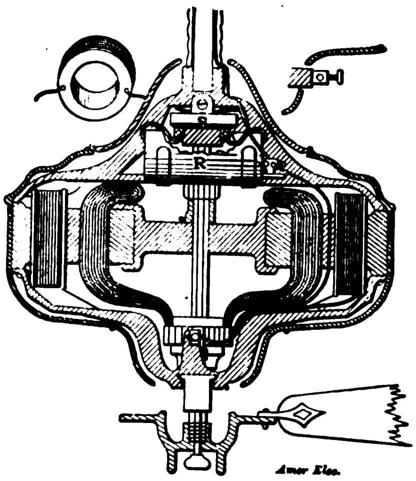

FIG. 68.—SECTIONAL ELEVATION OF BATES CEILING MOTOR.

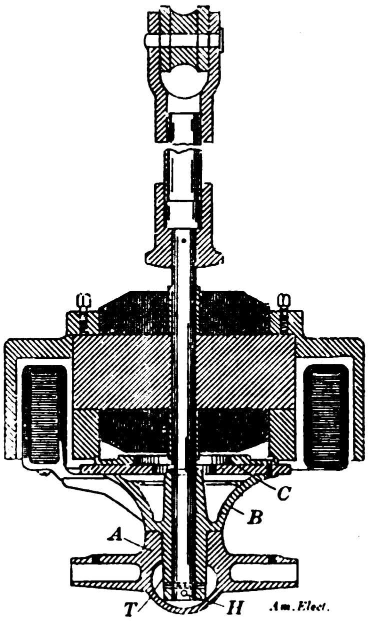

FIG. 70.—SECTIONAL ELEVATION OF DAYTON CEILING FAN MOTOR.

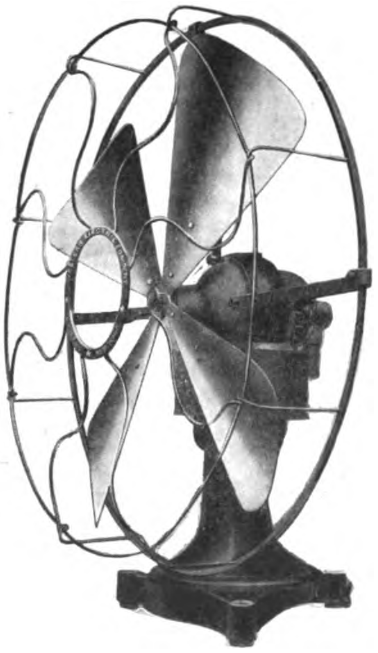
with which the fan-blade sockets are integral, is screwed onto a hub at the bottom of the casing, and contains a large cup for the retention of the oil that trickles through the bearing. Oil is supplied to this bearing from the reservoir located immediately beneath the commutator.

There is, properly speaking, no armature shaft, the casing, *B*, revolving about the stationary axle, *H*, which is held in the socket by means of set screws. The Dayton standard fan is supplied ordinarily with four blades for all circuits except 500 volts, and runs at 215 r.p.m. The 500-volt fan is provided with two blades and runs at 210 r.p.m.

The general appearance of the Western Electric Company's desk fan motor for 1904 is similar to that of the well-known type of the past year. Fig. 73 is an external view and Fig. 74 is a cross-sectional view of the machine. The field-magnet is of the inverted horseshoe type, which style of construction allows a short pedestal and small enclosing castings to be used, thereby making the weight of the motor unusually low, as a large proportion of the weight is in the "working material." The weight of the motor is further reduced by the use of a forged steel field magnet. The armature is of the slotted drum type, wound with double silk-covered wire, which is insulated from the core by pressboard tubes in the slots and pressboard discs over the end plates. The field-magnet coils are wound on pressboard spools, and being exposed to the direct action of the moving air, an exceptionally low-running temperature is obtained. The large diameter of the armature, the forged steel field magnet, field coils of small diameter cooled by moving air, a short air-gap and careful shaping of pole tips, all affect the efficiency of the motor favorably.



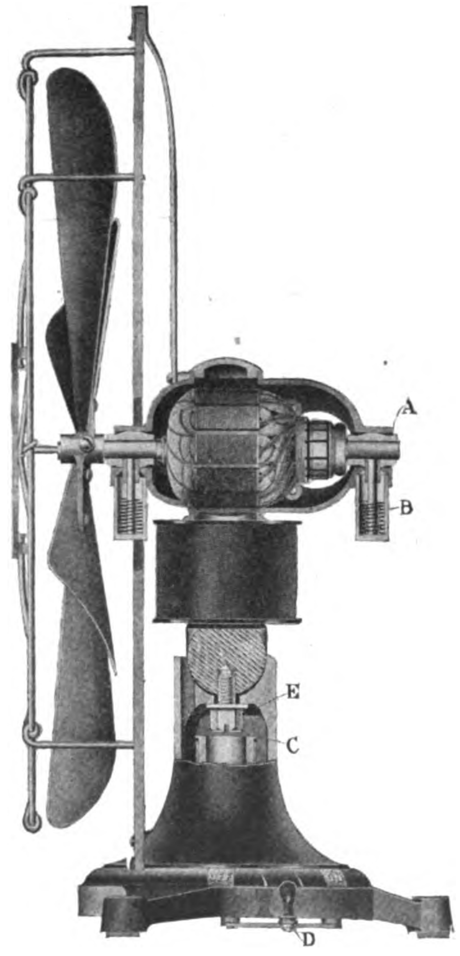


FIG. 73.—WESTERN ELECTRIC DESK FAN MOTOR.—FIG. 74.

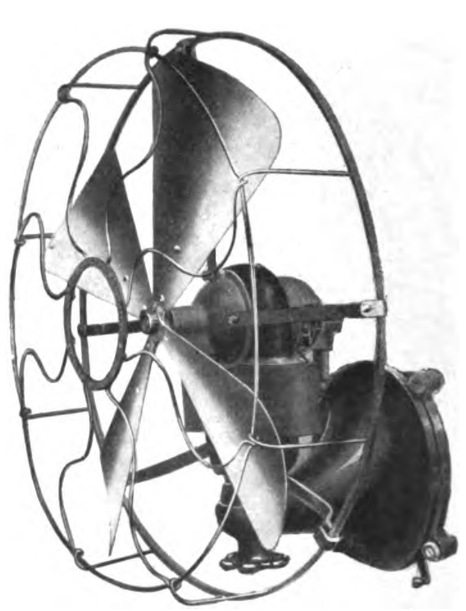

FIG. 75.—WESTERN ELECTRIC BRACKET MOTOR.

The commutator is made of hard-drawn copper segments, separated by best mica insulation. The bearing bracket enclosing the commutator end of the armature is of such a form as to furnish protection from any dirt or dust falling upon the fan, but it is sufficiently open to allow the commutator to be readily inspected. The bearing brackets contain babbitt sleeves and are provided with lips which overhang flanges on the commutator cap and on the fan hub to prevent the throwing of oil. From the recesses in the bearing brackets formed by the lips, the oil is drained back to the oil cups through ducts in the castings. A cap covers the end of the shaft and bearing and prevents leakage of oil and entrance of dust.

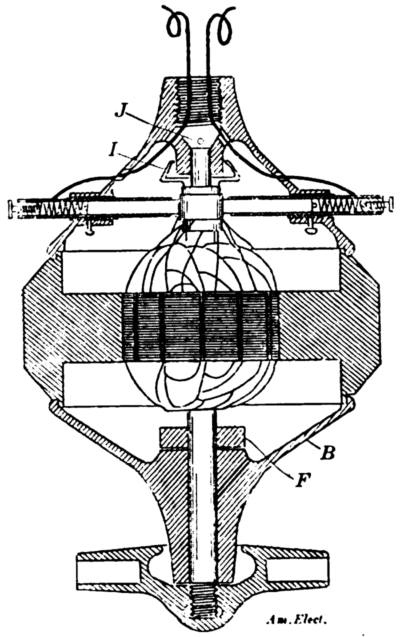

FIG. 72.—CROSS-SECTION OF DAYTON "JUNIOR" CEILING FAN MOTOR.

The brushes are of specially prepared graphite, circular in cross-section, and self-adjusting. The brush holders are a modification of the cartrdige type and are provided with triggers which bear upon the ends of the brushes, pressing them against the commutator. They allow almost the entire brush to be used up, and as there is no clamping, the brushes are not likely to break. The brushes can be readily renewed without disturbing any of the electrical connections.

The speed-regulating rheostat consists of an iron drum, upon which is wound German silver wire, embedded in and protected by a complete coating of white enamel, so as to eliminate any possibility of short-circuiting or grounding on the adjacent frame. The drum is mounted on a porcelain base carrying the speed-regulating switch and binding posts, and located within the pedestal.

These motors are wound for operation on standard direct-current circuits of 110, 220 and 500 volts. The field magnet coils are connected in series with the armature for all voltages. This type of motor is also made with the bracket form of mounting, as shown in Fig. 75. The fan can be turned to any desired position by the adjustment of a single hand screw, and the adjustment can be made while the fan is running at full speed. The motor frame swivels upon a ball and socket joint and has a horizontal range of adjustment of 180° and a vertical range of 45°.

The Western Electric Company's ceiling fan motors are shown by Figs. 76 and 77. Fig. 76 is a cross-sectional view of the Western Electric Standard ceiling fan motor. It is bipolar and has a slotted drum armature, the core being mounted directly on the shaft. The yoke ring and magnet poles are one casting of semi-steel. The armature winding is of double silk-covered wire wound in round holes and insulated from the core by pressboard tubes and end discs. The field magnet coils are wound in four sections, each section being thoroughly insulated with a double wrapping of heavy insulating tape dipped in Sterling insulating varnish. As in the desk fan motor, the armature is of large diameter in order to obtain a large number of slots and coils.

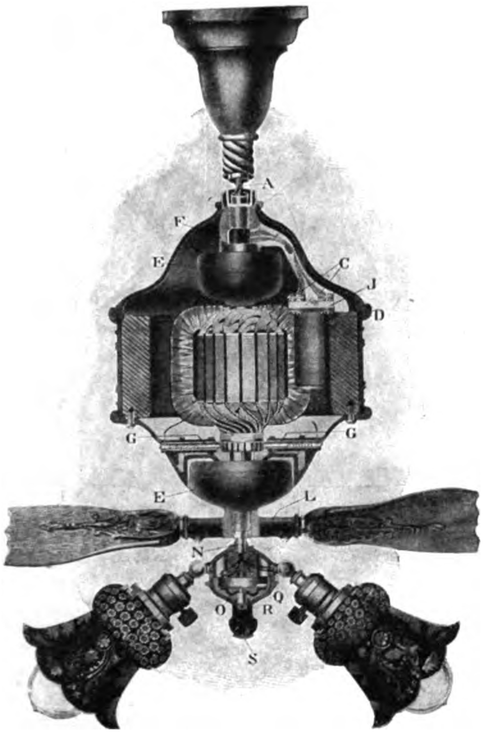

FIG. 76.—SECTIONAL VIEW OF STANDARD CEILING FAN MOTOR.

These machines are equipped with non-spillable oil reservoirs, which flood the bearings constantly with oil. The well is partly covered and a flange extends from the top of the well nearly to the surface of the oil, somewhat like an invertible inkstand, and this prevents the oil from spilling when the motor is laid on its side or even inverted. There is left a sufficient opening around the shaft to allow thorough washing of the well with benzine at the end of the season.

The brushes and holders are of the cartridge type, and the brushes are graphite pencils, each pressed toward the commutator by a helical spring behind it. The spring is designed to give a constant pressure to the brush until it is almost entirely used up.

The weight of the motor is supported by a strong cast-iron bracket fastened to the frame with machine bolts. The bracket also supports the upper bearing and a steel tube extending through the armature shaft, which is hollow. This tube contains a six-wire cable, including the wires for the chandelier lights and the wires connecting the speed-regulating rheostat to the switch. The rheostat, which gives three speeds to the fan, is made of German silver wire wound on an iron drum and embedded in a coating of white enamel. The rheostat is mounted on a porcelain base screwed to the cast-iron bracket. The base serves as a connection board, having six binding posts for connections of the chandelier lighting leads and rheostat leads.

The upper cover can be removed to get at the upper oil well and the connection board without taking the fan from the ceiling hook. The bearings are of babbitt and are self-aligning.

The blades are white basswood and have a sweep of 60 inches; the width across the face is 8¾ inches. They are pitched to give an unusually large wind output, while the input is only 120 watts. The speed is 210 r.p.m. These motors are wound for 110, 170, 220, 250 and 500 volts; the 170-volt and 250-volt motors are intended to run in groups of three and two, respectively, in series on 500-volt circuits, in which case a wall switch rheostat for three-speed control is furnished.

Fig. 77 is a cross-sectional view of the Western Electric Company's "Western" ceiling fan motor. This is a single-speed motor. It is bipolar and has an armature similar to that of the company's Standard machine just described. The field magnet yoke is of a special grade of soft cast-iron, and the magnet poles are of forged wrought iron, bolted to the yoke. The poles have extended tips which give the pole-faces a large angle of embrace; the coils are wound on pressboard spools and are of small diameter as compared with the size of the pole-face. The brackets supporting the upper bearing and switch and the upper covering to which the suspension rod screws, are cast integrally with the frame. The Western fans are equipped with oil reservoirs, but they do not have the non-spillable feature of the Standard oil wells, although the method of lubrication is the same. Before removing the fan from the ceiling hook, the oil should be withdrawn from the wells by means of a small oil pump provided for this purpose. The switch in the upper part of the motor is operated by a key and a rod extending through the hollow armature shaft.

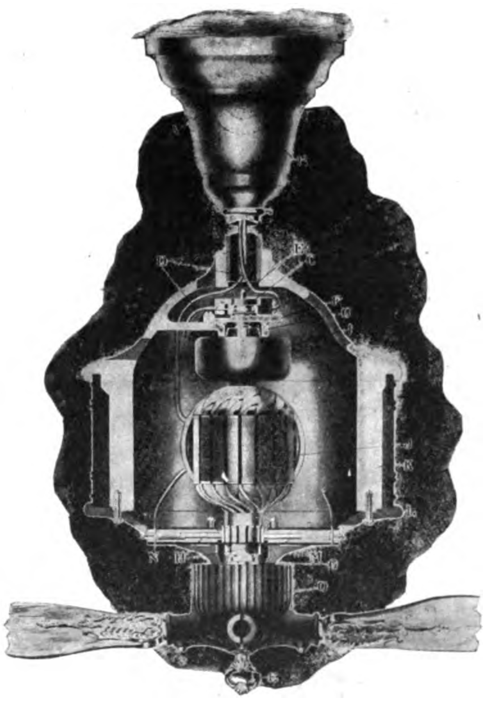

FIG. 77.—SECTIONAL VIEW OF WESTERN CEILING MOTOR.

The Western fans are furnished with or without the switch; the fan with the switch is designated "No. 1," and the other is "No. 2." No. 1 motor is wound for 120, 220 and 500 volts, while the No. 2 machine is designed to operate singly on 110, 170, 220, 250 and 500 volts or in series groups of two 110-volt fans on a 220-volt circuit; five 110-volt fans on a 550-volt circuit; three 170-volt fans on a 500-volt circuit, or two 250-volt fans on a 500-volt circuit. The blades are of white basswood, free from blemish, and have a sweep of 54 inches. The motors run at 200 r.p.m. with an electrical input of 90 watts.

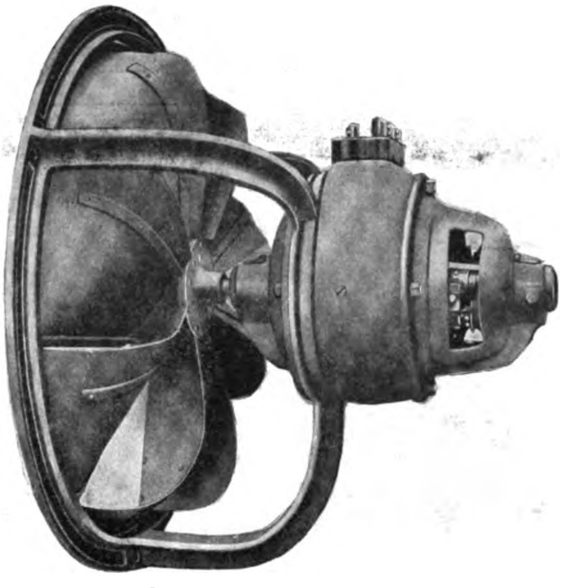

FIG. 78.—WESTERN ELECTRIC 24-INCH VENTILATING FAN.

Fig. 78 illustrates one of the Western Electric Company's ventilating fan outfits. This comprises a standard power motor mounted as shown in the engraving. The machine is multi-polar, with a cast-steel yoke ring to which cast-steel magnet poles are bolted. The poles are of circular cross-section where the coils embrace them, and are provided with polar extensions. The armature is of the usual slotted drum type, and is equipped with form-wound hand-insulated coils. The field magnet coils are machine-wound also, and thoroughly insulated. These outfits are built in sizes ranging from 24 inches to 72 inches fan diameter; the speeds range from 750 to 270 r.p.m. Similar outfits are also built in sizes of 12 and 16-inch fan diameters; these are equipped with bipolar motors of the same type as the Western Electric desk fan motor.

Figs. 79 and 80 illustrate the desk and bracket motors of The Robbins & Myers Co., Springfield, Ohio. The motor is a bipolar machine with a slotted drum-wound armature of rather large diameter. The field-magnet is a single-piece casting of iron and the coils are form-wound and hand-insulated. The armatures are machine-wound, the slots being, of course, heavily insulated before the winding process begins. The brushes and brush-holders are of the pencil and cartridge type, the brushes being 5/16-inch carbon pencil 1¼ inches long. The holders are mounted in insulated clamps in the rear journal cap and the complete holders and brushes may be removed without disturbing any connections or other parts of the machine. The commutator is insulated with mica throughout and the leads from the armature are bound to an asbestos insulating ring on the rear collar of the commutator in order to obviate the liability of their breaking by reason of vibration or rough handling of the machine in transit. An unusual feature in machines of this size consists in the use of a journal sleeve which is adjustable to take up wear. The sleeve is split lengthwise along the top and fits snugly into the central hole of the housing. Two screws are set into the end of the hub at such an angle that setting them up draws the split sleeve more closely around the shaft. Lubrication is provided by underfeed wick oilers.

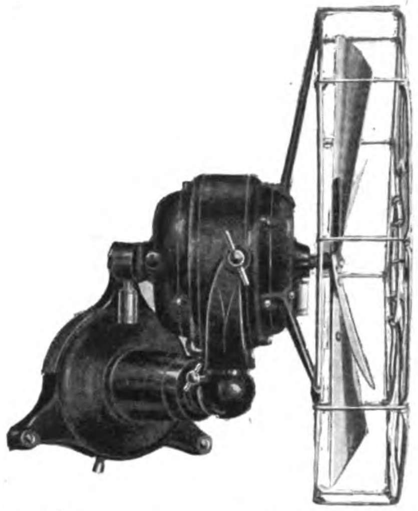

FIG. 80.—ROBBINS & MYERS BRACKET MOTOR.

The machines are provided with three-speed rheostats and switches, which give 1000, 1400 and 1800 r.p.m. for the 12-inch fan, and 800, 1150 and 1500 r.p.m. for the 16-inch fan; the regulating switch also serves to break the circuit for stopping the machine. The switch parts are insulated with mica, and the resistance wire is wound on a triangular iron frame heavily insulated with asbestos. The power consumption of these machines ranges from 35 to 45 watts for the 12-inch fan, and from 85 to 95 watts for the 16-inch fan, according to the actual voltage on the various circuits for which the motors are wound. The machines are built for the standard direct-current circuits of 110, 220 and 250 volts. When two or more motors are operated in series, the regulating switches are constructed so that they cannot open the circuit, but the speeds of all of the fans may be regulated, of course, by any one switch, or by two or more in combination. The mounting of these machines has been changed from a universal joint to the swivel and trunnion style here shown.

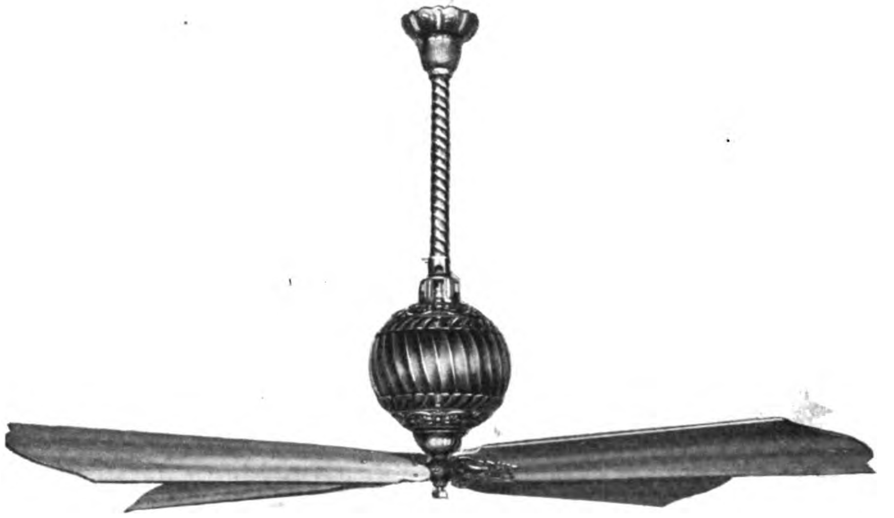

FIG. 82.—ROBBINS & MYERS STYLE "A" CEILING MOTOR.

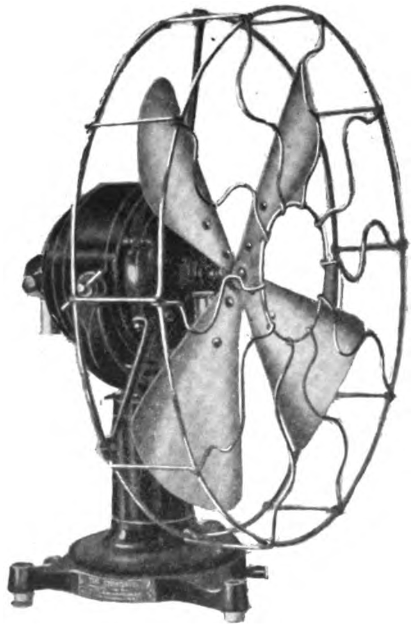

FIG. 79.—ROBBINS & MYERS DESK MOTOR.

Fig. 81 illustrates the Robbins & Myers oscillating desk fan brought out this year. The motor is of the same general construction as the standard machine just described, but it is pivoted on a ball-bearing in the pedestal so as to swing about its vertical axis. It is caused to oscillate by a deflector plate carried at the upper end of an arm which is pivoted to the lower part of the fan guard. The lower extension of this arm carries a counterbalancing weight and is arranged to impinge against two rollers mounted adjustably on the base. These rollers may be set at any point within a reasonable range and their position determines the angle through which the motor oscillates. When the lower end of the deflector arm strikes against one of the limit rollers, the arm is thrown over to the other position, shifting the deflector blade to the opposite side of the horizontal axis of the machine and thereby reversing the direction of movement about the vertical axis.

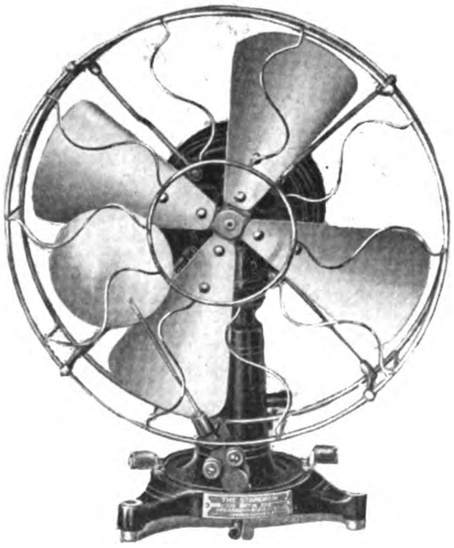

FIG. 81.—ROBBINS & MYERS OSCILLATING MOTOR.

Fig. 82 shows the Robbins & Myers "Style A" ceiling fan motor. This is a bipolar machine with a cast-iron yoke-ring to which drop-forged steel magnet poles are bolted; the poles are provided with extended tips so as to increase the area of the air-gap. The magnet coils are form-wound, taped, dipped in Sterling varnish and baked. The armature core is slotted and drum-wound; the coil slots are insulated by fibre troughs 1-64 inch thick and the coils are wound directly into the slots. The machine is usually furnished with four fan

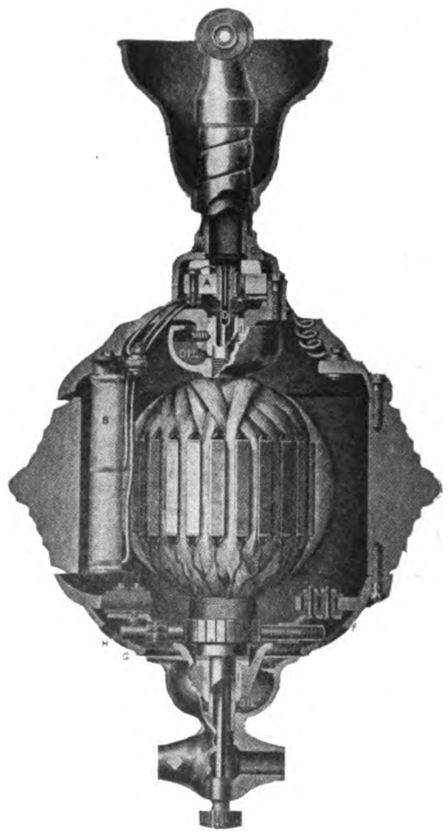

FIG. 83.—CROSS-SECTION OF STYLE "B" MOTOR.

blades and wound for 110, 170, 220 and 250 volts. The 170-volt and 250-volt motors are intended to be operated in series on 500-volt circuits, and when equipped with switches one motor of a series may be cut out without interfering with the other motor or motors. The sweep of the blades is 60 inches and the speed is 200 r.p.m. The "Style B" Robbins & Myers ceiling fan is somewhat similar in external appearance to the "Style A" machine, but the construction of the field-magnet is different. Fig. 83 is a sectional elevation of the motor. The field-magnet is a single-piece iron casting of the shape shown by Fig. 84. This construction provides a large air-gap area in comparison with the magnet-core area and yet allows the field-magnet coils to be put in place and withdrawn without necessitating removable poles or shoes. The other details of construction and insulation are similar to those just described in connection with the "Style A" machine. In both machines cartridge brush-holders and carbon pencil brushes are used. The arrangement of the armature shaft and switch is also similar in the two machines. The armature shaft is hollow, in order to permit the switch spindle, *D*, to pass up through it from the thumb piece, *E*, at the bottom of the fan, to the switch, *A*, at the top. The switch, in conjunction with the resistance coil, *B*, gives two speeds to the 110-volt and 220-volt machines. The motor is not furnished with the switch and resistance unless so ordered, the construction being such that the switch and resistance can be inserted or omitted without changing any of the remainder of the structure.

The bearings are lubricated by immersion in two large oil baths or reservoirs, the cups of which are mounted on the armature shaft and revolve with it. The basin or cup at the bottom of the shaft is cast solid with the fan-blade hub, as indicated in the engraving.

In addition to these machines the company has brought out a standard 500-volt fan, which runs at 200 r.p.m. and requires 0.2 ampere at the rated voltage. The general construction is similar to that of the two fans just mentioned, but more room is provided for the windings in order to permit the use of the extra-heavy insulation

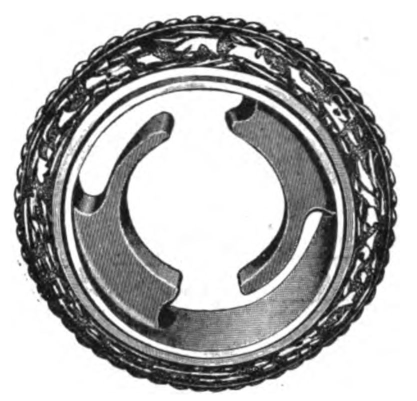

FIG. 84.—FIELD MAGNET, ROBBINS & MYERS STYLE "B" CEILING MOTOR.

The ceiling fan motor of the Century Electric Company, St. Louis, Mo., illustrated by Fig. 86, is a single-phase alternating-current machine, and has the distinction of including in its construction a practically separate starting motor. The working motor is of the squirrel-cage induction type with an external rotor mounted in the main casing, which revolves and carries with it the fan blades. Fig. 87 is a sectional elevation of the machine. The stator, *J*, is mounted on the stationary part of the structure, which also carries a bi-polar starting magnet, *H*, the cores of which are parallel to the axis of the machine. The revolving member which carries the rotor also carries a three-pole armature and three brushes located in between the three armature poles. Each armature pole carries a coil and the three coils are connected together star fashion, and their free terminals are connected to the three brushes. The brushes are pressed by helical springs against a two-part commutator, to the segments of which the field coils are connected, one terminal of each field coil being led to each of the segments, and the other field terminals being connected to the line. This obviously makes the starting motor a series machine of the simple three-coil armature type which has been used to a considerable extent in very small battery fan motors. The brush-holders are heavy castings, and the relation between the weight of the brush-holders and the tension of the springs which press the brushes against the commutator is such that the holders are thrown back by centrifugal force when the armature reaches the proper speed for the induction motor to take hold and bring the armature up to normal speed.

The armature shaft is hollow and revolves about a long hollow axle, *D*. At the lower end of the shaft is provided a ball bearing consisting of hardened steel washers, *M*, and steel balls, *N*. The bearing is immersed in an oil reservoir, *K*, which is attached to the stationary part of the machine, of course. The suspension hook, *B*, is insulated from the stem of the machine by means of an insulator, *C*, and a felt strip, *E*, is interposed to take up any vibrations which would otherwise be transmitted to the hook. The standard windings are for 100 to 110 volts and 60 cycles, but machines are supplied for any lower voltage and frequency desired.

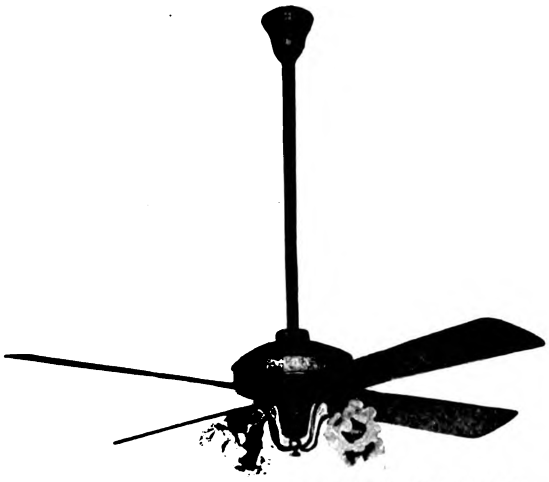

FIG. 86.—CENTURY CEILING FAN MOTOR.

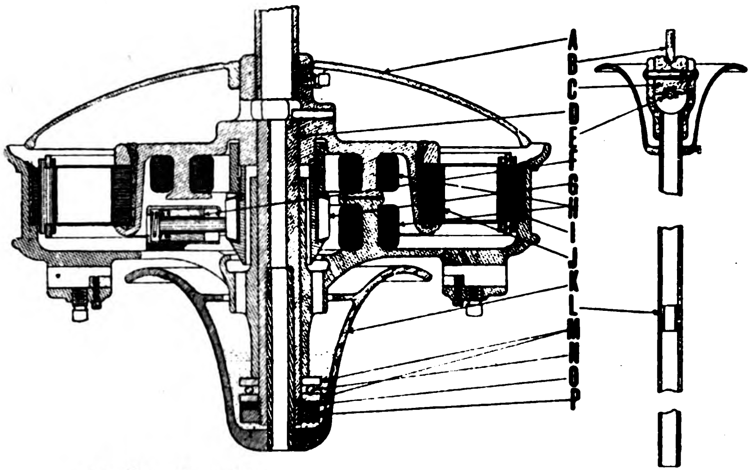

FIG. 87.—SECTIONAL ELEVATION OF CENTURY CEILING MOTOR.

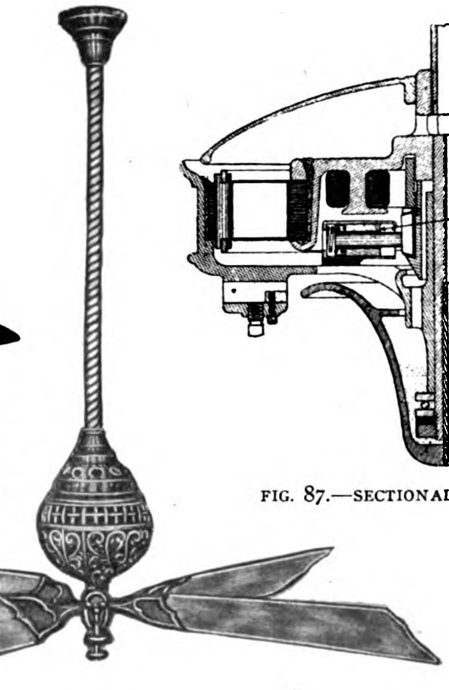

FIG. 85.—TUERK ALTERNATING-CURRENT CEILING MOTOR.

Fig. 85 shows the Tuerk ceiling fan motor built by the Hunter Fan and Motor Company, Fulton, N. Y. The motor is of the squirrel-cage induction motor type, with an ingenious speed-reducing arrangement of leather-faced friction wheels between the motor shaft and the fan shaft. The blades have 60 inches sweep and their speed is 175 r.p.m. The motor requires 100 watts, and is wound for all standard alternating-current voltages, and for both high and low frequencies.

The direct-current ceiling fan motor of the Sterling Electric Motor Company, Dayton, Ohio, is shown by Fig. 88. The motor is a bi-polar machine with the field-magnet yoke-ring and poles cast in a single piece and equipped with form-wound coils, taped and varnished. The armature, which is of the slotted-drum type, is also equipped with form-wound and individually insulated coils. A single bearing of unusual length is employed, and this is lubricated from the oil reservoir shown in the engraving. The speed-regulating rheostat is of fireproof construction, and is located above the motor, so that it has full ventilation, and the heat generated in it cannot affect the bearings or windings of the machine. The regulating switch is also located at the top of the motor and operated by means of a spindle extending through the hollow armature shaft, as in the cases previously cited, and terminating in a key below the fan-blade hub. The switch has been very greatly strengthened since last year; the old construction showed a tendency to become weak and cause trouble in the contacts. The base plate of the fan has also been strengthened in order to insure rigidity and maintain the proper relations between the armature and the field-magnet under all conditions. The brush-holders are of the usual cartridge type, with radially-fed brushes which can be removed and replaced without disturbing any other part of the machine. Every part of the machine is made to gauge by automatic machinery, so that all repair parts are strictly interchangeable with the originals. The motor is wound for the usual direct-current voltages.

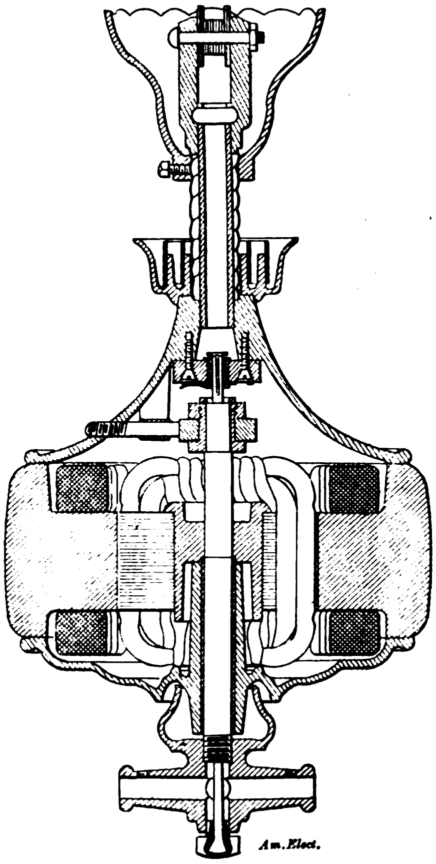

FIG. 88.—STERLING CEILING MOTOR.

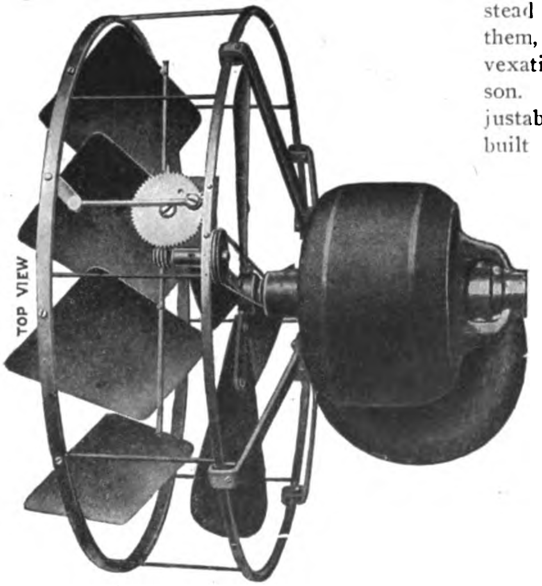

FIG. 89.—COLEMAN FAN GUARD.

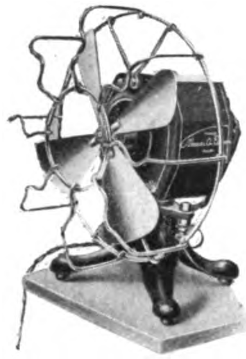

FIG. 91.—EDISON BATTERY MOTOR.

The Coleman combined fan guard and deflector, Fig. 89, made by the Coleman Manufacturing Company, New York, has been improved in several details since last year. The deflecting vanes are coupled by two links, and one of the vanes is also linked to a crank-pin on the small worm wheel at the top of the guard. This wheel is driven by a worm, the shaft of which receives motion through a grooved pulley and a leather belt passing around the motor shaft. The grooved pulley has been made larger this year, and the use of two links, coupling the vanes in two pairs, instead of a single bar coupling all four of them, has eliminated a minor but very vexatious trouble that developed last season. The supports of the guard are adjustable to fit any make or size of motor built to drive the ordinary propeller or disc type of fan of 16 inches diameter or less.

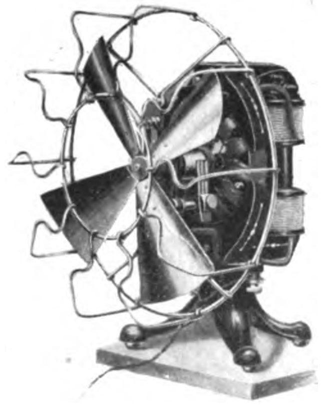

FIG. 90.—EDISON BATTERY MOTOR.

The battery fan motors of the Edison Manufacturing Company, New York, are illustrated by Figs. 90 and 91. The former is the larger of the two; it is a bipolar machine, with a field magnet of the Van Depoele type, the magnet being of cast-iron in a single piece. The armature core is liminated and slotted around the periphery; the winding is of the Gramme ring type. The motor will run a 9-inch fan 150 hours on one charge of the battery ordinarily supplied with it, which is of the well-known Edison-Lalande type. The field-magnet of the smaller motor, Fig. 91, is also bipolar, but of the enclosed type, and the magnet and yoke-ring are cast in a single piece. The armature is of the polar type, with three polar projections, and the core is laminated. The motor drives a 7-inch fan and will run 150 hours on one charge of the battery. The latter is of the same type as the battery used with the 9-inch machine, the only difference being in the number of cells required.

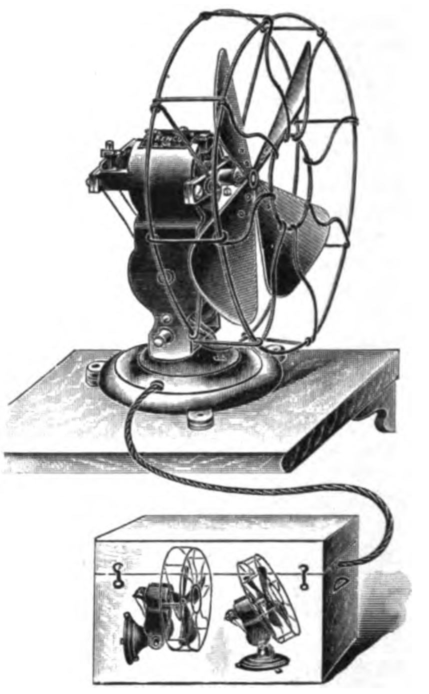

FIG. 92.—KNAPP BATTERY MOTOR.

Fig. 92 illustrates a new battery motor brought out this year by The Knapp Electric and Novelty Company, New York. This little machine shows a remarkable efficiency for one of its class. The field-magnet consists of stamped steel polar extensions mounted on the ends of a round wrought-iron core. The armature is of the drum type with six slots and teeth. The machine is series-wound, of course, and supplied with either one of two windings; one for 2 volts, at which e.m.f. the motor requires 1½ amperes, and the other for 5 volts and ½ ampere. The brushes are of strip copper and the tension is adjustable, which is an unusual feature in machines of this type. The field-magnet is pivoted to the base and can be tilted so as to direct the stream of air below the horizontal line or above it; the pivot mounting is provided with positive stops so that the machine cannot be slipped out of position. The magnet can be tilted backward to such an extent as to convert the machine into a bracket motor, the base being merely screwed to the wall instead of mounted on the horizontal support. The motor is ordinarily supplied with twenty cells of dry battery which are connected four in series and five in multiple for operation with the 5-volt winding. It is stated that about 300 hours of service can be obtained from first-class dry batteries if the machine is not used more than 4 hours a day. For more continuous service the life of the battery is, of course, much shorter.

Figs. 93, 94 and 95 illustrate some of the types of electrically-driven fans built by the B. F. Sturtevant Company, Boston, Mass. Different types of motors are used for different classes of service. Fig. 93 shows an eight-pole open machine direct-connected to a cast-iron or Monogram blower type of fan; Fig. 94, an eight-pole semi-enclosed motor direct-connected to a fan of the propeller type, and Fig. 95 illustrates the enclosed bipolar machine as used for driving fans of the propeller type. The motor in Fig. 94 can be made fully enclosed by the use of covers to close up the openings in the case. The field magnet ring of the bipolar machine is of cast-iron with detachable steel or wrought iron magnet cores. The machines having steel cores are provided with polar extensions cast integral with the magnet cores, and those having wrought iron cores are provided with cast-iron shoes. The field magnet coils in all cases are form-wound of double cotton-covered magnet wire and are insulated in a thorough manner. The coils after being assembled upon the magnet cores are given a break-down test of 1500 volts (alternating) applied for one minute.

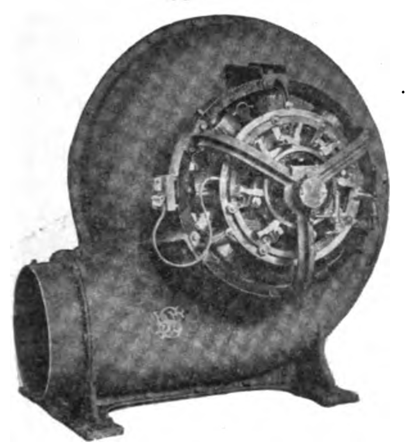

FIG. 93.—STURTEVANT EIGHT-POLE MOTOR.

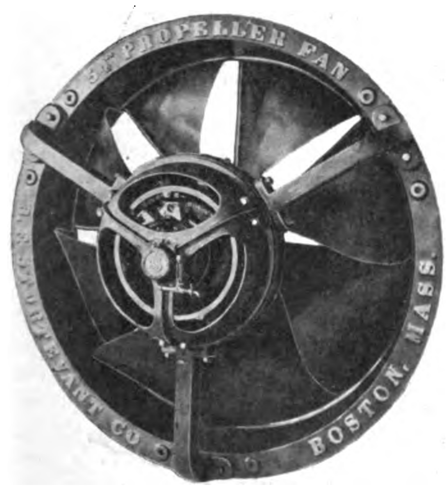

FIG. 94.—STURTEVANT EIGHT-POLE VENTILATING FAN MOTOR.

All the motor armatures are of the toothed-drum type, having form-wound armature coils insulated in the most thorough manner by the use of heavy cotton tape and fish-board and horn fibre. They are thoroughly saturated with a waterproof insulating compound and baked for a sufficient length of time to drive out all moisture. The commutators are constructed only of drawn or drop-forged copper bars insulated with the most carefully selected amber mica and thoroughly tested before being attached to the armature. The insulation between the segments and the shell is of micanite, no fibrous material of any kind being used in the commutator construction. The commutators are assembled under great pressure at a high temperature, thus assuring solid construction, and one in which the mica between the segments is not liable to creep and produce sparking due to high mica.

On motors of ⅜ horse-power (driving a 30-inch propeller fan) and under, the brushes are round carbon pencils fed in cartridge-type holders by helical springs. In larger machines ordinary rectangular carbon brushes are used, fed in holders of the sliding-socket shunted type, the pressure being regulated by an adjustable flat phosphor-bronze spring. All motors are furnished with self-oiling, self-aligning boxes. Before being shipped, every machine is given a full load run for a sufficient length of time to attain maximum temperature, and every part is critically examined before it leaves the testing department. Every means possible is employed to insure that nothing but strictly first-class machines leave the works.

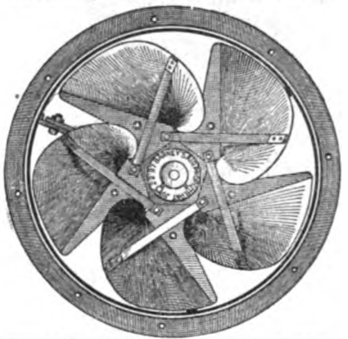

FIG. 96.—BARNEY AIR PROPELLER.

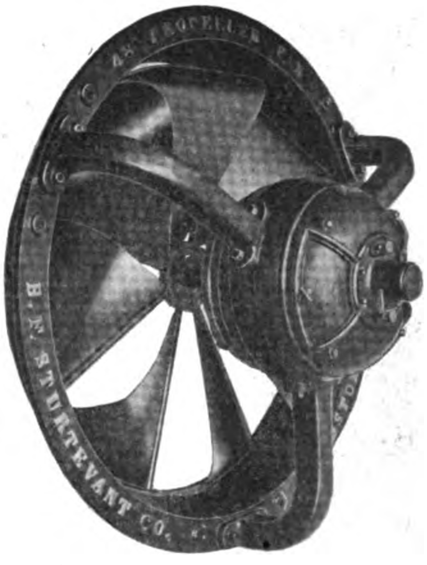

FIG. 95.—STURTEVANT BIPOLAR VENTILATING FAN MOTOR.

Figs. 96, 97 and 98 illustrate the fans of the Barney Ventilating Fan Works, Boston, Mass. The type shown by Fig. 96 is known as the Barney air propeller, while the fan shown by the other two engravings is referred to as a compound ventilating wheel. The blades of the propeller fan are made of Harvey-cleaned steel and are of rather unusual shape, as the engraving shows. The outer edges are braced to the central hub so as to avoid vibration while running, and the gradual curve of the blades is said to result in the delivery of a practically solid stream of air. The shaft runs in two self-adjustable ball bearings which are provided with automatic lubrication; both of the bearings are on the front side of the fan. The fan is well adapted for direct connection to an electric motor and is extensively used that way. The diameters range from 12 inches to 84 inches. The compound ventilating wheel is illustrated by Figs. 97 and 98. It is provided with a double set of blades which are curved somewhat similarly to the blades of the simple propeller fan. The two series of blades are flared in opposite directions, the blades on the rear being adapted to draw air into the wheel, while those on the other side beat away the surrounding air and tend to form a vacuum in advance of the column of air drawn through by the first set of blades. These fan wheels are built in diameters ranging from 24 inches to 84 inches.

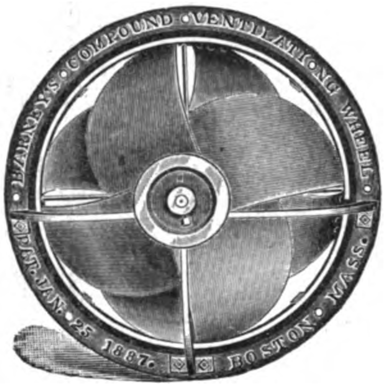

FIG. 97.—BARNEY COMPOUND VENTILATOR.

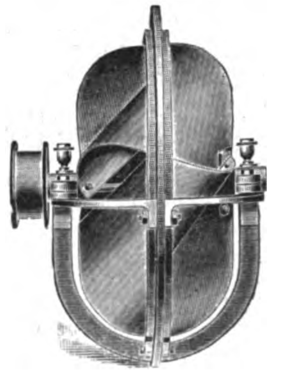

FIG. 98.—EDGE VIEW OF BARNEY COMPOUND VENTILATOR.

Figs. 99 and 100 illustrate two forms of direct-driven Davidson ventilating fans built by the Massachusetts Fan Company, Waltham, Mass. The shape of the blades is the same in both; they are built with a compound propeller curve such that the fan picks up the air at a very low velocity and delivers it at a comparatively even pressure throughout the whole surface of the blades. This construction is said to obviate back-lash entirely. The blades are made of cold-rolled copper, a composition commonly called yellow metal, or galvanized steel, according to the conditions of operation. When the fan is to be used for moving steam or vapors containing corrosive gases, such as are encountered in dye houses, bleacheries, sulphite mills, etc., either the copper or composition blades are employed. The standard construction for moving air only is galvanized steel. The fan blades are attached to a long cast-iron hub at two points and at the outer rims they are riveted to a heavy endless wrought iron ring which is stayed to one end of the cast-iron hub, as clearly shown in Fig. 100. This construction is said to make the fan capable of withstanding enormously high speeds, 10,000 feet per minute at the rim being the limit ordinarily. The most efficient speeds, however, range from 4400 to 6000 per minute at the rim. The bearings are of the reservoir self-oiling type, the oil being fed to the bearings by wicking in the smallest sizes and by oiling rings in moderate and large sizes. All of the bearings are fitted with removable babbitted sleeves, hammered and reamed to fit the shaft. When the fans are used in places that are inaccessible for oiling, bronze-graphite sleeves are used. A special feature of the Davidson fan is a ball-bearing thrust collar which takes the backward thrust of the fan blades and is said to reduce the required driving power from 20 to 30 per cent, as compared with the same fan used without the ball-bearing thrust collar. The fans are built in sizes from 12 inches to 60 inches in diameter and for all classes of service. Direct-driven fans from 12 inches to 48 inches in diameter are mounted as shown in Fig. 99, and larger fans are mounted as shown in Fig. 100. The motors are supplied for all of the standard direct-current voltages.

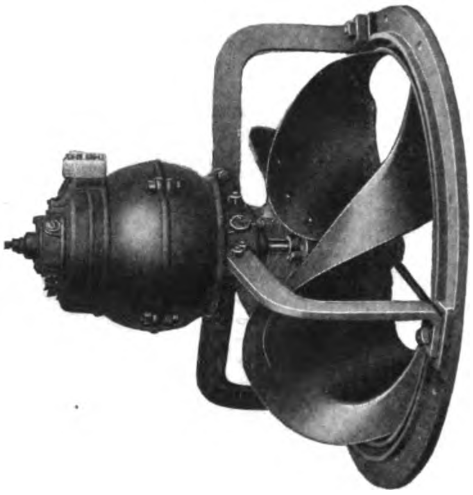

FIG. 99.—DAVIDSON VENTILATING FAN.

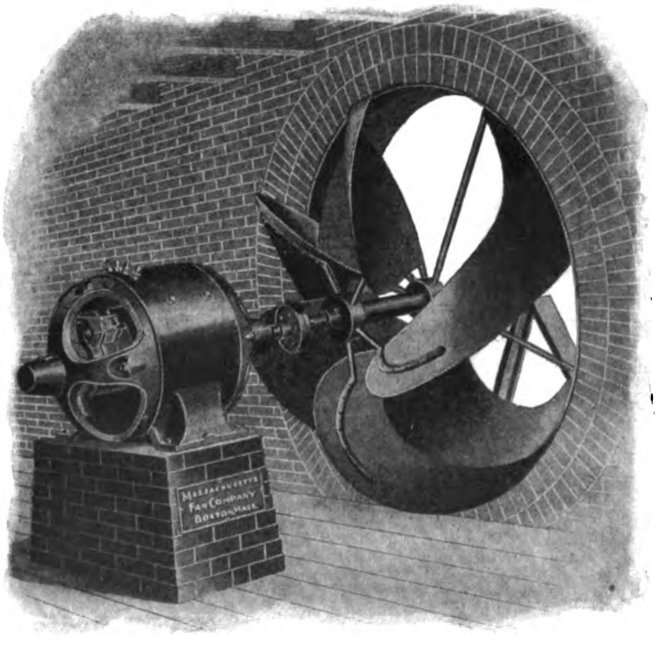

FIG. 100.—DAVIDSON VENTILATING FAN.

The American Blower Company, Detroit, Mich., builds a very complete line of ventilating fans of the disc type. Fig. 102 illustrates the direct-connected form of fan built in sizes ranging from 18 inches to 42 inches in diameter. The mounting for larger fans is very similar to that shown here, the chief difference being in the addition of stiffening flanges to the rim of the casing. A notable feature of the "A. B. C." fan is the number of blades; twelve of these are used and they are so disposed that each blade overlaps the one next to it. The blades are riveted to two large central discs and are also braced to a third smaller disc, as shown in Fig. 101. These central discs not only serve to stiffen the fan, but prevent any backflow of air through the center, which is one of the disadvantages of the ordinary form of disc fan. The peripheral speeds range from 4500 to 9000 feet per minute. All of the "A. B. C." fans are provided with ring-oiling bearings of the type shown by Fig. 103. Each bearing has two oil rings and is self-aligning in all directions, the journal housing being mounted on a horizontal pivot and the bracket which carries this pivot being mounted on a vertical swivel in the main framework. The bearings are provided with babbitt sleeves or liners which may be replaced without dismantling the journal box. The motors are supplied for all of the standard direct-current voltages.

Abstracts from Foreign Contemporaries

New Surface Contact Railway System.—The London *Electrician* describes the "G. B." surface contact system, a demonstration of which was recently given at Ilford. As shown in the illustrations, the bare line conductor, consisting of stranded galvanized iron cable, is drawn through plain butt-jointed 5-in. stoneware pipes, and is suspended at convenient intervals by vitrified clay insulators. If found necessary, the electric conductivity of the cable may be raised by including a copper conductor. The galvanized steel pivots of the insulators are carried through one side of the glazed pipe conduit, and are all electrically connected together and with the track rails. This is to ensure a direct path to the rails for any possible leakage current from the cable, thus practically preventing a serious difference in pressure between the studs and the rails due to surface leakage on the clay insulators. Although the total depth of excavation does not exceed 19 in. in standard practice, even this depth may be reduced by 6 in. or 7 in. for special purposes. As seen from Fig. 1 the whole conduit is embedded in concrete. Access boxes, placed at intervals of from 200 yds. to 400 yds. along the track, consist of cast-iron bodies with manganese covers. The two cable ends, entering a box at opposite sides, are led to terminal bars, mounted on insulators within the box. Drainage pipes, leading from the bottom of these boxes, conduct away any water which may accumulate in the earthenware pipes. Every 7 ft. 6 in.—corresponding to the distance between studs—a short vertical earthenware tube is cemented to the main horizontal pipe (Fig. 1). Into this vertical portion of the pipe system the laminated stalk of the stud is let, the upper part of the intervening space between it and the tube being subsequently filled up with bitumen, a packing of jute yarn preventing this material from falling through. A loosely fitting contact plunger, consisting of a laminated body and a carbon contact piece, slides in the brass-lined fork of the stalk as indicated in Fig. 1. It is electrically connected with the stalk by flexible copper conductors and is held up from the cable against the force of gravity by an insulated phosphor-bronze spring, the separating distance being about 5-16 in. The stalk is connected to the cast-iron stud by a somewhat flexible joint, but this does not prevent it making good electrical and magnetic contact. A recessed granite block receives the stud which is level with the track and whose surface measures 2½ in. by 14 in. By directing the flame of a blowpipe against the stud, the bitumen beneath is made to melt and the stud as a whole may be withdrawn, this operation occupying, it is said, but seven minutes. In addition to the ordinary standard equipment, each car is provided with a magnet rigidly suspended beneath the car and a battery of accumulators. It may be mentioned that the accumulators serve for starting only, being charged up during ordinary running. One pole of the magnet is in the form of two parallel iron bars, and is suspended at a distance of about 2 in. above the centre of the track. Between these two bars are a number of iron tongues (Fig. 2), suspended by springs, but free to move a considerable distance up and down. These are all connected at their lower ends by one flat chain belt (not shown in the illustration), about ⅝ in. wide, which is kept parallel to the track at a distance of approximately ⅜ in. by the springs and tongues referred to. In order to have a continuous supply of current, the belt is made longer than the distance between any two studs. As the car comes over each stud both the flexible chain belt and the sliding plunger are attracted downwards, and the former, on coming in contact with the stud, completes the electric circuit. It is stated that the net force with which the plunger, weighing 6½ oz., is drawn downwards, is equivalent to the weight of 6 oz. at the beginning, increasing about 16 oz. when the carbon contact touches the cable. If a non-magnetic cable is used, the figures are given as 3 oz. and 6 oz. respectively. The gauge of the trial track, which was one-fifth mile in length, was 4 ft. 8½ in., and the paving consisted of granite in bitumen, granite in cement and hard wood. The steepest gradient was 1 in 32, the sharpest curve having a radius of 54 ft. A double-deck car, with a total seating for 54 passengers and fitted with two 25-h.p. motors and series-parallel controllers had been fitted up with the auxiliary equipment necessary for the new surface-contact system. Its weight, fully equipped, was stated to be 10 tons. When running empty round the track, the current taken by the car varied between 20 and 35 amperes, the latter current corresponding to the steepest incline, the pressure being kept constant at 500 volts. The leakage of the experimental track was measured and found to be 0.05 ampere; and it may be mentioned that the ground upon which the track was laid was very moist. When a bucket of water was thrown on the track, the leakage of current between the rails and a live stud began with 0.5 ampere, and then fell gradually. In order to show the current-carrying capacity of the contacts, the car brakes were applied and the car set in motion. By this means a current of about 95 amperes was taken through the studs. The energy absorbed for exciting the magnets was measured during the tests, and amounted to 325 watts. On one occasion, a stud was thickly smeared with mud, and the car slowly brought over it; this, however, did not prevent current being successfully picked up. In case a stud should remain alive after the chain belt has passed, the supply is interrupted by means of chains, fixed to the end of the car and trailing on the track, coming in contact with the live stud and causing a maximum cut-out on the car to operate.

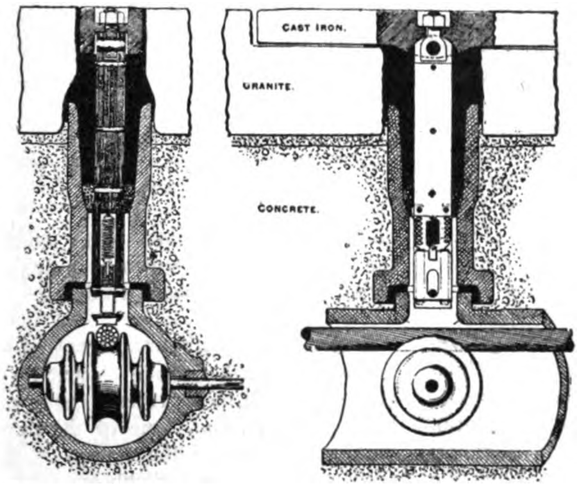

FIG. 1.—SECTIONS OF STUD.

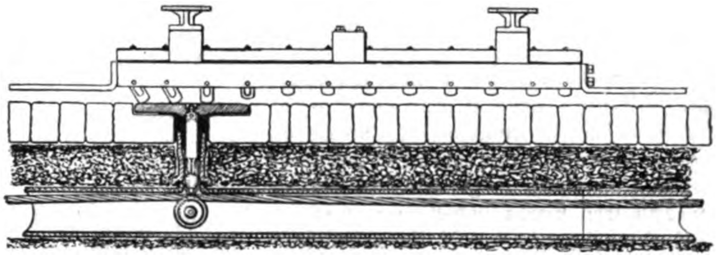

FIG. 2.—CURRENT-COLLECTING DEVICE.

Heat Transference Through Boiler Plates.—London *Engineering* contains a paper giving the results of an investigation conducted by the Physikalische Reichsanstalt on the passage of heat through metallic plates. It was necessary, first, to develop a suitable method, which was done by Holborn and Dittenberger. The experiments were completed by L. Austin. What has been investigated is the passage of heat from oil to water, or from water to oil, through an iron wall three centimetres in thickness. A certain transition resistance has to be overcome when heat passes from a solid wall to a liquid. The transition resistance is not so great as in the case of solids and gases, yet it is generally larger than the resistance which the metal itself offers to the passage of heat. The apparatus consisted of a small boiler of wrought iron, having two chambers separated by the plate to be investigated. Each chamber contained a stirrer, a suitable thermometer, and was heated by Bunsen burners. The dividing partition was drilled to receive thermocouples, by means of which the temperature gradient in the iron plate, and between the iron and liquid, could be determined. One of the first effects to be noticed was the decrease in the difference in temperature between the surface of the plate and the liquid, when the stirring apparatus was put into service. This difference decreased with increase in the speed of the stirrer, apparently approaching a limit. Measurements were made of the heat passing from the plate into the water, and in the reverse direction. The following results were obtained: With a heat flux from metal to water, the transition resistance varies between 1.2 and 2 centimentres of iron, according to the degree of boiling in unstirred water. Stirring reduces it to 0.75 centimetre. If the water is only warm, the resistance may be equivalent to 10 centimetres, which, by stirring, is reduced to 1 centimetre. When the water is not boiling, the resistance increases somewhat with a decrease in temperature. With a heat flux from water to metal, the transition resistance is constant with different temperatures, and is greater than with the reversed flux when the water is not stirred, and as great as with the reverse flux when the water is stirred. If the transition resistance be due to a film of water adhering to the iron that film should have a thickness of about 0.1 millimetre, since iron conducts 100 times better than water, and since a maximum resistance for water of 10 centimetres was observed. The thickness of this film is independent of the condition of the surface of the iron, as cleaning had no effect. It is thought that the vibration of locomotive boilers may have an effect somewhat analogous to mechanical stirring, and this would account for the better results obtained from such boilers, than from stationary boilers. While mechanical stirring would assist in raising the steam in boilers, its application seems to be impractical.

Tandem Connection of Induction Motor. —Ernst Danielson contributes to the *Elektrotechnische Zeitschrift* an article on the use of induction motors in rolling mills and in iron works in general. In a large Swedish iron works induction motors are used throughout, most of them being of the ordinary type, so that their speed cannot be easily varied. One motor, however, is used which, without losses in a rheostat, can be operated at the nearly synchronous speeds of 428, 375 and 333 r.p.m. The machine consists of a combination of two motors; the main motor, which is an ordinary 14-pole induction motor, and an auxiliary motor, which can be operated as well as a two-pole or as a four-pole motor. To get a speed of 428 revolutions the main motor is operated alone, while the auxiliary motor is without current. To get 375 revolutions, the auxiliary motor is connected so as to act as a two-pole motor and is connected in tandem with the main motor. To get 333 revolutions, the auxiliary motor is connected so as to act as a four-pole motor and is connected in tandem with the main motor. The power is always 150 horse-power. At 333, 375 and 428 revolutions and full load the efficiency is 87, 88 and 89 per cent and the power factor 81, 83 and 92 per cent. It is necessary to design the auxiliary motor so that the leakage is very small and the magnetizing current is also small. In the above motor only the direct tandem connection is used. If one would also apply the so-called differential tandem connection it would be possible to get with the same motor two other speeds, namely 500 and 600 r.p.m. It would only be necessary to provide the rotor of the auxiliary motor with slip rings. The author discusses the following three possible tandem connections between a main motor and an auxiliary motor. Fig. 3 shows the direct tandem connection; Fig. 4 shows the differential tandem connection in which the main motor is connected to the supply network, while Fig. 5 shows the differential tandem connection in which the auxiliary motor is connected to the supply network. The arrangement of Fig. 4 gives a better efficiency than that of Fig. 5, but in Fig. 4 the motor does not run up by itself to the desired speed while it does so in Fig. 5.

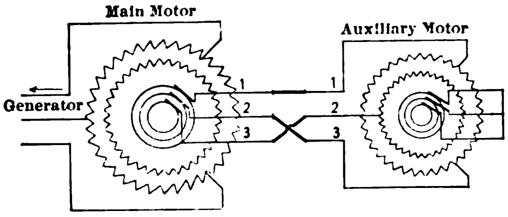

FIG. 3.—TANDEM CONNECTION OF INDUCTION MOTORS.

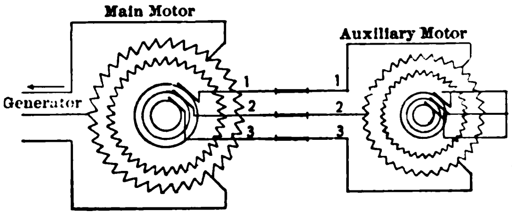

FIG. 4.—TANDEM CONNECTION OF INDUCTION MOTORS.

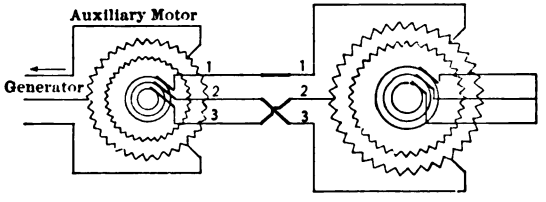

FIG. 5.—TANDEM CONNECTION OF INDUCTION MOTORS.

Electromechanical Compounding System. —The *Elektrotechmische Zeitschrift* describes in a recent issue the electromechanical compounding system of Routin. In the regulation of steam-driven dynamos, the speed must be adjusted by varying the admission of steam to the engine and on the other hand the voltage must be varied by changing the excitation. Both changes should be made simultaneously, but the changes of admission of steam require time, since the mechanical devices are subject to the law of inertia. The condition for the successful regulation is, that with increasing current consumption and with decreasing voltage or decreasing speed, the admission of steam should be increased and the excitation simultaneously increased, while with decreasing current consumption and increasing voltage or speed, both the admission of steam and the excitation should be diminished. The device of Routin, as shown in Fig. 6, consists of an iron core, on which is acting the difference of the ampere windings of a main current coil and of a voltage coil. Through the main coil flows the current given out in any moment from the machine, while the shunt coil (which is connected in opposition to the main coil), is connected across the terminals of the generator is in series with a resistance which may be regulated by a sliding contact. Simultaneously with this sliding contact, another sliding contact moves which, by its changed position on the resistance influences the excitation of the machine. The dimensions of the coils are so chosen that the action of the shunt coil is always superior to that of the main current coil. The iron core of the solenoid is coupled to the devices which determine the steam admission to the engine, and carries a weight which gives an attractive effort downwards. When the iron core sinks downwards the steam admission is increased, and if it rises upwards the steam admission is diminished. The motion of the iron core is the result of the differential action of the two ampere windings.

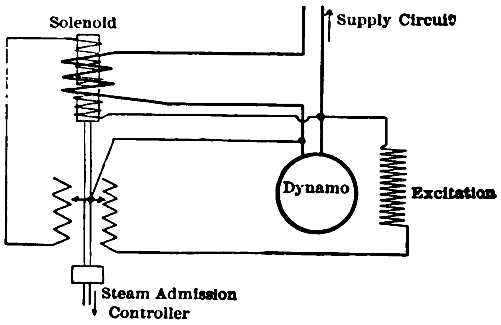

FIG. 6.—ELECTROMECHANICAL COMPOUNDING SYSTEM.

English Switchboard Practise. —The Stepney Borough Council electricity works are described in a recent issue of the London *Electrician*. One of the most admirable features of the station is the arrangement of the switchboard, which is simplicity itself. Where possible, all connections are quite permanent, and the few loose insulated wires are all labelled. Small conductors, such as voltmeter leads, are all enclosed in screwed steel barrels, from which they emerge through circular junction boxes fixed at convenient points. The board itself is divided into two sections, one of which is situated on a spacious gallery at the end of the engine room and the other immediately underneath, on the ground floor. It is built up of 2-in. slate panels carried by angle irons, and that portion on the gallery is divided vertically into three, the positive being on the right, the negative on the left and the neutral in the middle. The positive and negative panels are each provided with four main bus bars, as shown in Fig. 7. By means of short bars at right angles to these, and suitable plugs and sockets, any feeder can be plugged on to any bus bar. Similarly, separate bus bars may be employed for separate generators, or they may all be plugged together. This arrangement permits of feeders which supply distant points being raised to a higher potential than those supplying points close to the station. The dynamo cables come up through the gallery floor to the back of the board and are connected to their respective panels, but the feeder cables are carried upward and over the intervening space of about 4 ft. to the wall of the building and thence to the cable subway. Thus, dynamo and feeder cables never come into contact, and until the latter enter the street all positives are kept on one side of the subway and all negatives on the other, the neutrals being suspended from the roof.

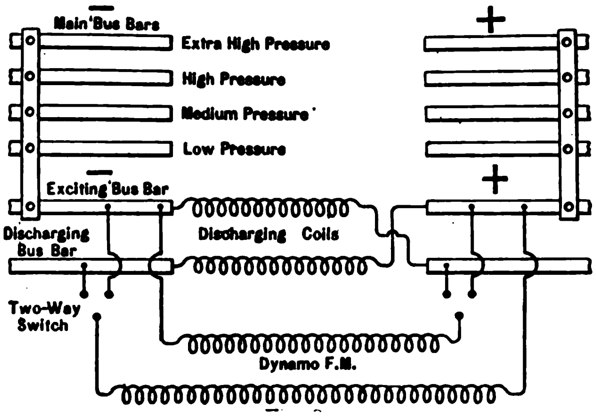

FIG. 7.—DIAGRAM OF CONNECTIONS.

The field switch is interlocked with the main switch in the usual manner and the field magnets may be excited at any voltage from 480 to 530, depending upon the voltage of the bus bar from which exciting current is obtained. There are eleven feeders in all, each of which is provided with a knife switch and ammeter. Referring to Fig. 7 it will be seen that there are two smaller bus bars immediately under the main bus bars, the top one supplying the exciting current, and the lower one is called the "discharging" bar. Instead of employing a separate coil for each dynamo for damping the rises of potential due to self-induction obtained when breaking the field, only two coils are used for all the machines in the station. According to the direction in which the fields are wound, they are connected up as shown in the diagram, and the result is a considerable simplication and reduction in the number of switchboard connections.

The Vogt Gas Engine.—A novel type of gas engine, which is, according to Mr. H. A. Humphrey, possessed of a number of distinct advantages over the usual type, is described by him in a recent issue of London *Engineering* in some detail. The most radical departure from the usual practice is the filling of the working cylinder with water. This cylinder is horizontal and opens at each end into two chambers, also filled with water. At the upper part of these chambers the air and gas are admitted . After an explosion has taken place in one chamber, the gases force down the water contained in it, and thus move the piston horizontally. At the end of the working stroke an air valve opens, admitting air under pressure, which drives out the products of combustion. On the return stroke the air valve closes, as does also the exhaust valve, and part of the water in the chamber is ejected through a special valve. The gas valve opens, admitting gas under pressure. Compression begins, the gas valve closes, and the compression of air goes on. At the end of compression the mixture is exploded, and the cycle is repeated, the same process being carried on in the other chamber. This method of operation gives two impulses per revolution. The power of the engine is controlled by stopping the escape of air from the cylinder on the return stroke, and by the amount of gas admitted and the quantity of water allowed to escape. The proportion of air and gas is constant for all loads. The presence of water in the cylinder enables the piston and stuffing boxes to be kept tight without much friction, as they are under water. It does away with the

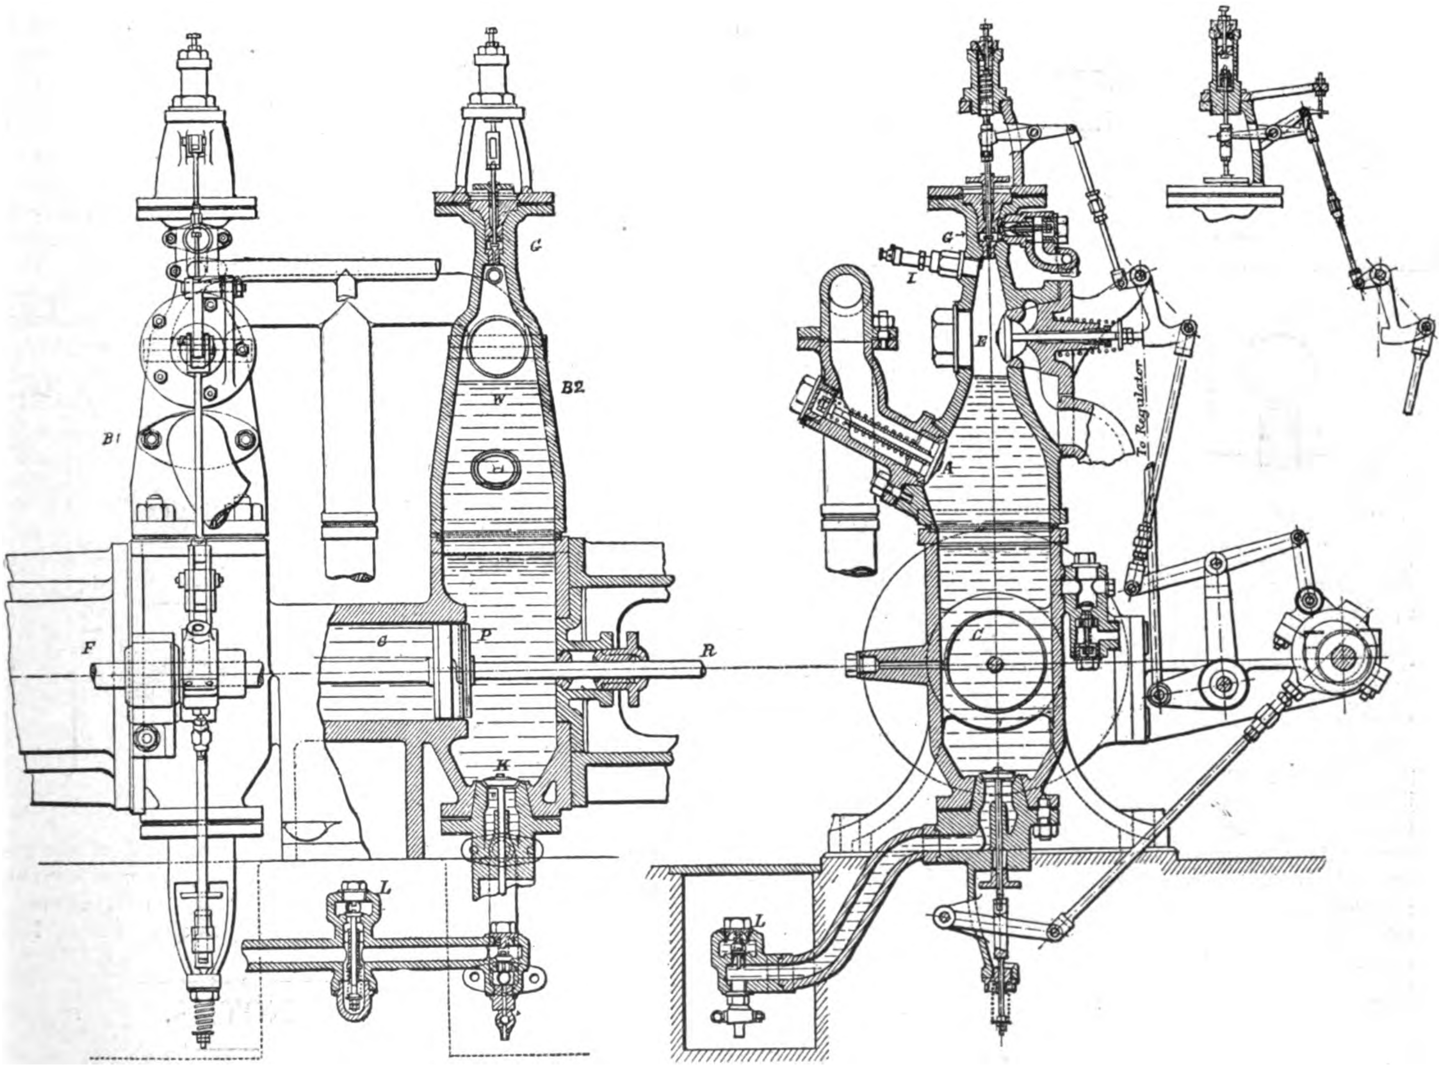

FIG. 8.—SEMI-SECTIONAL ELEVATION AND CROSS-SECTIONAL VIEW OF VOGT GAS ENGINE.

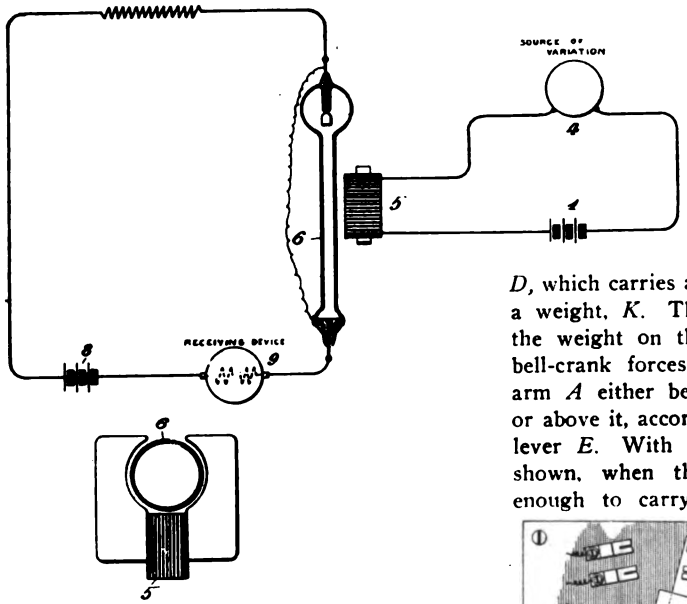
necessity of a water-jacket for cooling the cylinder, and prevents unequal expansion between the piston and the cylinder. At the end of each stroke a little fresh water is admitted to the cylinder, and part of the hot water is drawn off. As the gas does not come in contact with the working cylinder, it is not necessary that it should be clean. Any dust or soot will be carried off in the water. Tests of a small engine giving but 1¾ horse-power are said to have shown a gas consumption of only 16 to 18 cubic feet of London city gas per horse-power—a performance as good as that of a 200-horse-power gas engine of the ordinary type. Calculation shows that the speed of the piston may be five or six metres per second before the water column will be broken up. Four metres per second is generally high enough for the piston speed of a gas engine. It is stated that a 1000-horse-power engine is to be built, in order to test the capabilities of a large machine of this type.

SOME RECENT ELECTRICAL PATENTS

Mercury Vapor Tube Electrical Repeater. The latest development of the now well-known Cooper Hewitt mercury vapor tube, as disclosed in a patent issued to the inventor, appears to be susceptible of an application of vast importance to the telephone industry. Mr. Hewitt has found that the resistance of his mercury vapor tube lamp may be varied by electromagnetic influence so that fluctuations in a circuit to which an electromagnet is connected may cause corresponding variations in the resistance of the lamp or tube. This effect is produced by arranging the electromagnet so that its flux must pass through the conducting vapor in the tube. Fig. 1 illustrates the elemental features of the invention; the magnet, 5, is supplied with current from a source, 1, and the current strength is varied by the device 4. The mercury vapor tube is connected in a circuit with a source of current, 8, and a receiving device, 9. The variations in current strength caused by the device 4 are reproduced in the receiver 9. It is scarcely necessary to point out that these two devices may be a telephone transmitter and a telephone receiver, so that the invention may find application as the long-sought telephone repeater to reproduce current fluctuations efficiently. Fig. 2 shows a modification in which the magnet is constructed with poles which embrace the vapor tube exactly as the field magnet poles of a dynamo embrace its armature. Patent No. 749,791.



FIGS. 1 AND 2.—ELECTRICAL REPEATER.

Quick Motion Switch. —Fig. 3 herewith illustrates an ingenious quick-motion switch mechanism devised and patented by W. F. Irish. The drawing, taken from the patent, shows the switch adapted for control by a tank float, but it may be applied otherwise, of course. The switch arm, *A*, is pivoted at *a*; the actuating lever *E* is pivoted to one arm of a bell crank *D*, which carries at the end of the other arm a weight, *K*. The downward pressure of the weight on the horizontal arm of the bell-crank forces the roller *e* against the arm *A* either below the pivot, as shown, or above it, according to the position of the lever *E*. With the parts in the position shown, when the float *F* descends far enough to carry the roller *e* above the pivot *a*, the weight *K* will force the lever *E* bodily to the left, and the latter will, of course, carry the arm *A* with it. As the roller *e* rises from its position shown in the drawing toward the pivot *a*, the lever *E* is pivoted to one arm of a bell-crank, *D*, away from the stop *b*, so that the weight *K* is free to act as described after the roller *e* passes the pivot *a*. Patent No. 751,174.

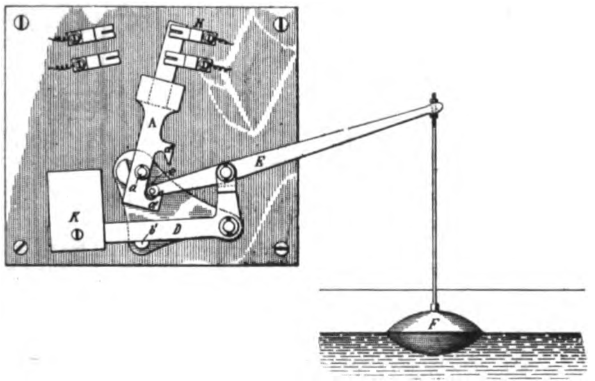


FIG. 3.—QUICK MOTION SWITCH.

Magnetic Clutch.—It is the custom in the construction of magnetic clutches to use two members of magnetic material, one of which carries a winding and therefore constitutes a magnet, and the other of which serves as an armature for the said magnet. This arrangement has the disadvantage, of course, that the coil must revolve when the magnet revolves, entailing the use of collector rings and brushes in order to lead the exciting current to the moving coil. Fig. 4 illustrates a form of clutch which has been devised by E. M. Hewlett in order to eliminate this feature. The clutch consists of a stationary member, *9*, of magnetic material, which carries the exciting coil, *11*, and is therefore the magnet of the system; two circular armatures, *6* and *6-a*, mounted on independent but co-axial shafts, *1* and *2*, and a friction surface, *7*. It is obvious that when the winding is excited, the discs *6* and *6-a* will be attracted by the magnet and also attract each other at the center. Whether both of them move axially or only one is a matter of constructional detail. Regardless of this point, the excitation of the coil obviously draws the two discs together, causing the friction surfaces to bind. Fig. 5 shows a modification of the arrangement, in which the air-gap between the revolving member *6-a* and the stationary member *9* is similar to that in a dynamo and is not altered by the axial movement of the revolving member. With this construction, presumably, the right-hand revolving member does not move axially. Patent No. 747,706.

NOTES.

Machinery Dealers' Association.—The third annual convention of the Southern Supply and Machinery Dealers' Association will be held at Old Point Comfort, April 12 to 14 inclusive. The headquarters will be at the Hotel Chamberlain, and a very large attendance is expected. Special railway and hotel rates have been secured, particulars concerning which may be obtained from Mr. P. E. Blow, Knoxville, Tenn., president of the Association.

The Electrical Club Journal.—The first number of this publication appeared last month, and reflects much credit upon those responsible for it. The Journal is published by members of the Westinghouse Electric and Manufacturing Company's staff at Pittsburg, and its entire contents are contributed by the older engineers of the company. The particular object of the club is to promote fraternal relations between the younger engineers there, and the scope of the Journal is such as to make it of value to those men. It goes without saying, therefore, that the magazine is of a most useful character to young engineers in other manufacturing establishments or branches of electrical work.

Allis-Chalmers Company to Build Electrical Machinery.—This well-known manufacturer of steam engines and mining machinery has completed arrangements for entering the electrical field as a builder of generators and other apparatus. It is reported that this move is due to the fact that the General Electric Company, after perfecting the Curtis turbine, adapted it to the exclusion of reciprocating engines for large work, and declined to enter into an arrangement with the Allis-Chalmers Company for the building of the turbines in that company's shops. With the Westinghouse and General Electric Companies both building steam turbines the field for large Allis engines in this country has been reduced to slim proportions. Mr. John Kelly, who was for many years practically the chief engineer of the Stanley Electric Manufacturing Company, will be chief of the Allis-Chalmers electrical staff, and will have as an advisory associate Mr. William Stanley, Jr., the originator of the Stanley Company.

Wireless Telegraphy from Running Railway Trains.—Experiments recently made by Professor Biscan, Teplitz, Austria, with a view of using wireless telegraph apparatus from running railway trains, are said to have so far given quite satisfactory results, wireless dispatches being safely received and transmitted over distances as high as 7 km. from the station erected in Teplitz. The possibility of ensuring wireless communication with running railway trains has thus been evidenced. The car containing the apparatus was coupled to the back of the train, two wires leading outside of it. These wires were conveyed horizontally on both sides of the roof of this car and of three ordinary railway cars, terminating in a horizontal free point; they were intended to replace the antennæ otherwise used in connection with wireless telegraph stations to enforce the effects of electric waves. As soon as the train approached the Teplitz wireless telegraph station up to the distance above mentioned, whence a continuous supply of dispatches was to be given, the telegraph apparatus in the car would begin working, the paper ribbon containing the telegrams running off the roller in a manner quite analogous to an ordinary telegraphic apparatus. Similar experiments were carried out some time ago on the Berlin-Zossen military railway.

Mr. Dooley's Electrical Double Again.——The clever imitator of Mr. Finley Peter Dunne who occasionally writes for *The Electrical Times*, London, has broken out again and most amusingly, as follows:

DEPORTMENT FOR CONDUCTORS.

"Well," said Mr. Dooley, "I see be th' pa-apers that they're comin' along wid th' trams in West Ham, slowly but surely; there isn't so much as a thruck in th' pla-ace yit, but th' rules f'r th' conducthors is all finished an' will be advertised in a gazette extrayordinairy, be order iv th' council sittin' in conclave. Be th' time they've got th' conducthors th' trams will be ready. West Ham isn't a pla-ace f'r you and me, Hinnissy; they're too good f'r this wur-ruld iv sin an' sorrow; in th' nixt wur-ruld ye'll be able to tell which is a West Ham Councillor be his havin' no tail. Th' morals iv West Ham were threatened by th' elictric trams; th' soshulists an' passive resisthers was in da-anger iv contaminayshun be th' introducshun iv conducthors. Thin th' tramway committy stepped in. 'The council an' ratepayers are aware,' they says in their rayport, 'iv th' solicitood iv your committy f'r th' future state iv their souls, peace be wid thim. Your committy have given th' ingineer a motor-car f'r respectaybility; they've seen to th' dacency inside th' cars; an' now they've drawn up wan thousand two hundred an' fifty-fure rules f'r th' diportmint iv th' villainous conducthors.' Th' rules was inthroduced be Alderman Ikey in camera, because iv th' low-down doin's iv conducthors which was onfit f'r th' hearin' iv dacent folk; on'y th' councillors was prisint, an' th' sittin' was sustained an' prolonged. I'll tell ye a few iv th' rules, Hinnisy, which have leaked out be th' indiscreshuns iv councillors.

"'*Rule Sivin.*—Conducthors must not have button-holes. *Rule Sivin (a).*—If they've got them——'"

"I call that downright ondacent," said Mr. Hennessy; "phwat's to kape their trousis up, begob?"

"Divvle take ye f'r a red-nosed ould 'rangatang," cried Mr. Dooley, "who's tellin' this story, me or you, I'd like to knaw?"

"Gowan," said Mr. Hennessy, meekly. Mr. Dooley snorted once or twice and proceeded. "'*Rule twinty-one.*—Conducthors' clothes must be kept together be boults an' nuts. All nuts must be freshly polished every mornin' in a lathe provided f'r th' purpose. *Rule fifty-nine.*—If a nut wur-ruks loose, th' whole service must be sthopped whilst th' conducthor finds a spanner. *Rule wan hundred an' sivinty-five.*—Iv'ry conducthor to wear a watch an' chain, synchronised be Greenwich time. *Rule two hundred an' nine.*—No conducthor to wear a chain outside his coat, which must be bolted up tight. *Rule two hundred and ninety.*—Conducthors must stand wid their backs to th' dure to look f'r passengers comin' sideways. *Rule four hundred.*—Conducthors must keep their eyes on th' tram in front on penalty iv instant dismissal without a reason. *Rule four hundred an' six.*—Conducthors must keep their eyes on th' time an' see that th' driver——'"

"Hould on," said Mr. Hennessy; "he's got to be lookin' backwards, an' front, an' at his watch which is bolted inside his coat, all to onct. Phwat talk have ye?"

"The Council wants smart men," said Mr. Dooley. "*Rule sivin hundred an' thur-ruty* says 'conducthors' beards must be freshly trimmed each mornin' to angle iv thur-ruty degrees; dismissal f'r error iv more than five degrees. *Rule wan thousand an' fifteen.*—Conducthors wid no beards must be clean-shaved twice a day. No beards to be grown in th' Council's service. *Rule eleven hundred an' eighty.*—If a tram be smashed th' cost iv it will be sthopped fr'm th' conducthor's wages. *Rule elevin hundred an' ninety-sivin.*—Conducthors not to wear flowers in their button-holes. Only vegetables allowed. *Rule twelve hundred an' twinty-wan.*—Conducthors whin takin' fares fr'm young ladies to look th' other way. If ladies are there, conducthors must look at th' roof. *Rule twelve hundred an' twinty-nine.*—Any person wid dirthy clothes to be fur-rust disinficted be th' conducthor. If he rayfuses, th' conducthor may apply 500 volts, but quietly an' gently. If th' raysistance iv his skin is too great, th' conducthor may call th' polis, but th' traffic must not be sthopped.'

"That's a few iv th' rules," said Mr. Dooley, "an' they'll get a fine lot iv men. I dunnaw but phwat th' West Ham cars wont be travellin' chapels be th' time they're done, wid a altar at wan end an' houly wather as you go in be th' dure, not forgettin' th' collectin' box to buy insect powder f'r the seats. Th' conducthors will be houly men, an be th' time they understhand all th' rules they'll have grown wings. I see meself enterin' humbly th' sacrid veecle wid bowed head. 'How much, houly father?' I says. 'Th' fare is wan penny, my son,' says the conducthor, 'an' whativer else ye like to give to th' cause; we will now sing hymn wan hundred an' thur-ruty-sivin,' he says, switchin' on th' elictric organ under th' seats. As f'r th' women, I foresee throuble, Hinnissy. Think iv th' number iv gals wantin' to marry, an' a couple iv hundred smart an' handsome Saint Anthonys wid never a wink or a smile, rayfusin' to hilp th' ladies on an' off f'r fear iv th' future iv their souls."

"Phwat'll happen thin, avick?" asked Mr. Hennessy.

"It's difficult to say whin women is mixed up wid things," replied Mr. Dooley, "but I've heard that th' manager is inventin' an automatic conducthor. You put his wages in a slot once a week, an' he does his wor-ruk properly, not forgettin' th' chuckin' out. At th' end iv th' week you draw off his takin's, an' he never sthrikes."

"Merciful heavens!" exclaimed Mr. Hennessy.

The Lamme Single-Phase Railway Motor.

The description of the Lamme single-phase alternating-current motor, which we print this month, will undoubtedly be read with the greatest interest by those who are at all concerned in electric traction, and we venture to predict that the simplicity of the method followed by the inventor to obtain practical commutation will be a surprise to most designing engineers. We do not refer to the constructional expedients of perforating the pole ends and using high-resistance commutator leads; the former is an obvious means of keeping down the field-magnet self-induction without entailing prohibitive armature reaction, and the latter is about twenty years old in direct-current designing. The development of the proper relation between the field counter e.m.f and the armature counter e.m.f and the determination of the numerical ratio between the two appear to be the most important features, so far as the English patent specification discloses the method of design. According to the figures given in the specification, if the ratio of field to armature ampere-turns be put at .625 then the relation between the field-induction (L), number of magnet poles (p), revolutions per second (s), counter e.m.f (e) generated in the armature winding, and the frequency (f) of the supply current in cycles per second reduces to

$$L p s = 2 e f.$$

It seems scarcely credible that such a complex problem is susceptible of so simple a solution.

Owing to a rather surprising obscurity of exposition in the patent specification, the inventor is made to say that the "self-induction" of the field-magnet is proportional to the frequency, number of turns of wire and magnetic flux, and in the second equation (on page 118 of this issue) that the counter e.m.f. of the armature (lap-wound) is proportional to the number of poles, as well as the number of armature turns and (by deduction) the magnetic flux per pole. Of course, both of these statements are incorrect and are probably not what the inventor intended to say. The term "self-induction" appears to have been used to express the idea of counter e.m.f. induced in the field windings by the alternating flux in the cores. In the preceding paragraph, therefore, an e.m.f. symbol should be substituted for the inductance symbol, L. We confess to have been unable to unravel the puzzle of the use of "poles" in the denominator of the fraction in the patent specification, notwithstanding the explanatory statement that "armature wires $= 2 \times$ poles $\times$ armature turns in series." This statement leaves the inference that the "armature ampere-turns" referred to throughout the specification are only those in series, but on the other hand, the ratio between field ampere-turns and armature ampere-turns is made one of the controlling factors, and it is not apparent that there should be any general relation between all of the field ampere-turns and the ampere-turns in series in the armature, independent of the number of poles; the relation would naturally be either between field ampere-turns *per pole* and armature series ampere-turns, or else between total field ampere-turns and total armature ampere-turns. As we are not expecting to design any Lamme motors, however, and Mr. Lamme's knowledge of elementary alternating-current mathematics and machine design is not in the least likely to be questioned by any sane person, we will leave those who are more vitally interested to struggle with the patent specification.

Referring again to the use of high-resistance leads from the armature winding to the commutator, it is as well, perhaps, to point out that the chief function of these is to keep down the current induced in the short-circuited coil by the alternations of the field flux, whereas in direct-current practice they were used to reduce the inductance of the short-circuited coil and incidentally to keep down the current induced in it by the cutting of lines of force due to the motion of the coil in the magnetic field. The ultimate object is the same in both cases, *i.e.*, proper commutation, but the need for such auxiliaries has been eliminated in direct-current practice by improvement in design. It is difficult to imagine what sort of refinement in the design of the series alternating-current motor can develop which will reduce the transformer effect in the armature winding sufficiently to obviate the use of some auxiliary means for preventing the induction of an abnormal current in the coils short-circuited by the brushes during commutation, and as Mr. Lamme's expedient is about the simplest that will serve the purpose it will probably be permanent so far as simple series motors are concerned.

The conclusions to be drawn from the reasoning given in the English patent specification are that the new series motor will necessarily be somewhat heavier than the direct-current machine of the same class, since it is impracticable to magnetize the field-magnet material to anything like the same degree; that the full-speed efficiency should be fully as high as that of the direct-current motor, and the efficiency at intermediate speeds and during acceleration considerably higher, since speed control may be effected by means of transformers instead of dead resistances; and that the torque characteristic of the alternating-current machine will be better than that of its direct-current rival of equal rating for the reason that the field-magnet iron *must* be worked at low degrees of magnetization at normal speeds, so that there is more flux per field ampere-turn. If the direct-current machine were allowed the same weight, however, so that lower magnetic densitites would be practicable, it would doubtless show better torque characteristics than the series alternating-current motor. Furthermore, the higher efficiency of the alternating-current machine is to some extent offset by its low power factor when starting up and while running at slow speeds and the existence of a fractional power factor at higher speeds. And, within the ordinary working range of practice, it is evident that the power factor and output per unit of weight tend in opposite directions; that is, the higher the power factor, the heavier will be the motor.

Wireless Telegraphy.

We are really beginning to despair of ever seeing the fruition of even the most modest ambitions of wireless telegraph enthusiasts. At the outset we mildly suggested that wireless telegraphy might prove of incalculable practical value for signalling between ships and lighthouses, shore stations, etc., over relatively short distances, but that its field was obviously limited, and we were promptly put down as belonging in the category of pessimists and obstructionists. Time has developed numerous "inventors" of wireless systems, produced magnificent fields for all such systems—on paper—and brought forth inspiring recitals of "intentions," claims, predictions, etc., *ad infinitum*. But we have been pained to note that whenever anyone has called upon wireless telegraph apparatus actually to do something practical and fulfill one hundredth of one per cent of the roseate promises made for it, something "unexpected" has happened. The legitimate market for operative wireless apparatus has never been satisfactorily supplied; the United States Signal Corps has had a succession of discouraging experiences with wireless telegraph apparatus and promoters; attempts at practical wireless operation on an important scale made in this country have turned out exasperating fizzles. Under the circumstances we acknowledge that the first clause of our original prognosis was wrong and are tempted to substitute the opinion that wireless telegraphy shows no symptoms of proving valuable under any industrial circumstances whatever. This, however, would scarcely be justified, since there are a few ship and shore stations at work.

Fan Motors for This Season.

It will be evident to readers of our annual fan-motor article in this number that the limit of improvement in the construction of these machines has been about reached. All of the changes since last year are in minor details and have been made in order to add to the convenience of the user rather than to increase the efficiency and reliability of the apparatus, the maximum of these two characteristics having been already obtained. A notable development in the line of fan motors, however, is in the provision of means for diffusing the air currents produced by the fans. The oscillating, revolving, or otherwise restless motor has become an accepted type, and the number of machines of this class is rapidly increasing. For the general cooling of rooms of moderate size, they are undoubtedly advantageous, while the older type of motor giving a direct stream of air is probably best suited for individual service. All of them, however, are extremely meritorious little machines, and we have no intention of making any invidious comparisons; each type has advantages over the other under certain conditions.

Machine Tool Motors.

In the interests of the manufacturers of electric motors it is to be hoped that the application of these highly useful machines to the driving of machine tools will not be abused or carried to extremes that will prove boomerangs, as has occurred in other lines of electrical work. Nothing reacts more disastrously upon the advocate of any engineering practice than the discovery by "parties of the second part" that the practice is not justified or that the methods involved have been applied injudiciously. We hasten to interpolate the statement that we strongly advocate the use of electric motors wherever sound engineering principles require or allow it. It is not often, however, that individual motor drive is economical in very small units; it is also frequently inadvisable to obtain variable speed by means of complex systems of supply. Both of these two methods have their fields, of course, and they are by no means small ones; but neither method can be indiscriminately applied without ultimately bringing motor drive into disrepute as to fulfilling all of the promises made for it.

The feature of variable speed in machine-tool motors appears to have been carried to excess in some instances. The users of such tools have been apparently content for years with six, or at most eight, speed rates; it would appear, therefore, somewhat unnecessary to increase the number by two or three hundred per cent. in a single jump. The machine-tool man would probably have been delighted with ten or a dozen speeds and never have thought of demanding any more if a few well-meaning builders had not voluntarily offered them as an inducement. Of late, it may be said, the tendency is strongly toward limiting the number of speeds to a rational value, such as twelve, but it is extremely difficult to undo an error in policy which favors the other man unwarrantably.

It is not practicable to discuss here fully the several methods of obtaining variable motor speed in their relation to economy. A book could be written on the subject. The method of supplying current at three or more different fundamental voltages which can be combined in different ways has, of course, the merit of reducing the motor itself to the simplest possible construction and also involves less variation in field-magnet strength for a given number of running speeds than either the simple three-wire distribution with equal voltages on both sides of the neutral wire or the two-commutator motor used on a two-wire circuit. The double-commutator machine has, on the other hand, the great advantage of being workable on any simple two-wire circuit, and will give double the range in speeds on a three-wire circuit that a single-commutator motor will give with the same arrangement of field gradation. It seems clear to us, viewing the matter impartially, that the choice between multiple voltages and multiple motor armature windings depends to a great extent upon the magnitude of the plant. For a very large factory or works, where first cost is not of so much relative importance and where the establishment can afford to employ thoroughly competent men to look after the electrical apparatus, a multivoltage system giving not over four fundamental voltages would probably be preferable in most cases; under other conditions the double-commutator machine appears to have the advantage, generally speaking.

A HOME-MADE SENSITIVE MIRROR GALVANOMETER.

BY JOHN D. ADAMS.

The galvanometer here described is of the mirror or reflecting type, and in common with instruments of this class, is intended to be used with a suitable source of light and a screen or scale. The design is such that the instrument can be readily constructed by any one familiar with experimental work. Fig. 1 is a front elevation of the galvanometer, Fig. 2 a vertical section through the center and at right angles to the view in Fig. 1, and the remaining illustrations are details.

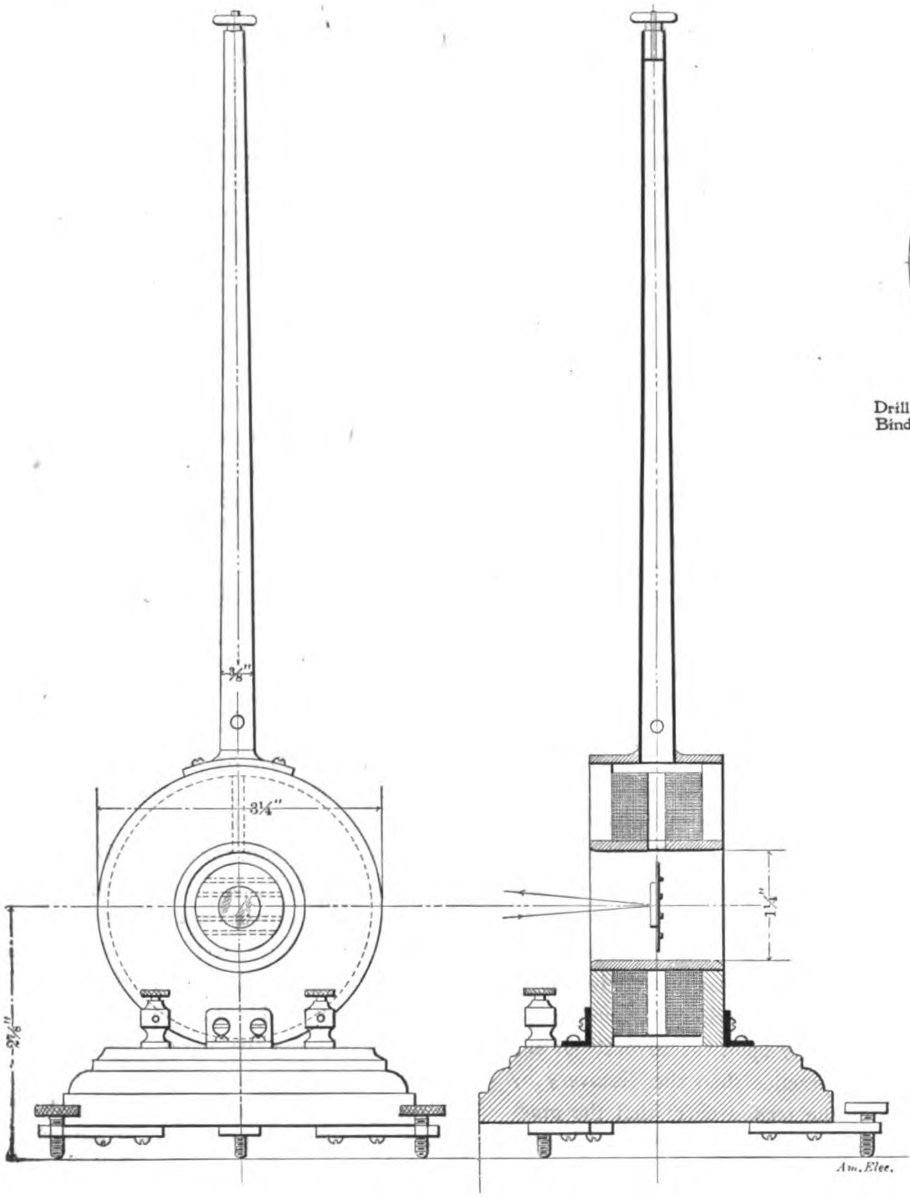

FIG. 1.—ELEVATION AND VERTICAL SECTION OF GALVANOMETER.—FIG. 2.

The base, Fig. 3, is made preferably of hard wood, such as walnut or cherry, and of the dimensions specified in the sketch. Upon this is mounted a spool containing the winding; the spool is secured to the base by means of two angle pieces and eight small wood screws (of brass). The core of the spool is best made of a piece of fibre tubing, but it can be made by winding a strip of tough shellacked paper 1⅝ inches wide around a 1¼-inch mandrel until the paper is ⅛ inch thick. Before starting to wind the paper tube, a layer or two of oiled paper should be wrapped around the mandrel to prevent sticking. After the tube has been built up to the required thickness of wall, it must be allowed to dry hard before being handled; if facilities are available, it should be baked out slowly in an oven at a temperature of about 100° Fahrenheit. When hard, the end should be trimmed off smooth and accurately at right angles to the bore of the tube, and a square hole, 3-16 inch square, cut through one side exactly midway of its length and with its axis precisely radial to the axis of the tube.

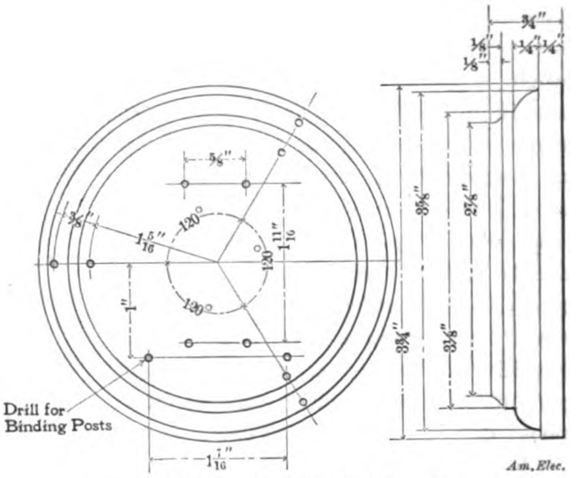

FIG. 3.—PLAN AND ELEVATION OF BASE.

The bobbin or spool heads are made of the same material as the base unless hard rubber is available for the purpose, in which event it should be used. If the heads are of wood, they must be glued on securely. A good method is to lay one head on a flat true surface, cover one end of the core tube with glue, and insert it in the hole in the head, pressing the end of the tube fairly down on the flat surface under the head so that it touches that surface uniformly all around. Then put on the middle disc which serves as a partition between the two halves of the winding. This is 3 inches in diameter and 3-16 inch thick; the hole in its center must fit very snugly over the outside of the tube. A radial slot 3-16 inch wide is cut from the periphery of this partition disc to the central hole, as indicated by the dotted lines in the left-hand part of Fig. 4, which shows the complete spool or bobbin. The purpose of this slot is to allow the suspension thread which holds the mirror to pass. In order to guard against interference with the suspension thread by any stray fibres of insulation on the wires of the winding it will be advisable to paste a disc of tough bond paper on each side of the partition disc so as to cover the radial slot and convert it into a rectangular channel. The other head disc is then put on in the same way as described above, and the partition disc is then centered between the two heads and fastened in position by a few drops of glue at the core. After the glue has set, all surplus glue should be removed, and the screw holes drilled in the heads for the screws which hold the bobbin to the base and those which hold the suspension-tube socket at the opposite edges of the head discs. The mouth of the core tube should be chamfered out into a bell-shape, as indicated in Fig. 4, so as to give a greater range of swing to the beam of reflected light.

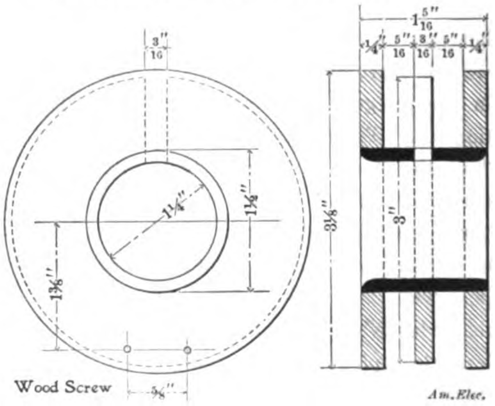

FIG. 4.—PLAN AND SECTIONAL ELEVATION OF BOBBIN.

Each compartment of the bobbin is wound with No. 30 or 32 double-silk-covered wire; single-cotton-covered wire may be used, so far as insulation is concerned, but silk-covered wire is better because more turns can be put in the available space. In beginning the winding, the inside end of each half should be led out through a small hole in the head disc of that half. The two halves must be wound in opposite directions; that is, after winding one half, the bobbin must be turned around, end for end, and the other half wound in its compartment by running the lathe in the same direction as before. The outer ends of the two halves are connected together over the edge of the partition disc, preferably about midway between the top of the bobbin or spool and the base. A protecting strip of thin imitation leather 13-16 inch wide and 9⅝ inches long might then be wound over the wire, giving the spool the appearance of having only one coil. The glued joint in this strip should come at the under side of the spool, and a 3-16-inch square hole should be cut in the center to coincide with the opening in the center disc.

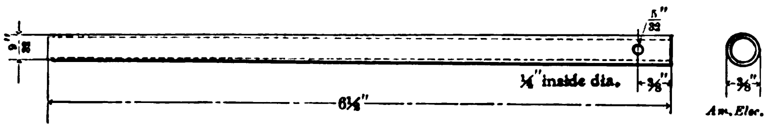

FIG. 5.—DETAILS OF SUSPENSION TUBE.

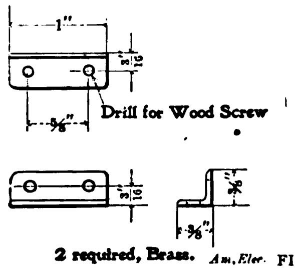

FIG. 6.—BOBBIN BRACES.

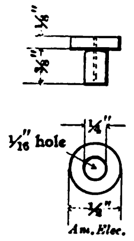

FIG. 7.—SUSPENSION TUBE PLUG.

The spool is placed centrally upon the base and attached thereto by means of the two angle pieces, as shown. These angles are bent from a piece of strip brass 1 inch long and ⅜ inch on each side. Round-head brass screws are used here, making countersinking of holes in the angle pieces unnecessary. After the spool is secured to the base in this manner a piece of 1-16-inch brass, 1⅜ x 1 5-16 inches with a ⅜-inch hole in the center, should be bent to the curve of the spool head edges and fastened thereto by means of four round-head brass screws. This is the socket for the suspension tube. The latter is a piece of heavy ⅜-inch brass tubing 6½ inches long, filed tapering and polished in the lathe. At a point ⅜ inch from the larger end a 5-32-inch drill is run through, and then a second time at right angles to the first. These holes are for the purpose of observing the silk fibre in order to see that it hangs perfectly clear. Before putting on the leveling screws, the base should be set on a flat horizontal surface and the suspension placed in the socket on top of the spool and soldered fast in a vertical position. A little wooden plug is fitted snugly into the end of the tube, with a 1-16-inch hole bored lengthwise through it. Through this small hole the silk fibre passes, and after the approximate length of the fibre is determined, it is held fast by a little piece of wood forced in the hole. To adjust the magnetized needles to such a height that they will hang in the exact center of the paper tube, the plug is moved bodily up or down in the top of the brass suspension tube. The fit of this plug should be such that it can be readily moved yet have sufficient friction to hold it in position; or else a smooth-nose set-screw must be provided to hold it wherever it may be set.

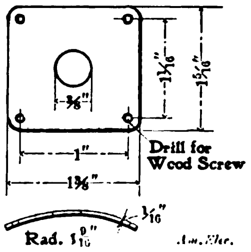

FIG. 8.—SUSPENSION TUBE SOCKET.

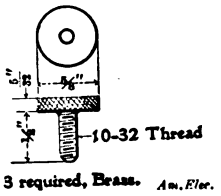
On the back of a circular piece of cardboard about the thickness of a visiting card and 1⅛ inches in diameter are fastened by means of shellac 5 small pieces of magnetized cambric sewing needles, and on the other side a small piece of ordinary mirror glass. Of course, a small concave mirror would throw a more clearly defined spot of light on the screen, and this should be used if obtainable; but the ordinary glass will serve very well if the scale is kept well shaded. It is well not to magnetize the needles until after they are fastened in position on the back of the card, as they are then less likely to have the magnetism jarred out of them or to be placed on the card with opposite poles pointing in the same direction. The card acts very well as a damper in bringing the needles to rest. The needle disc should be suspended by a fibre of cocoon silk if the maker can obtain it; if not, a piece of ordinary fine sewing silk may be untwisted and one fibre taken out; in order to straighten this, it should be moistened and hung up by one end with a little weight at the other and allowed to dry. One end of the fibre is attached by shellac to the cardboard disc, and the other end fished up through the brass tube and made secure in the wooden plug at the top, as described before.

On the under side of the base three radial lines should be drawn 120° apart and two holes drilled on each line at the points indicated, to receive the screws for holding the leveling lugs. On the upper side of the base the four holes for the small wood screws of the angle feet are drilled, and two holes must be drilled clear through for binding-post screws. The leveling is done by means of three screws threaded into the three projecting brass lugs, set 120° apart on the under side of the base. These lugs are made from 3-16 x ½-inch. flat brass, two holes being drilled and countersunk in each piece for the wood screws and one hole tapped for a 10-32 machine screw. Rounding the projecting ends of these lugs to ¼-inch radius is advisable. The leveling screws may be turned from ⅝-inch brass rod and should have knurled and rounded noses or ends. The thread is 10-32 and the shank ½ inch long.

The instrument built by the writer was placed on the end of a long table lying east and west and the leveling screws adjusted until the silk fibre was seen, through the holes in the base of the tube, to be hanging perfectly free. The source of illumination, which was placed on the opposite end of the table, consisted of an ordinary kerosene lamp set in a soap box standing on end with its bottom facing the galvanometer. A hole ¾ inch in diameter was bored through the bottom of the box at such a height that the light coming through would strike the mirror. A 1-inch board about 4 feet long and 6 inches wide was then nailed on the bottom of the box, parallel to the table and below the light hole, to serve as a scale. The soap box kept the light from the scale quite satisfactorily.



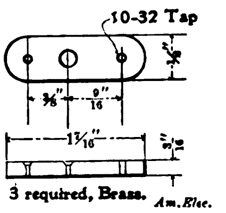


FIG. 9.—LEVELING SCREW AND LUG.—FIG. 10.

The apparatus set up in this manner would readily detect the current generated by touching the points of a brass pin and steel needle to a drop of salt water. In order to make the position of the instrument independent of the earth's magnetism, a small magnetized bar about 3-16 x 4 inches was placed across the brass tube and made adjustable as to height. It is hardly necessary to add that no iron screws should be used in the construction.

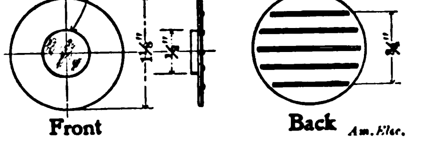

FIG. 11.—FRONT, SIDE AND REAR VIEWS, SHOWING ARRANGEMENT OF MIRROR AND MAGNETS.

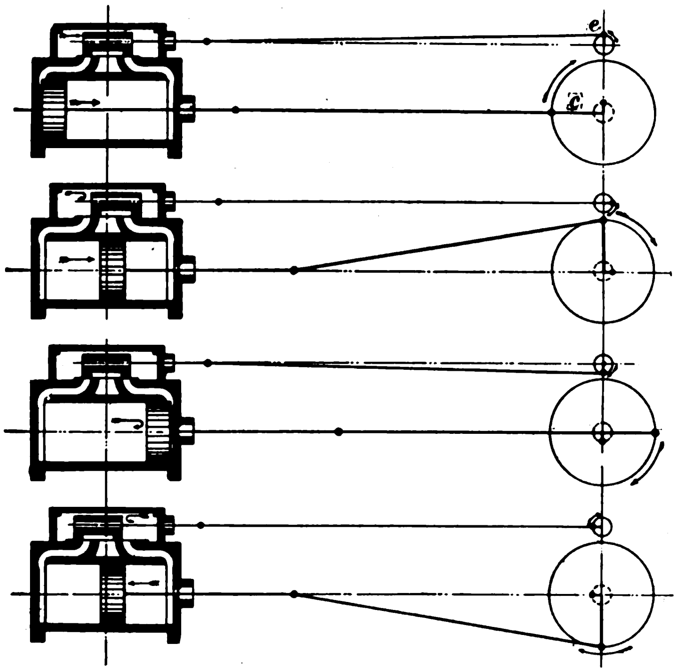
VALVE GEARS.

BY C. C. MAJOR.

Relation Between Piston and Valve Position and Crank and Eccentric Angles.

"Slide vale" is a term usually applied to flat-faced valves having a reciprocating motion in a straight line, although special valves as piston valves, Corliss valves and others having cylindrical surfaces are virtually slide valves. Fig. 3 shows a section through a plain D slide valve and ports of an engine. The valve is shown in its central position. The portion, *s*, extending beyond the outside edge of the port is the steam lap, and that portion, *e*, beyond the inside edge is the exhaust lap.

One of the most important points in the study of valves and methods of setting them correctly, is to thoroughly understand the relations existing between the linear positions of the valve and piston, and the corresponding angular positions of the crank and eccentric. In order to bring out more clearly the object or purpose of steam and exhaust-lap of a valve, the relative positions of the various parts will first be shown when the valve has no lap and just covers the steam ports.



FIGS. 4, 5, 6 AND 7.

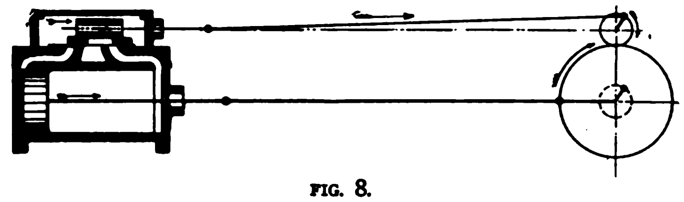


FIG. 8.

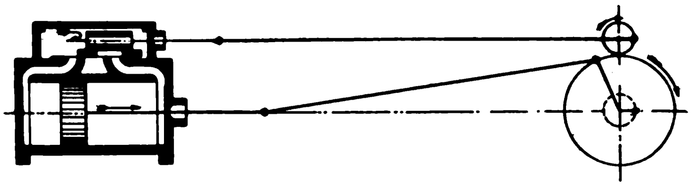

FIG. 9.

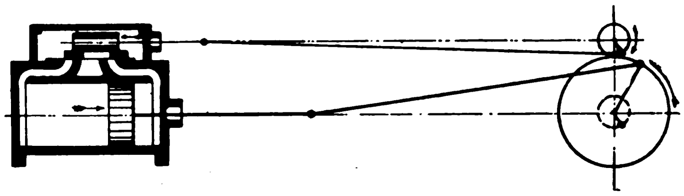

FIG. 10.

In Fig. 4, the valve is in its central position covering the ports. The piston is at the end of its travel, the crank, *c*, is on the dead-center nearest the cylinder and the eccentric is at *e*, just 90° ahead of the crank. The angularity of the eccentric-rod would change the angle between the crank and eccentric but very little, as the rod is quite long as compared to the throw of the eccentric, so its effect may be neglected. The shaft is supposed to turn in the direction indicated by the arrows and when the eccentric has reached its dead-center farthest from the cylinder as shown in Fig. 5, the valve has opened the port wide and any further movement of the eccentric will begin to close the ports. The crank has passed through one-fourth of its revolution and the piston has traveled a little more than half its stroke.

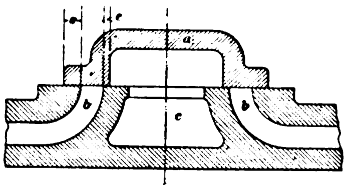

FIG 3.

As the eccentric moves past the dead-center, the valve is returning to its central position. Fig. 6 shows the crank on the dead-center farthest from the cylinder, when the piston has completed its stroke, and the valve has closed the admission port, cutting off the supply of steam. From this figure it is evident that the admission port is open until the piston has traveled its entire stroke and when the exhaust valve opens, which will occur as soon as the valve moves past its central position, the steam will be exhausted at the same pressure as the entering steam, that is, high pressure steam has followed the piston during its entire stroke and the expansive force of the steam has not been utilized. This is, of course, a very wasteful method of working, but is used in most of the small steam pumps and accounts for the large amount of steam required for their operation, which may vary from seventy-five to one hundred and fifty pounds per horse-power per hour.

Fig. 7 shows the eccentric on the dead-center nearest the cylinder; the valve has opened the opposite port wide. The piston is in the same position as shown in Fig. 5 and has the greater portion of its stroke yet to travel. When an entire revolution has been completed and the crank has reached the dead-center, the same condition exists as shown in Fig. 4.

In order that the admission port may be closed early in the stroke to utilize the expansive force of the steam, the outside edge of the valve is extended; that is, steam-lap is added, and the more lap, the earlier in the stroke will the admission of steam be cut off. Inside or exhaust-lap is added to cause the exhaust-port to open later in the stroke and to close earlier on the return stroke.

Figs. 8 to 12 show several relative positions of the valve, piston, eccentric, and crank, for a valve having both steam and exhaust-lap. The eccentric has been turned on the shaft to bring the outside edge of the valve a little beyond the edge of the port when the crank is on the dead-center nearest the cylinder and the piston is at the head end of its travel, as in Fig. 8. The distance that the valve is open when the crank is on the dead-center is the "lead." When a valve has lead, the steam port is opened and the cylinder clearance spaces filled with high-pressure steam before the piston begins its return stroke. This steam forms a cushion for the piston and helps to bring the moving parts to rest without jar or shock. When the eccentric has reached its dead-center farthest from the cylinder, as shown in Fig. 9, the head-end port is open wide and any further movement of the eccentric will begin to close the port. The valve will continue to move to the left and when it has reached the position shown in Fig. 10, the steam port will be closed; the position then occupied in the cylinder by the piston is the point of cut-off with the arrangement here shown; the piston has traveled about three-fourths of its stroke when the valve cuts off. From this position to that shown in Fig. 12 the piston will move under the expansive force only of the steam.

In Fig. 11 the inside edge of the valve

has just closed the port, thus preventing a further escape of exhaust steam. As the exhaust steam in front of the piston can not get out, it will be compressed into the clearance space, the pressure gradually rising and presenting an increasing resistance to the movement of the piston. This resistance or pressure of compression helps to bring the moving parts gradually to rest as the piston approaches the end of its travel. This position of the piston at the instant of exhaust closure is called the "point of compression."

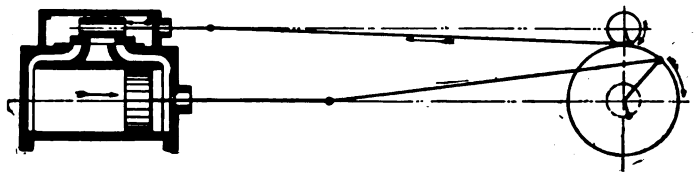

FIG. 11.

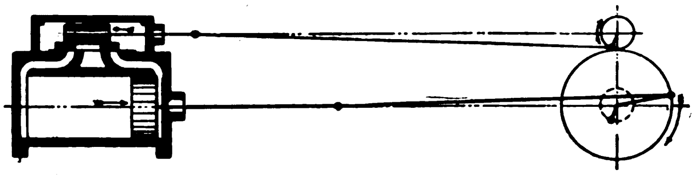

FIG. 12.

Fig. 12 shows the valve about to open the port leading to the space behind the piston. This is the "point of release" and should occur when the piston has nearly reached the end of its stroke. The object of having the exhaust port open behind the piston is to secure a wide opening of the port early in the return stroke.

Setting a Slide Valve.

In setting a plain slide vale, the first step is to place the engine on the center.

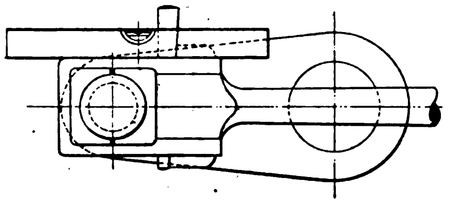

FIG. 13.

If the strap on the end of the connecting-rod is quite long and its upper surface parallel to the axis of the rod, a spirit-level may be used as shown in Fig. 13. When the air bubble is in the highest part of the glass and is exactly bisected by the line midway on the glass, the centers of the crank-pin and shaft are in the same horizontal plane and the crank is on the center. A more common method is turn the engine shaft in the direction it is to run until the crank is nearly horizontal. A straight edge is held against one end of the cross-head and the position of the cross-head marked on the guides. The mark may be more easily seen and need not scratch the metal if a piece of chalk is first rubbed on where the mark is to be made. While the crank is in this position, a center-punch mark is made on the frame in some convenient place to take one end of a bent scriber (see Fig. 14). With the other end, a line is drawn across the edge of the rim of the fly-wheel. The crank is then turned past the center until the cross-head reaches its former position and another line is drawn across the fly-wheel. The distance between these two lines is bisected and a center-punch mark made to locate permanently this point. The shaft is then turned until the center-punch mark is true with the scriber point; in this position it is on the center. The scriber shown by Fig. 14 is easily made and serves the purpose admirably. It may be made of ⅛-inch steel wire or 3-16 to ¼-inch round or flat iron. The ends are tapered and sharpened to fit a light center-punch mark.

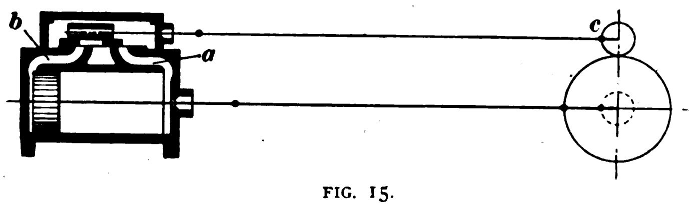

FIG. 15.

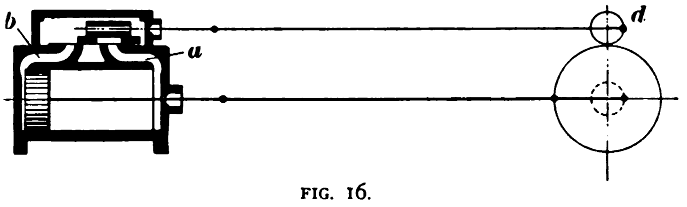

FIG. 16.

After putting the engine on the center, the valve is set about midway on the stem so that it (the valve) may move freely the required distance without danger of having the end of the valve-stem strike the wall of the steam chest. The valve should travel equal distances each side of the central position. To determine whether or not the valve has equal travel on each side of the center, the eccentric is turned on the shaft until it is on the center nearest the cylinder, as shown at *c*, Fig. 15. If the eccentric-rod is too short, the valve will not move far enough to the left and the crank-end steam port, *a*, will not be fully opened for the admission of steam. If the valve has over-travel, the port may be opened wide, but the length of time the ports are opened will not be the same for both ends. When the valve is in this position, the eccentric has to turn through only a slight angle to cause the valve to move far enough to cut off the admission of steam; consequently, an early cut-off occurs in the crank-end of the cylinder.

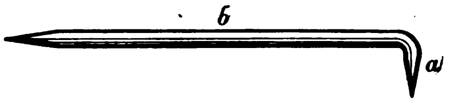

FIG. 14.

When the eccentric is turned to the opposite center, farthest from the cylinder, as at *d*, Fig. 16, the steam edge of the valve will move beyond the edge of the port *b*. As the valve has farther to travel in order to close the steam port, cut-off will occur later than it should, and a greater amount of work may be done in the head-end than in the crank-end; furthermore, the angular velocity of the fly-wheel will vary considerably during each revolution.

To adjust the length of the eccentric-rod, the eccentric is turned to the center nearest the cylinder and the rod lengthened until the edge of the valve is in line with the inner edge of the port; then the eccentric is turned to the opposite center to see if the same condition is obtained. If the valve has over-travel or is designed so as not to fully open the port, the eccentric-rod is adjusted to give the same amount of over-travel or port opening at each end when the eccentric is on the center.

After the eccentric-rod has been adjusted it is necessary to set the eccentric to give proper steam distribution. If the crank is on the center nearest the cylinder, the piston is at the head-end of the cylinder, of course. The eccentric should be turned around the shaft in the direction in which the engine is to run until the port leading to the head-end of the cylinder is open from 1-32 to 1-16 of an inch, according to the amount of lead desired; then fasten the eccentric to the shaft and set the crank on the opposite center and note if the lead is the same. The lead should be the same, but if there is only a slight difference, the valve may be moved on the stem to take up half the difference in the lead. If there is considerable difference for the two positions, part of this difference may be adjusted by moving the valve on the valve stem and part by moving the eccentric.

◆

INTERCOMMUNICATING TELEPHONE SYSTEMS.

The Samson Junior.

BY A. DALLAM O'BRIEN.

In previous articles a number of intercommunicating telephone systems have been described, in which the salient feature has been the automatic switch, whereby at the expiration of a conversation the instrument is returned to its normal condition. The automatic feature, while unquestionably a good one, need not necessarily be present in a system of this kind, and it is the purpose of this article to describe a type of telephone suitable for installation in all cases where intercommunication is required and which does not depend for its action upon the automatic return of the selective switch to its normal condition. The system described herein is capable of a number of modifications to suit various requirements of service and of wiring, and the absence of the automatic features enables the instrument itself to be contained in a small space.

The type of telephone shown in Fig. 1 is intended for non-selective private lines; the act of signalling from any telephone connected to the line rings the bells of all the instruments connected to the system. Thus it follows that an installation of this character is applicable principally in cases where it is desired to communicate with a number of stations at once, and where the absence of the selective feature is not an inconvenience.

In a large number of instances the selective feature is absolutely essential and for this purpose the instrument shown in Fig. 2 is designed. A push button is supplied for each station, and the depression of the button serves to signal the desired instrument. The internal arrangement of this type, which is shown in Fig. 3, is such that it is possible for only two stations to be connected at one time without interference; in order to provide for a number of simultaneous connections the instrument shown in Fig. 4 is supplied.

The general system of wiring used with all these instruments, except the first type, consists in connecting the various stations with a cable containing one wire for each instrument and additional battery wires, the number depending upon the class of installation; that is, whether local batteries are used at each station to furnish talking current, or whether a central battery is used to furnish current for all the stations connected to the system. With the class of instrument shown in Fig. 1 considerably less wiring is required than with the other types, as in this case it is only necessary to run four wires throughout the system and connect each station thereto. One wire is used to furnish current for signalling, one for the common return, one for the bells, and one to supply current to the transmitters through a retardation coil. The effect of this method is to bridge the battery across the talking wires and to connect the transmitters and receivers at the various stations in series and bridge them across the battery leads. The bells are also connected in multiple, so that a signal from one station rings at all stations. The same battery is used for both ringing and talking purposes. As this method of wiring is so simple and is used so extensively with private lines, it is hardly necessary to describe it further.

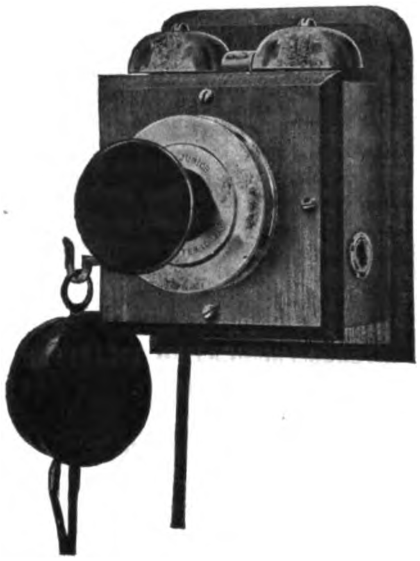

FIG. 1.

The desirability, if not the necessity, of a selective system of signalling in a private telephone installation usually leads to its general adoption, and the methods of wiring for such a system are shown in Figs. 5 and 6. The diagram in Fig. 5 shows an installation of three stations of the type illustrated in Fig. 4, connected so as to use a central ringing and a central talking battery. One wire from each station is run throughout and connected to a contact stud at each other station. Three additional wires are run throughout the system, one carrying talking current, the second ringing current, and the third acting as a common return for both the talking and ringing currents.

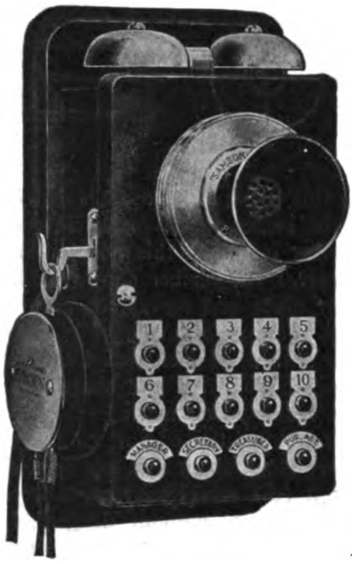

FIG. 2.

The hook switch at each instrument does not in itself act as a conductor, but carries four contact springs which serve to close the proper circuits. The bells are connected, as shown, to the home point of their respective instruments, and when the receiver is on the hook, through a contact spring to the common return. One side of the push button is connected to the switch lever, the other side carrying ringing current from the central battery. The transmitters are connected directly to the talking battery and are wired each in series with the primary winding of an induction coil, their local circuits to the battery being closed through the hook switch contacts and the common return when the receiver is removed from the hook. The secondary, or receiver circuit, is connected to the switch lever, and through the contact springs on the hook switch to the common return.

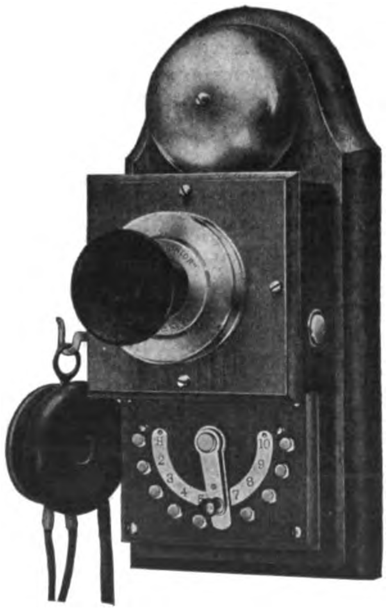

FIG. 4.

In order to signal any desired station, the switch lever is moved to the proper contact stud; to No. 2, for example, as shown at Station I in the diagram. The push buttons is then depressed and current flows from the ringing battery through the switch lever and contact stud at Station I, over line 2, through the bell at Station II, and thence through the contact springs at the hook switch at Station II, back to the ringing battery over the common return, thus signalling the station. The receivers being removed from the hook, the ringing circuit is opened and the talking battery circuit is closed through the transmitter and primary of the induction coil. At the same time, the secondaries and receivers at the connected stations are connected in a closed circuit through the line of the called instrument, the switch levers, the hook switch contact springs, and the common return wire.

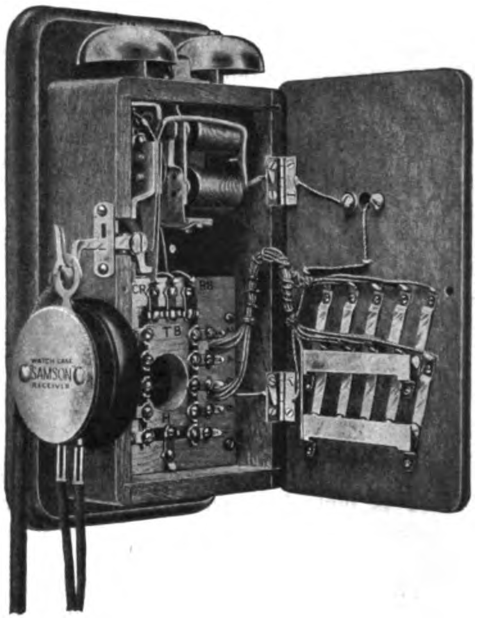

FIG. 3.

From this description it will be seen that the transmitters are furnished with current very much in the same way as are the operators' transmitters in a central office; in other words, they are connected in multiple across the leads from the talking battery. The difficulties arising from interference during simultaneous connections will depend upon the resistance of the battery leads and the internal resistance of the battery, but in general with a system of this kind the possibility of interference is negligible and simultaneous connections may be considered entirely feasible.

The diagram in Fig. 6 shows the arrangement of circuits when a central battery is used for furnishing ringing current and where local batteries are used at each instrument for furnishing the talking current. In this case, as will be seen from the diagram, one less wire is required throughout the system, and at the same time, the chances of interference are considerably reduced. The method of operation for this class of wiring does not differ from that of the central energy method, and the same description applies, the only difference between the two systems being the manner in which the battery current is furnished to the transmitters. The instruments are furnished, as a rule, with the type of watch-case receiver illustrated in the cuts, although when preferred they are equipped with the usual form of hand telephone. The transmitter is adjustable and has a movement of 25 degrees above and 16 degrees below the horizontal, the conducting cords being carried inside the transmitter mounting and connected in such a way that the frame of the transmitter is insulated from the circuit and does not act as a conductor.

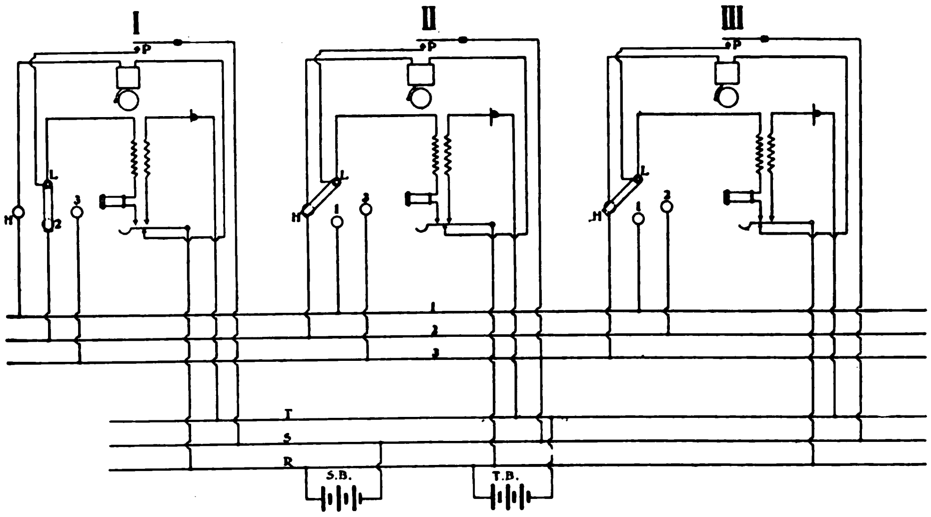

FIG. 5.—DIAGRAM OF CONNECTIONS FOR A THREE STATION SELECTIVE TELEPHONE SYSTEM.

The instruments are arranged for either exposed or concealed wiring, as desired, the case being designed for the style of wiring which it is proposed to use. In the exposed style of wiring the cable is fastened to the wall at the desired height and taps are made sufficiently long to serve as connections. The cover carrying the transmitter and switch block is removed, the telephone attached to the wall and the wiring brought in through a hole in the back board. This board is made of 1-inch wood and is grooved ⅝ inch deep, the groove serving to carry the cable. A hole 3¼ inches in diameter is cut through the back, the taps from the cable brought in and attached to the switch block in the instrument. The local wires to the instrument proper are connected within the case. Where it is desirable to use concealed wiring, the cable or taps therefrom are brought into the instrument through a hole in the back and connected to an internal switch block. The interior arrangement of these instruments is well shown in Fig. 3, the switch block, hook switch, local connections and push button strip being clearly illustrated. The push button centre is supported on the outside of the case by an escutcheon plate, the inside contact consisting of a long German silver spring; the number of each push is stamped on its supporting plate. The springs all make contact on a metal strip of sufficiently heavy gauge to have elasticity enough to produce a good rubbing contact. In this type of instrument, as has been previously pointed out, it is not possible for more than one pair to converse at a time.

With the switch arm type, illustrated in Fig. 4, a natural tendency to bend the arm when operating it is avoided by the addition of the extra arm which is fastened to the switch arm proper. The bells used for signalling purposes are equipped with double gongs mounted on a one-piece bracket, by means of which they are kept the proper distance apart. The hammer ball is covered by a formed punching held rigidly in place by the gong bracket and thus preventing any tampering with the hammer.

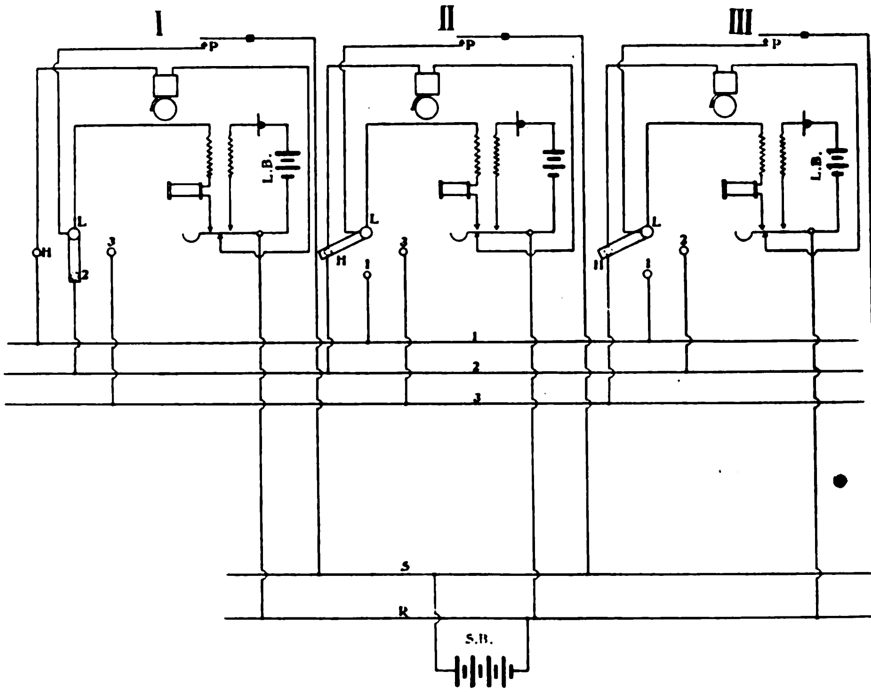

FIG. 6.—DIAGRAM OF CONNECTIONS WITH A CENTRAL SIGNALLING BATTERY AND LOCAL BATTERIES FOR TALKING CIRCUITS.

The induction coil is mounted in the interior of the instrument, and is equipped with a special connector for the receiver cord terminals. The compact arrangement of these instruments will be readily appreciated from the fact that the instrument shown in Fig. 1 is contained in a case 3⅞ inches by 4 inches, while the type shown in Fig. 2, having an equipment for six stations, is contained in a case 5¼ inches wide, 8¼ inches high and 2⅝ inches deep.

If desirable, desk telephones can be furnished for use with the systems described, the wires to the instrument being first terminated on a switch block, and the local wiring to the transmitter being made from the block through the medium of an instrument cord. With the common-battery desk set, the induction coil is mounted in the base of the stand, while with the local battery method of installation the induction coil is contained in the switch block. The push button strip, or strip containing the switch arm and contact studs, may be mounted at any desired point near the instrument.

In the common-battery type of installation, probably four cells of any good wet or dry battery will answer for furnishing the talking current, and four or five cells will be sufficient for ringing power. Where local batteries are used for talking purposes, two cells at each instrument will be sufficient, the common ringing battery consisting of four or five cells, according to the distance over which it is necessary to signal. With the switch-arm type of instrument, the signalling push button is mounted on the side of the case, as shown in Fig. 4, and with this type either the central battery or local battery system can be used without making any change in the internal wiring of the instruments.

The number of instruments that can be

connected to a system, using the type shown in Fig. 1, is limited only by practical operating conditions, while the other two types are equipped for any number up to 20 stations. The telephones described herein are manufactured and handled by the Electric Gas Lighting Company, of Boston, Mass.

NOTES ON INTERIOR WIRING.

BY ARTHUR B. WEEKS.

In Fig. 1 is shown a typical panelboard. Sixteen circuits radiate from this board; these circuits were run in open work, using cleats and circular loom, in the building where the photograph was taken. The ceiling is unfinished, so that wherever rosettes are located, a small strip of wood is nailed on the side of the joist to provide the proper bearing. Often pieces of pine are set in between joists for rosettes and porcelain cleats, depending upon the location desired for the light.

Where the wires come into the panelboard from above, it is not only neater but essential that they should be run in moulding, since so many wires could not be accommodated on the post in cleat work. Where the many circuits distribute above the panelboard on the ceiling, it gives a very neat appearance to use matched ceiling for several feet, to allow for the proper distribution of circuits. The moulding can also be cut to give a symmetrical appearance where several mouldings are placed side by side. Let the center form the apex of an obtuse triangle, and slope both sides down at the same angle. Also arrange the cleats symmetrically. The same regard for appearance should be observed in making connections from the moulding to the panelboard; flexible conduit should be used continuously from the moulding to the board. The wires back of the panelboard should not be crossed if it is possible to avoid it.

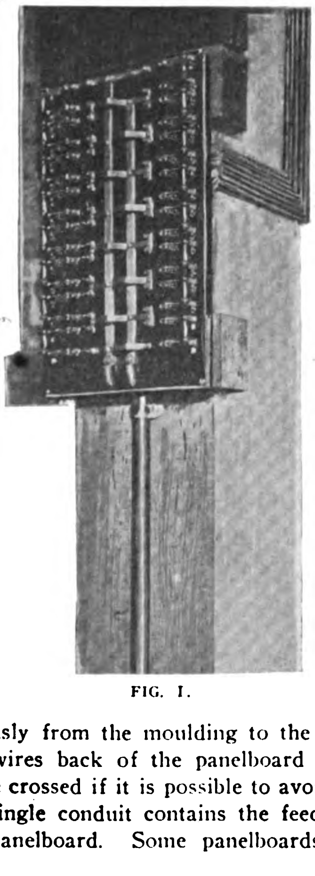

FIG. 1.

A single conduit contains the feeder for this panelboard. Some panelboards have continuous bus-bar connections; that is, there are connections at the top ends of the bus-bars for a feeder to the floors above. Fig. 2 illustrates such a case of wiring; in this illustration the panelboard is not in place. It will be noticed that two-wire mouldings is run from the panelboard to a point within a few inches of the ceiling, where the several circuits branch out in flexible conduit which is continuous from the end of the moulding to the porcelain cleats; this practice should always be followed in such cases.

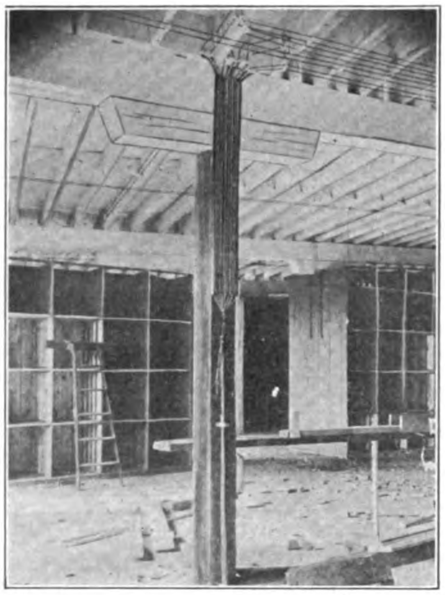

FIG. 2.

It is necessary to set the panelboard out from the post to clear the conduit, and to allow sufficient clearance for inserting the wires after the board is in place. Pieces of 2 x 4 scantling are nailed to the post for a bearing at each corner, and the panelboard is secured by screws to these blocks. If the posts are to be encased, the spacing blocks to which the panelboard is secured must be set out from the post according to local conditions. Fig. 3 shows such a panelboard in position. In all such cases, the carpenter should be consulted.

By taking advantage of the early stages of construction work in buildings, it is possible materially to cheapen the electric work. For example, when a circuit is to be run to light a stairway bricked up on all sides, and an iron plate is to be put into the floor at the doorway and after filled in with concrete, porcelain tubes can be put in on the ceiling level below and afterward be bricked over, then the job completed with iron plate, brick and concrete. This saves drilling holes through the walls by means of a hammer and a piece of gas pipe.

Where doorways are cut through old stone walls, sometimes three feet through, while the masons have the stones torn out preparatory to inserting a lintel over the doorway, have them cut a little more if necessary to insert iron pipes of the proper size, so that porcelain tubes can be inserted in the ends of the pipes after the stonework is all completed and the door hung. If a sliding door is to be used, care should be taken not to get the holes so low that the runway for the door will interfere with the tubes; otherwise, it will be necessary to drill new holes. Again, if workmen of other trades are still carrying on their work after holes have been drilled in the walls for wiring, pipes should be inserted in such holes to indicate beyond possibility of mistake their location and purpose; otherwise, plumbers will in all probability run pipes directly across the path of the leads and necessitate much extra work.

Plans are sometimes changed so that a partition comes in direct line with a baseboard receptacle. If the baseboard is not yet in place, and it is necessary to provide an outlet within a few feet of its originally contemplated location, and a change in conduit is impossible, an outlet box adapted for circular loom work can be placed where desired and loom can be run from the conduit box to the other box and a "blind" cover be put on the conduit box.

It is a good plan to find the true level of the floors before locating any baseboard or post receptacle boxes. Considerable electric work sometimes has to be changed because the receptacles have been put up in accordance with the baseboard ground and afterward some of them had to be raised several inches, or else the worse expedient of dipping the floor had to be adopted.

Before placing receptacles on posts, one should see the carpenter's plans to be sure of getting the right height for the receptacles, lest they come on the moulding on some posts and no two posts be alike. First of all, the floor line should be ascertained. When conduit is run vertically on posts which are to be encased the conduit should be no larger than absolutely necessary in any case, and put as close as possible to the posts. Should "headers" prevent a straight run, they should be altered.

To run conduit from an unfinished room to a ceiling fixture in a hall which is plastered, a ceiling outlet should be located in the hall at the proper depth and, after drilling through the wall, an outlet box should be placed in the adjoining room at the ceiling; the conduit is run from one box

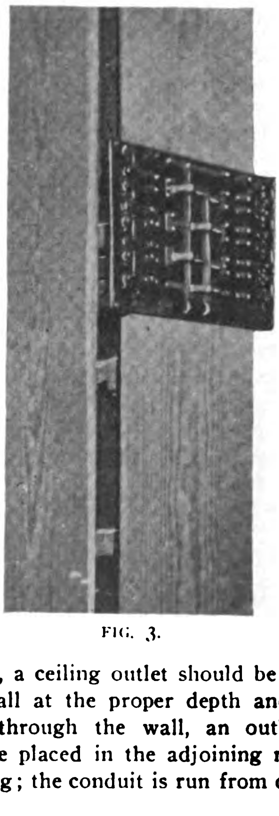

FIG. 3.

to the other, the wire pulled in the conduit, and a blind cover put on the box in the room. Put circular loom over the wire from the last box to the first cleat, and drop down in moulding to a switch if so desired.

One of the things to be ascertained before stringing wire for open work in any room is whether or not the room is to be whitewashed. If so, that work should be completed before running the circuits. Inspectors do not like to pass work when the cleats, rosettes, etc., are spattered with whitewash.

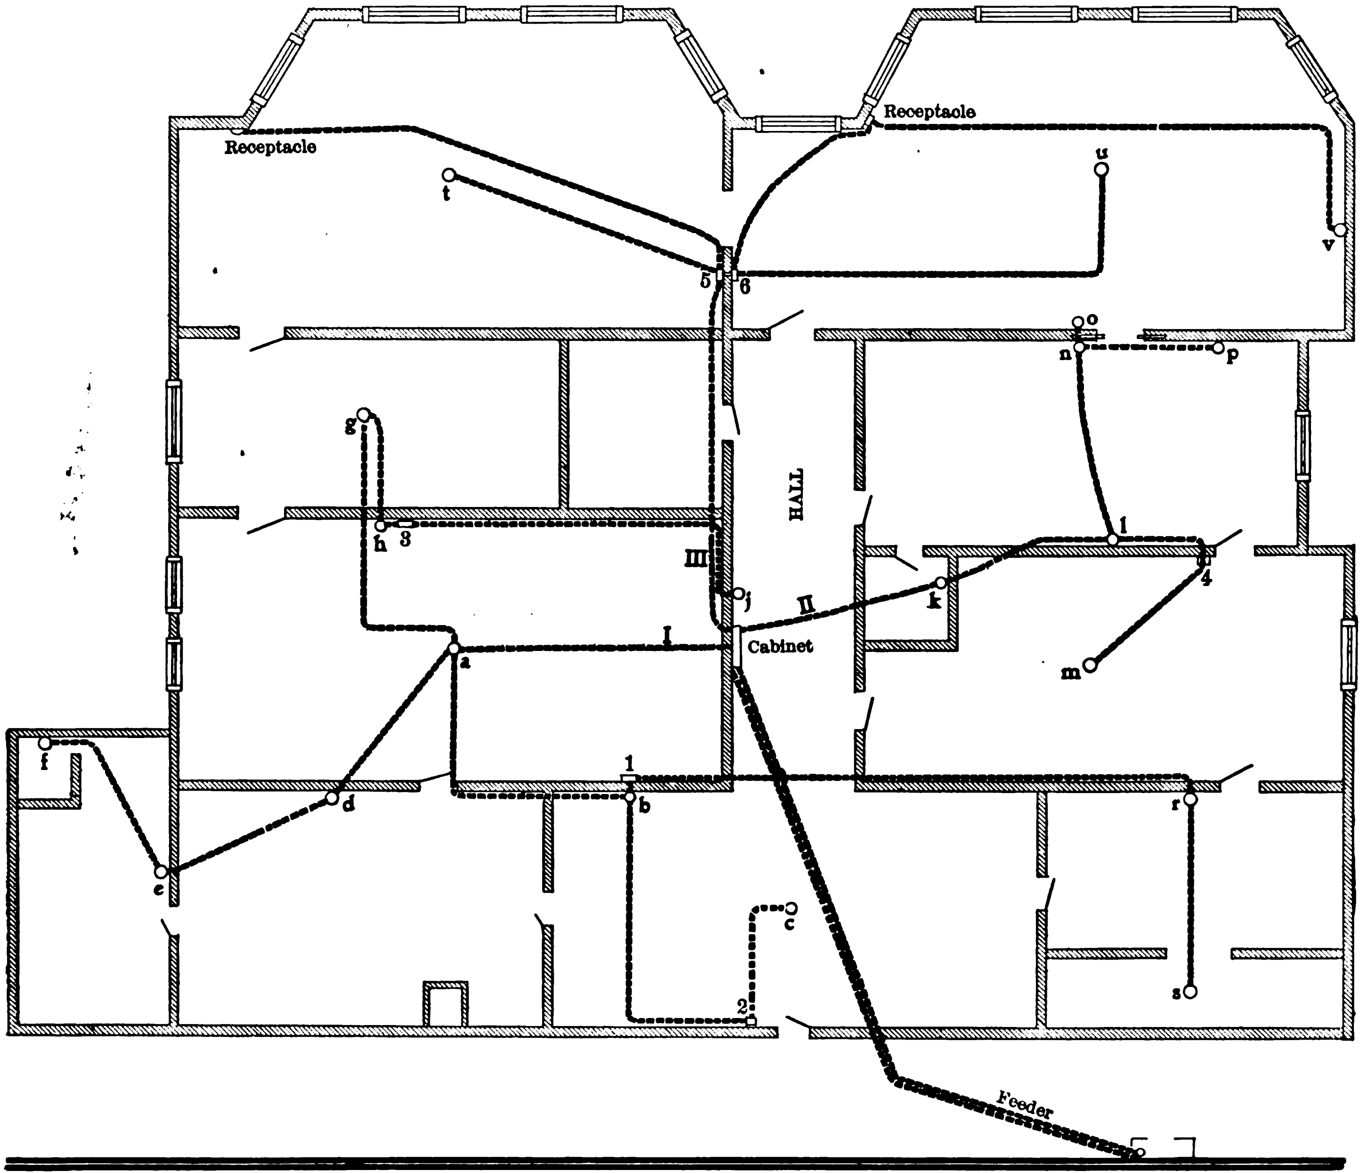

FIG. 4.—WIRING DIAGRAM FOR APARTMENT REQUIRING TWENTY-THREE LIGHTS.

Fig. 4 is the plan of a suite of rooms in an apartment block wired in conduit. The building is of steel construction; all side walls, ceilings and floors are furred. Outlets are indicated by circles and switches by squares. The total number of lights is twenty-three. A ¾-inch iron conduit runs from an outside hall center of distribution; No. 12 feeder wire is used. The distribution circuits are of No. 14 duplex rubber-core wire. The three-wire system is employed throughout the building, but only one side is tapped for this suite. The cabinet is located in the most convenient place, which happens also to be practically at the center of distribution.

Fig. 5 indicates the construction of the cabinet box in which the slate panel is located. All dimensions are plainly marked. A "ground" ⅜ x ¾-inch is nailed on the studs which form two sides of the cabinet, while the other two sides of the cabinet extend out even with the side grounds. The parts *A* and *B* are first nailed together, then *C* and *D*, and these are then inserted between vertical scantlings. The top and bottom walls, *A* and *D*, are brought out flush with the grounds *E* and *F*, which are nailed in place first of all. All parts should be securely nailed. In this case the holes for the conduit were at the top, in the wall *A*. These holes are, of course, bored before the parts are put in place.

Following the circuits, *I* starts from the cabinet, extends up to the next floor, and over on the rough floor to outlet box *a*; here there are three branches. This box is located centrally and secured in place on the joists or furring strips, according to the construction. The feeder enters this box at one of the top holes in order not to cross pipes, but not by the center hole, which is reserved for a fixture plug. From *a*, a branch feeder runs to the floor above, crossed over by the shortest path and drops to a side wall bracket at *b*; the switch *1* in the adjoining room would, of course, be lower than the bracket *b*. The switch box is mounted on a piece of flooring nailed between the studding, and conduit connects *b* with this switch, which controls the outlets *r* and *s*. From *b*, conduit runs down between the studding, out at the floor, and up to the switch *2* which controls the outlet *c* on the ceiling. From this switch box the conduit runs up above the furring strips for the ceiling and enters a side hole in the outlet box *c*.

The second branch from *a* runs over on the rough floor above and drops to the bracket outlet *d*, whence it runs down, over, and up to *e*; thence down to the floor, over again, and up to the outlet *f*. The third branch leaves the box *a* by a top hole, runs along on the floor above, and enters the box *g*, from which the line comes back on the floor above and drops to the bracket *h*. From here, conduit goes to the switch *3* and thence across by the nearest way to the hall lamp *j* near the cabinet. This completes one circuit of ten lamps. Circuit *II* is similar in character to circuit *I*.

Circuit *III* goes from the cabinet up to the floor above and down to the switch outlet box *5*. From here it runs back to the floor above and over to the ceiling outlet *t*. The adjoining switch-boxes *5* and *6* are connected by means of a nipple, since both are on the same piece of ⅞-inch board secured at the center of a studding. From the switch-box *5*, a branch drops down and crosses over on the rough floor to the baseboard receptacle. From the other switch-box, *6*, one branch runs to a baseboard receptacle and continues over to the side bracket lamp *v;* another branch runs to the ceiling outlet *u*, which can be reached by running the conduit just above the furring strips.

Wherever gas pipes have to be crossed on the floor, the floor should be cut out and the conduit dropped with a slight bend beneath the gas pipe.

If any changes are made in the course of conduit running, the wireman should not fail to mark them on the blueprint.

When installing conduit, always take the shortest course possible. Some of the lines shown on the accompanying drawing do not indicate the shortest distance from point to point, as they would intersect other lines and be misleading.

If for any reason changes are made so that the covers of baseboard receptacles or of switches are set deeper in plaster than was intended, longer screws can be procured, and by means of leather washers the parts can be built out and the cover put on in the proper vertical plane.

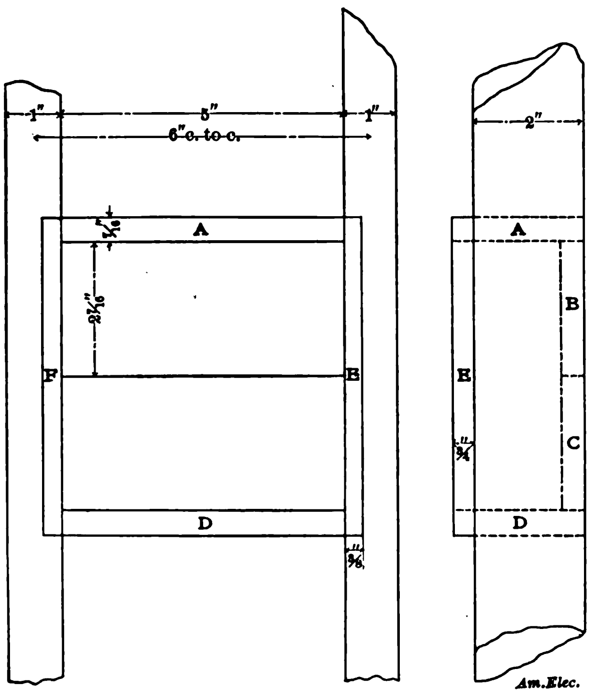

FIG. 5.—FRONT AND SIDE VIEWS OF CABINET BOX.

Lessons in Practical Electricity

ALTERNATING-CURRENT CIRCUITS—POWER FACTOR.

When several inductive devices are connected in series on an alternating-current circuit the total impedance of the group cannot be ascertained by adding the individual impedances arithmetically, as is done with resistance; the impedance of each device must be resolved into its component resistance and reactance, the individual resistances added to find the total resistance, the individual reactances added to find the total reactance, and the total resistance and reactance combined geometrically to find the total impedance. Referring to Fig. 1, for example, *a*, *b* and *c* represent two inductive and one non-inductive devices, the coils *a* and *c* being the inductive parts of the circuit. The resistance, reactance and impedance of each is inscribed on the diagram; the non-inductive device, *b*, has no reactance, of course, so that its impedance is equal to its resistance. The arithmetical sum of the three impedances is obviously 10.619; the correct sum, or total impedance of the group is

$$Z = \sqrt{(R_a + R_b + R_c)^2 + (X_a + X_c)^2},$$

The sum of the resistances is 6.555, the square of which is 42.97; the sum of the reactances is 6.167, the square of which is 38.03; the sum of these squares is 81, and the square root of 81 is 9. The total impedance, therefore, is 9 ohms.

When inductive apparatus is connected in parallel, which is the most frequent method in practice, the joint impedance of any given group of devices is ascertained by a similar method to that just described; but instead of considering individual resistances and reactances, the opposite properties of *conductance* and *susceptance* are considered. In direct-current work, it may be remembered, conductance is the reciprocal of resistance; in alternating-current work, the actual conductance of an inductive circuit is not taken, but a value which might be termed the effective conductance is substituted. The effective conductance is that value which is obtained by dividing the current by the e.m.f. and multiplying the result by the cosine of the "angle of lag." The quotient obtained by the division of the amperes by the applied volts is termed "admittance" of the circuit or device. The relation between admittance, effective conductance and susceptance is precisely the same as that between impedance, resistance and reactance, explained in the last Lesson. Fig. 2 is the triangle showing these relations; the symbols for the three properties are given on the diagram. The formula for admittance is therefore the same as that for impedance, if conductance be substituted for resistance and susceptance for reactance; thus:

$$Y = \sqrt{G^2 + K^2}.$$

Fig. 3 represents five pieces of apparatus connected in four parallel circuits; the individual resistances and reactances are inscribed on the diagram as before. Since the current, e.m.f. and angle of lag are not given, the individual conductances (effective) and susceptances must be derived some other way. The effective conductance of an inductive device is given by the formula

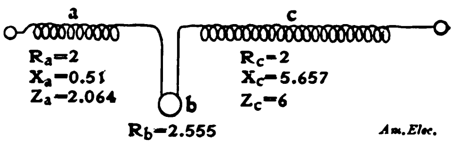

FIG. 1.

$$G = \frac{R}{R^2 + X^2},$$

and its susceptance by the formula

$$K = \frac{X}{R^2 + X^2}.$$

The coil *a* has a resistance of 100 ohms and a reactance of 40 ohms; its effective conductance, therefore, is

$$\frac{100}{10000 + 1600} = .00862,$$

and its susceptance is

$$\frac{40}{10000 + 1600} = .003448.$$

The total resistance of the lamp *b* and coil *c* is 240 ohms, and the total reactance is 60 ohms, *b* having no reactance. The effective conductance of the two, therefore, is

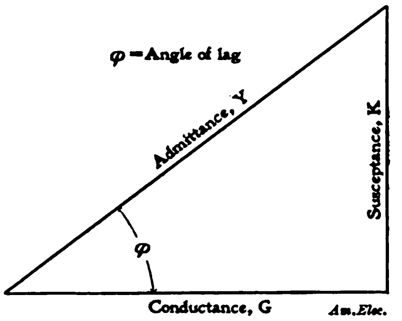

FIG. 2.

$$\frac{240}{57600 + 3600} = .003922,$$

while the susceptance is

$$\frac{60}{57600 + 3600} = .0009804.$$

Since the lamp *d* is non-inductive, its effective conductance is equal to its actual conductance, *i. e.*, the reciprocal of its resistance. The susceptance and effective conductance of *e* are determined in exactly the same way as those of *a*, of course.

The sum of all the conductances is .025234 and the sum of the susceptances is .0095566;

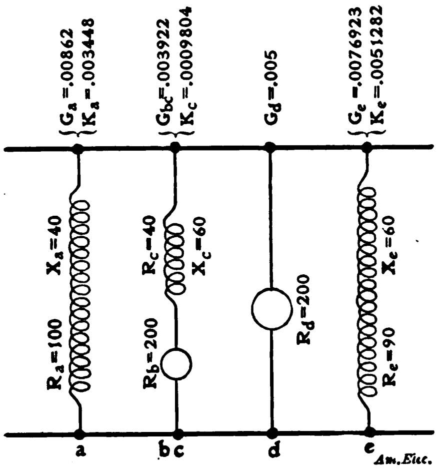

FIG. 3.

according to the admittance formula the total admittance, therefore, is .02698, and as impedance is the reciprocal of admittance, the joint impedance of the group is 37 ohms.

The following list of the relations between e.m.f., current, resistance, reactance, impedance, effective conductance, susceptance, admittance and functions of the angle of lag will be found useful::

$$Z = E \div I = \sqrt{R^2 + X^2} = R \div \cos \phi$$

$$X = \sqrt{Z^2 - R^2} = \sqrt{\left(\frac{E}{I}\right)^2 - R^2} = Z \sin \phi = R \tan \phi$$

$$Y = I \div E = \sqrt{G^2 + K^2} = G \div \cos \phi$$

$$K = \sqrt{Y^2 - G^2} = \sqrt{\left(\frac{I}{E}\right)^2 - G^2} = Y \sin \phi = G \tan \phi = \frac{X}{R^2 + X^2}$$

$$G = \sqrt{Y^2 - K^2} = \sqrt{\left(\frac{I}{E}\right)^2 - K^2} = Y \cos \phi = Z \cos \phi = \frac{R}{R^2 + X^2}$$

$$\begin{aligned} \cos \phi &= R \div Z \\ &= I R \div E \\ &= G \div Y \\ \sin \phi &= X \div Z \\ &= K \div Y \\ &= I X \div E \\ \tan \phi &= X \div R \\ &= K \div G \end{aligned}$$

In direct-current circuits, the power delivered to any circuit is the product of the applied or impressed e.m.f. and the current that flows; thus,

$$P = E I,$$

P being the power in watts. This is true also in an alternating-current circuit when there is no inductance nor condensance* present. This condition, however, is seldom realized in alternating-current work. In most cases the current is out of phase with the impressed e.m.f., and then the power in the circuit is equal to

$$P = E I \cos \phi.$$

ϕ being the angle between the two lines representing the e.m.f. and current relations, as before. Since this formula differs from the direct-current formula only in the addition of the expression "*cos* ϕ" and as multiplying the apparent power, $E \times I$, by it gives the true power, it is commonly referred to as the "power factor" of the circuit; sometimes it is represented by the symbol *p*, but most writers use the expression "*cos* ϕ."

The relation between the e.m.f. and current "phases" may be more clearly grasped, perhaps, by drawing sine curves representing any convenient values of e.m.f. and current out of phase to any extent less than one-quarter of a cycle and plotting the vectors corresponding to these curves. Thus, assume an e.m.f. of some conventional value and draw a half sine wave of such height that the distance from the base line to the crest of the wave will be 1.4 times the length of a straight line representing, to a convenient scale, the effective e.m.f. assumed. Then draw another half wave bearing the same relation to a current value either slightly greater or slightly less numerically than the chosen e.m.f. value, and displaced from the e.m.f. wave horizontally. Now draw a vertical line from the base line up to the crest of the e.m.f wave, as shown in Fig. 4; this will represent the maximum e.m.f. to the scale originally selected in plotting the curve. Duplicate this line on another part of the paper, as shown by Fig. 5; set the points of a pair of pencil dividers on the base line and the crest of the current curve in Fig. 4, and with them draw the arc shown in Fig. 6 from the vertical e.m.f. line to the base line. Then locate on this arc a point that is the same height distance above the base line as the intersetion *x* in Fig. 4; this may be readily done by drawing a line parallel with the base line at the same height as the intersection *x*, and cutting across the arc with it, as shown at *y*, *z*, Fig. 7. From the intersection *x* draw a line to the bottom of the vertical e.m.f. line, as shown in this last sketch; this will represent the magnitude and phase of the current as compared with those of the e.m.f. represented by the vertical line. Obliterating the construction lines leaves the diagram as in Fig. 8; the angle ϕ between the e.m.f. and current lines is the angle of lag, and the cosine of this angle will be the power factor of a circuit in which the maximum e.m.f. and current values are those assumed and in which the current lags behind the e.m.f. to the extent represented by the curves of Fig. 4. It should always be borne in mind by the student, however, that both the e.m.f. and the current have no actual direction in space; it is customary to refer to the angle of lag as though it were an actual angle between two forces which have actual and different directions, but this is merely a mathematical fiction employed for convenience in making calculations.

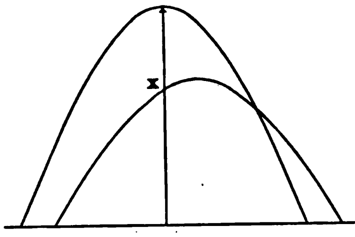

FIG. 4.

FIG. 5.

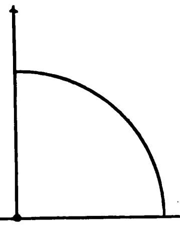

FIG. 6.

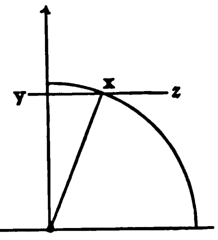

FIG. 7.

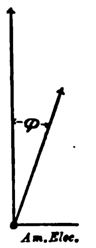

FIG. 8.

The sine of the angle of lag is termed the "inductance factor," for the reason that if it be multiplied by the impressed e.m.f. the result will be the inductive e.m.f., or e.m.f. due to the self-induction of the circuit. It (the inductance factor) is commonly represented by the letter *q*. Thus

$$E q = E_x,$$

E_x representing the inductive, or reactive, e.m.f., as explained in the last Lesson. Since E_x is also equal to the product of current and reactance $I X$, when X represents the reactance of the whole circuit, $E q = I X$.

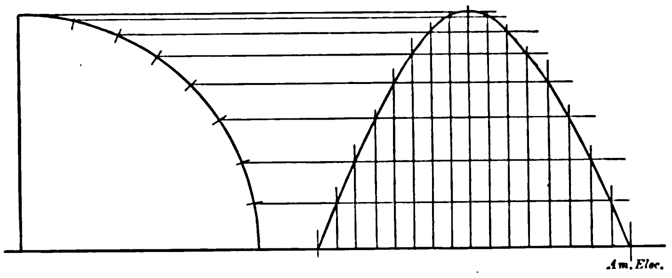

FIG. 9.—CONSTRUCTION OF A SINE CURVE.

A sine curve is constructed as follows: Draw a base line, and from it carry a perpendicular line up to the height corresponding to the maximum value (1.4 times the effective value) of the e.m.f. or current to be represented. From the top of the vertical line, draw a circular arc down to the base line; divide this arc into eight equal spaces by little cross lines and draw horizontal lines from the intersections of these cross lines and the arc, parallel with the base line. Then draw 15 equidistant vertical lines from the base line across the horizontal lines just completed; the doubly consecutive intersections of the horizontal and vertical lines will be points on a half sine wave. See Fig. 9.

---

*This term will be explained in a future Lesson.

Letters on Practical Subjects

Mr. Ellison's Problem in Broken Wires.

To the Editor, American Electrician:

The accompanying diagram (Fig. 1.) is submitted as a solution of Mr. Ellison's broken wire problem which appeared in the January number. The method of locating the break is the ordinary application of the Wheatstone bridge, making one of the line wires from the home station to the break the unknown resistance and assuming the resistance of the ground at the far end to be negligible. On this basis the resistance of the line wire will be

$$R = \frac{A\ B}{C};$$

and knowing the resistance per mile or per thousand feet of the wire, the distance is of course readily ascertainable.

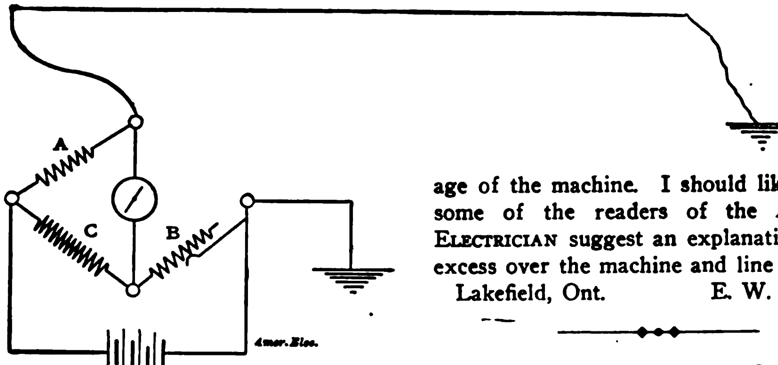

FIG. 1.—PROBLEM IN BROKEN WIRES.

John J. Marshall.

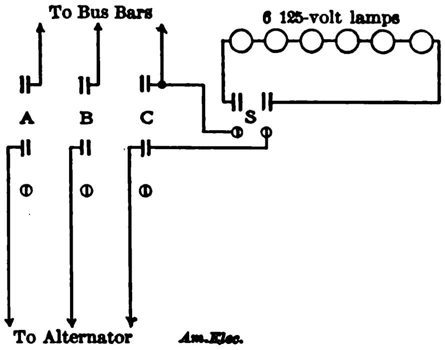
Voltage on Synchronizing Lamps.

To the Editor, American Electrician:—

In synchronizing a 550-volt alternator with the bus-bar e.m.f., we have found trouble due to excessive voltage across the synchronizing lamps. The voltmeter shows 540 to 550 volts at the bus-bars and the same between each pair of leads from the terminals of the generator being synchronized, but the voltage across the lamps is over 700 volts. The accompanying diagram shows what the essential connections are between the bus-bars, the synchronizing lamps and the machine being thrown in. The machine is three-phase and the frequency is 60 cycles. The switch *A* and the synchronizing switch *S* are closed for synchronizing, so that when the machine is in step with the line the lamps are dark. Before it gets into synchronism, however, the voltage across the lamps runs up as high as 720 volts, so that we have to use six 125-volt lamps in series instead of five 110-volt lamps corresponding to the voltage of the machine. I should like to have some of the readers of the American Electrician suggest an explanation of this excess over the machine and line voltage.



CONNECTIONS FOR SYNCHRONIZING.

Lakefield, Ont. E. W. Bailey.

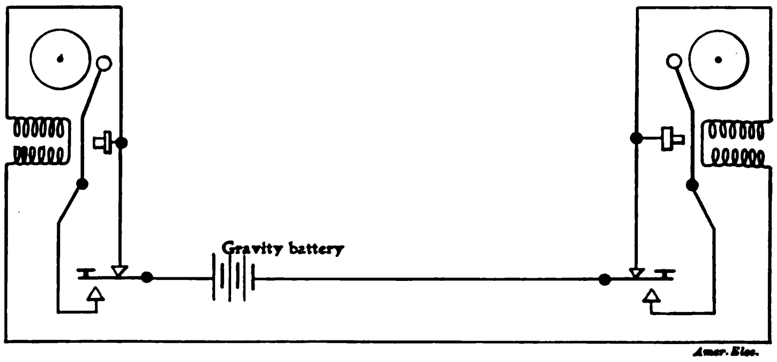
Mr. Smith's Problem in Bell Connections.

To the Editor, American Electrician:

The accompanying diagram is submitted as a solution to Mr. Martin Smith's problem published in the December number of the American Electrician, the requirements of which were that two ordinary vibrating bells should be operated from a two-wire circuit with one battery and two push-buttons. Referring to the diagram, it will be evident that two-way push-buttons are used and that so long as they are not depressed the circuit is closed through the battery and the magnets of both bells, so that the bell clappers are normally held up against the bells. This makes the system a closed-circuit one, so that a gravity battery is required. If one of the push-buttons be depressed, the circuit will be opened and both of the armatures will fall against their backstops. This action by the bell armature at the distant station does not affect the circuits in any way, but when the armature of the home bell falls back against its stop, it recloses the circuit which has been opened by the depression of the push-button and the two magnets are again energized and therefore pull the hammers against the bells again. These actions, of course, continue as long as the push-button is depressed, the vibrator of the home bell causing both of the bells to ring, while the vibrator of the distant bell has no effect because the armature of that bell is not connected to the circuit in any way.



SOLUTION OF MR. SMITH'S PROBLEM IN BELL CONNECTIONS.

John E. McKivitt,
Frank Carswell.

[Note.—The foregoing solution is the only one thus far received which is at all practical, and the ingenuity involved is highly commendable. We have received a great many proposed solutions, but most of these were substantially identical with the undesirable arrangement described in the editorial note appended to Mr. Smith's letter in the December number; the remainder were either too complex or inoperative.—Editor.]

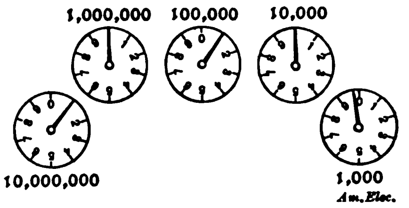
A Tricky Meter Reading.

To the Editor, American Electrician:—

I enclose herewith a copy of a meter reading as it appeared on a customer's meter. I did not think it particularly difficult until several experienced meter readers made mistakes in determining the reading; but in view of that fact it may be of interest to your readers.



A TRICKY METER READING.

New York. Ralph Ryder.

[We shall be glad to have interested readers submit readings of these meter dials, for publication or not, as they prefer. The correct reading is on file in this office. —Editor.]

Queries and Answers

IMPORTANT.—No attention will be given to any inquiry which does not give the full name and address of the inquirer.

Can the two-cycle gasoline motor described in the February number be used in a launch, and if so, what size should the hull be? J. D.

Yes, the motor will drive a 20-foot open launch at a fair speed.

What effect do small particles of copper in the bluestone of a gravity battery have upon its efficiency? R. L. L.

Practically none; pieces of copper of appreciable size, however, mixed with the bluestone crystals will impair the action of the battery somewhat.

What is a split-pole generator? (2) Does it deliver direct or alternating current? L. S.

It is one form of Lundell direct-current dynamo built by the Sprague Electric Company. The magnet poles have a slot from a point very near the pole face to a point very near the yoke-ring; hence the name "spilt-pole."

How can an apparatus requiring 6 amperes and 110 volts, direct current, be operated from a 500-volt direct-current circuit, using lamps to take up the difference in voltage? T. P. H.

A rather elaborate bank of lamps will be required; you will have to connect four groups of 100-volt 16-c.p. lamps in series, each of the four groups containing 12 or 13 lamps in parallel.

Can ordinary dry batteries be used to run a small motor instead of storage batteries? V. V. W.

Yes, if you refer to the very small motors wound for battery current, such as the Knapp and the smaller of the two Edison machines described in the fan motor article, this issue. Batteries of the Edison-Lalande or Gordon types are preferable, however.

Is it practicable to use acetylene gas in the ordinary gas burners or gas stoves? If not, why? E. K.

No, for the reasons that the gas clogs up the burners and the delivery opening of the ordinary gas burner is too large. The clogging is due to the excessive proportion of carbon contained in the acetylene gas, which requires a special burner to produce proper combustion.

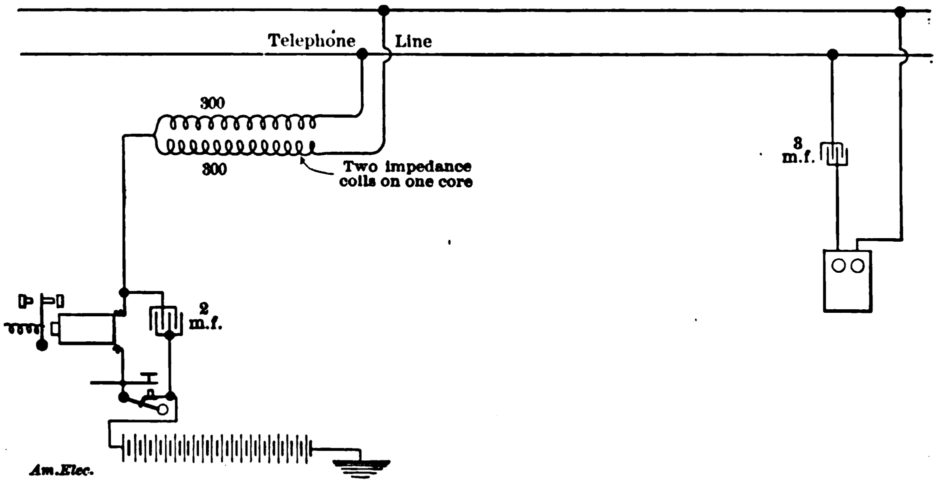
If the external resistance of a circuit supplied by 130 cells of Daniel battery should be increased from 120 ohms to 140 ohms, how many cells of battery must be added to the original 130 in order to prevent the increase in external resistance from reducing the current in the circuit? T. F. H.

The external resistance has been increased 20 ohms, and $\frac{20}{120} \times 130 = 21.66.$

As you cannot add a fraction of a cell, 22 is the proper number to add.

We have a metallic-circuit telephone line and desire to connect a set of telegraph instruments at one end and at a point about one-third the length of the line distant from the far end. Please give a diagram showing the proper connections and specify whatever special instruments will be necessary. A. E. C.

The telegraph instruments may be connected as shown by the accompanying diagram, using ordinary 150-ohm Western Union relays. Each pair of impedance coils must be wound differently. The diagram shows only one set of instruments; both sets are connected to the line in exactly the same manner except that the positive terminal of the other battery must be grounded so that the two batteries will agree. Each set of telephone instruments should be put in series with a condenser, as indicated.



If one boiler is disconnected from a battery, will the boiler foam or will the entire battery foam? (2) How can the requisite throw of an eccentric be ascertained for a Corliss engine with the usual releasing gear? O. F. S.

If the boiler which is disconnected ceases to do work when it is disconnected, the mere act of disconnecting it will not cause it to foam. If, however, it remains connected to a pipe supplying a working engine and the amount of steam required by the engine exceeds the working capacity of the boiler it will probably foam when disconnected from the battery. Similarly, if the entire battery of boilers is being worked to the limit, disconnecting one of them will increase the load on the others and tend to produce foaming in them. (2) This depends upon the type of gear employed. The best plan is to ask the manufacturer of the engine.

Can the complete field ring and magnet poles of the 2-kw. double-current machine described in "Electrical Designs" be built up of laminations instead of using laminated poles cast into a solid iron ring? I have a lot of 9-inch armature discs available for the purpose; what difference would the extra ¼ inch in the outer diameter make? (2) Where can I obtain castings for the two-cycle gas engine described in the February number? C. F. S.

Yes; while laminating the yoke-ring is not necessary, the machine will give better results that way than if a solid yoke-ring were used. The excess of ¼ inch in diameter will merely make the machine a trifle heavier than it needs to be. The laminations should be clamped between two heavy iron rings conforming to the inner and outer circles of the yoke-ring and the magnet structure should preferably be mounted in a light cast-iron housing. (2) Probably from Parsell & Weed, 129 West 31st Street, New York City.

The ordinary mufflers that are used with gas or gasoline engines to deaden the noise of the exhaust impose back pressure on the engine and thereby reduce its power. Would it not be practicable to lead the exhaust from a gasoline engine into a well in the ground, having 70 times the cubical capacity of the engine cylinder, and to lead the exhaust gases out of the well through a three-inch pipe? The exhaust pipe of the engine is 2½ inches in diameter. (2) Would there be any danger of explosion in the well? H. P. W.

Such an arrangement would probably be effective enough, but it would seem to be unnecessary in view of the fact that mufflers can be obtained which do not reduce the power of the engine to an objectionable extent. (2) This would depend upon the performance of the engine. If the combustion was incomplete in the engine or any charges went through unignited there would be liability to explosions in the well.

Please describe two different methods of adjusting the compounding of a direct-current dynamo. (2) How are storage batteries put in and out of commission? D. P. R.

There is only one practical way of adjusting the compounding of the ordinary dynamo, and that is by varying the resistance of a shunt conductor connected to the terminals of the series winding. If the series winding were divided into sections with taps led out from the junctions of the sections, the compounding could be adjusted by cutting in or out one or more of the sections, but this would be an extremely clumsy method. (2) When a storage battery is put in commission the plates should be assembled in the jars, the electrolyte poured in and the battery immediately connected to the charging circuit. The first charge should be at its full rated capacity and after it is fully charged, that is to say, when the electrolyte begins to bubble, the charging current should be reduced to as low a point as possible without causing the bubbling to cease, and the battery should then be overcharged somewhat. The proper amount of overcharging varies with different types of battery. In order to put a battery out of commission it should be fully charged, then the electrolyte drawn off and the cells filled with pure water. The battery should then be allowed to discharge as far as it will, then the plates should be taken out of the water, thoroughly dried immediately, and put where the air does not have free access to them.

LARGE PIPE ORGAN FOR ST. LOUIS EXPOSITION.

One of the most interesting musical and semi-electrical features of the St. Louis Exposition will be the immense pipe organ built by the Los Angeles Art Organ Company, of Los Angeles, Cal., for the Kansas City Convention Hall Company, and which will be the official concert organ at the Festival Musical Hall. It is, we understand, the largest pipe organ in the world. It has 130 miles of electric wire, 140 speaking stops, 1300 magnets, 99 mechanical movements and weighs 250,000 pounds.

Fig. 1 herewith shows the organ set up in the factory, without the display pipes; and its relative size can be inferred from the surrounding objects. The instrument will be played from two independent consoles. The most important console is movable (Fig. 2) and is connected to the organ by an electric cable 150 ft. long. This console contains the radiating and concave pedal clavier, the five manual claviers, the 140 draw stop knobs, the five tremulant draws and the 36 coupler draws, the 46 push buttons belonging to the adjustable combination system, and all the foot pedals controlling the expressive powers of the whole organ, etc., etc. This console is for the virtuoso who performs in the usual manner with hands and feet.

The second console is stationary, and is entirely devoted to the builders' double-roll automatic self-playing attachment. Through the agency of the double or twin rolls, the most complicated orchestral scores can be rendered with absolute accuracy, and compositions can be performed which are far beyond the powers of the most accomplished organist. This console resembles that first described, except that it does not possess the manual and pedal claviers, which are not necessary where the double-roll, self-playing attachment appears. Within its arms, so to speak, sits the musician, with the calls of six claviers upon his hands and feet, having at his immediate command the vast tonal forces (represented by 10,000 pipes) of this gigantic organ; his hands simply engaged in manipulating the draw-stop knobs and combination buttons, and his feet controlling the flexible and expressive powers of the instrument. The double rolls do all the rest.

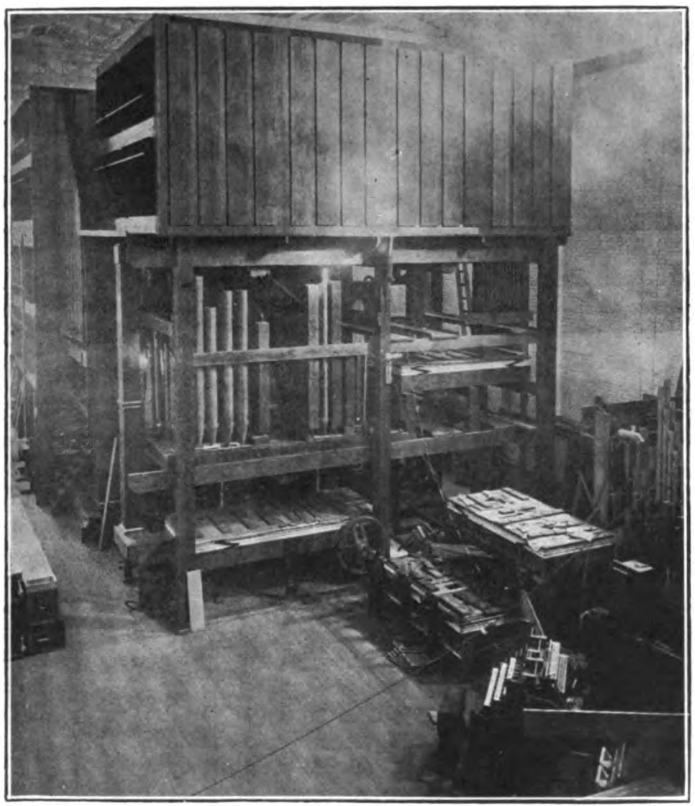


FIG. 1.—FLEMING ELECTROPNEUMATIC PIPE ORGAN.

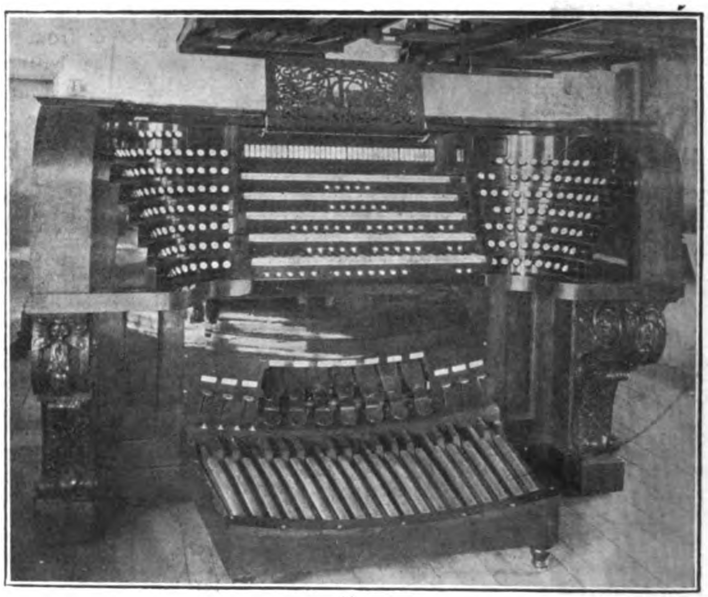

FIG. 2.—MOVABLE CONSOLE OF ORGAN.

The bellows of the main portion of the organ will be operated by two 10-h.p. motors, at 220 volts, direct current. The echo organ bellows will be operated by a 1½-h.p. motor of 220 volts, direct current. The wind-chests, through which the wind from the regulators is distributed to the 140 speaking stops, and the 10,059 pipes, are 12 ft. long and of widths sufficient to give every rank of pipes planted thereon ample speaking room.

The organ is constructed under the Fleming electropneumatic system, which gives the most satisfactory results. The organ contains 1300 magnets, as noted above, for both key and draw-stop actions. There are 130 miles of wire in magnets and cables, from No. 20 up to No. 34 B. & S. gauge. There are also 1616 automatic combination knobs for setting combinations electrically throughout the organ. There are five automatic electric swell engines for the actuation of the swell shutters. There are above 7000 open circuits in the organ. The company's special contact wire is used in the key and coupler actions. The single-contact system is used, so arranged as to be durable and always reliable. The coupler action contacts clean themselves automatically, and all trouble is thereby prevented. The storage batteries used will have four cells of two volts each, with normal discharge of 50 amperes for eight hours. There will be a motor-generator of 220 volts, direct current, with a capacity of 10 volts and 40 amperes, to charge the batteries.

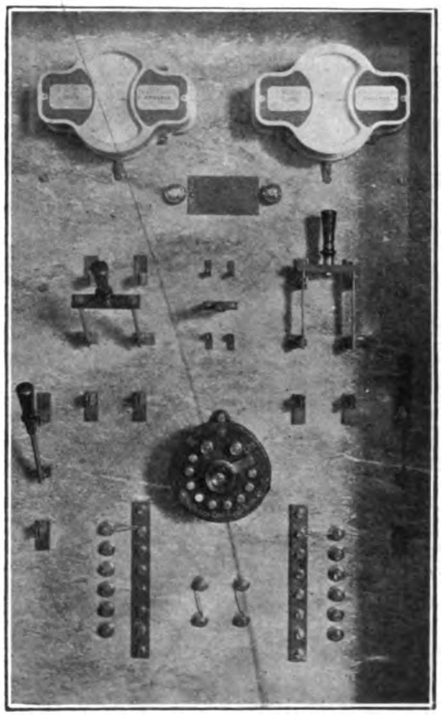

FIG 3.—ORGAN SWITCHBOARD.

The switchboard (Fig. 3) has a voltmeter and ammeter to show the discharge voltage and strength of the batteries at all times. There will also be a polarity indicator, also a pilot lamp, which will indicate, to a certain extent, the strength of the batteries. There are also a voltmeter and an ammeter on the switchboard, one showing the voltage charging the batteries and the other showing the amount of the current going into the batteries. Switches are provided for throwing the generator on and off, and for throwing the current off the organ when not in use. The switchboard consists of a marble slab mounted in a handsome oak case with glass door for display purposes.

New Apparatus and Appliances

CRANE MOTOR CONTROLLERS.

Controllers for crane motors and other service where frequent starts and reversals are involved must, of course, be unusually substantial in order to withstand the wear and tear of constant usage. They must also be simple and positive in action and afford the desired degree of control with the fewest manual movements. In order to meet these requirements, the Westinghouse Electric and Manufacturing Company has brought out the types of controller illustrated by Figs. 1 and 2 herewith. Practically the only difference between the two forms is in the manner of mounting the resistance coils and the rheostat mechanism. The type shown in Fig. 1 is for moderate outputs and that shown in Fig. 2 is for heavy service. The rheostat is of the commutator type, the contact plates being mounted horizontally on the periphery of a slate slab instead of radially as in the ordinary rheostat. The contact brushes or fingers are mounted on the outer ends of the four spider arms shown in the illustration, and these also carry blow-out magnets to reduce the sparking when the circuit is opened. The controllers are of the reversing type, so that only one handle has to be manipulated. Moving the handle to the left from the "off" position operates the motor in one direction, and moving it to the right operates it in the reverse direction. The distance through which the handle is moved determines the speed of the motor, of course, by cutting out more or less of the resistance coils. When the controller is located in the rear of a crane cage the brush spider is controlled by means of a bell-crank and link-rod, as shown in Fig. 1. The resistance conductor in the controllers for motors of small capacity is of the coil type, with ventilating spaces between the coils, which are separated by non-combustible insulating blocks, as shown in Fig. 1. The conductor in the controllers for large motors is of the grid type, as Fig. 2 indicates upon close inspection. These controllers are built for motors ranging from 10 to 75 horse power. For motors of less than 10 horse power, the company builds the ordinary face-plate or dial type of rheostat front; the brushes are mounted on a four-arm spider, as in the apparatus just described, but blow-out magnets are not required.

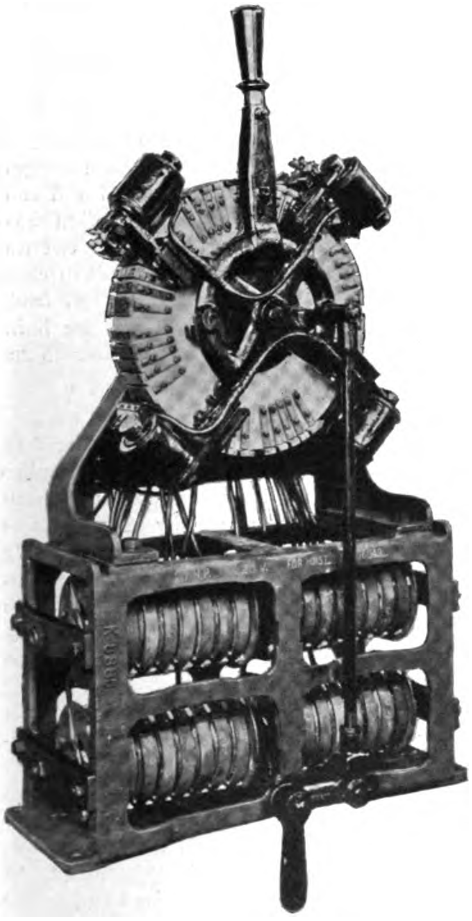

FIG. 1.—CRANE MOTOR CONTROLLER FOR MODERATE OUTPUT.

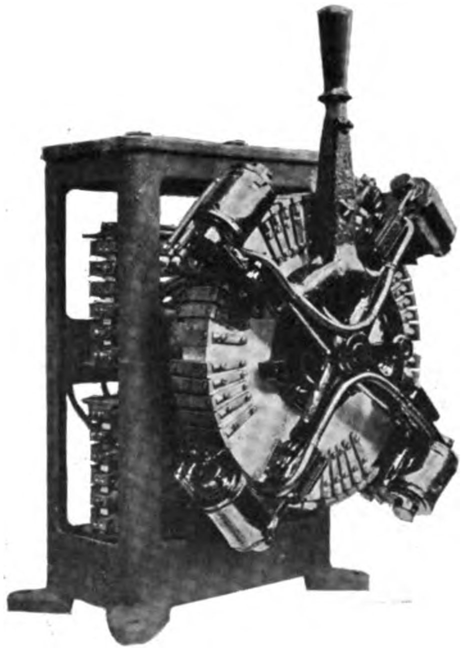

FIG. 2.—CRANE MOTOR CONTROLLER FOR HEAVY OUTPUT.

"IDEAL" GENERATORS.

Fig. 3 herewith illustrates a new line of direct-current generators now being built by the Ideal Electric & Manufacturing Company, Mansfield, Ohio. These machines are built with four poles up to the 40-kw. size and six poles in sizes larger than 40 kilowatts. The magnet frame is of cast-iron, with the field magnet cores cast-welded into it; the frame is divided horizontally, as shown in the engraving. The magnet cores are of cast-steel, of circular cross-section, and equipped with cast-iron pole-pieces or shoes, shaped so as to obtain the requisite gradation of the commutating magnetic fringe. The armature is of the slotted-drum type, and the coils are machine-wound, hand-insulated, varnished and baked before going in the slots; the winding is of the straight-out or "barrel" type, as indicated by Fig. 4. The core is ventilated by transverse ducts at short intervals. The armature discs of the larger machine are mounted on a spider keyed to the shaft; in small machines, the discs are threaded directly on the shaft and keyed thereto. The end-plates which compress the armature discs together are provided with ribbed flanges which ventilate the projecting portions of the winding at each end of the armature. The winding is held in the slots by binding wires.

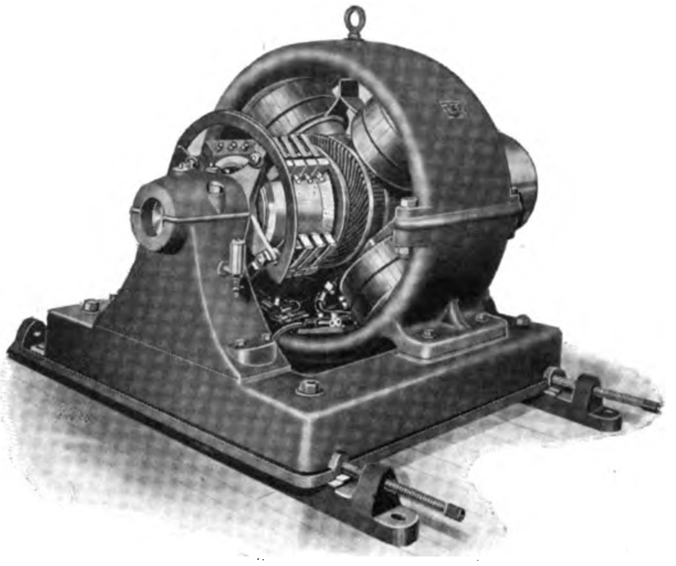

FIG. 3.—"IDEAL" DIRECT-CURRENT GENERATOR.

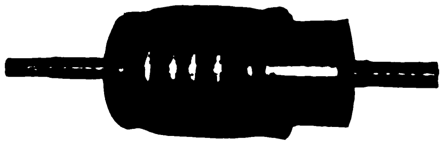

FIG. 4.—"IDEAL" ARMATURE

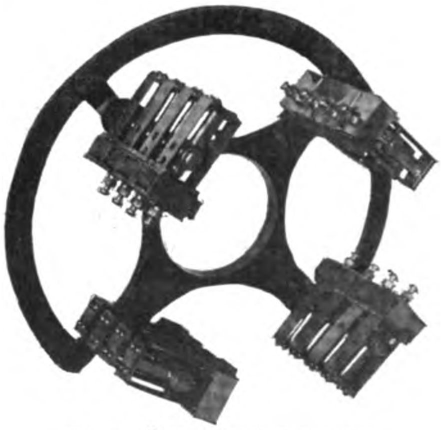

FIG. 5.—"IDEAL" BRUSH RIGGING.

The brush-holders are of the so-called parallel-motion type, with the brushes bolted to plates which are secured to the extremities of two flat springs, the other extremities of which are bolted to the stationary part of the rigging. Fig. 5 shows the complete brush rigging of a four-pole machine, from which engraving the construction will be evident. Copper-coated composition brushes of carbon and graphite are used, and the cross-section is such, it is stated, that the current density at the brush faces does not exceed 30 amperes per square inch. These machines are said to show full load temperature rises of not over 63° Fahrenheit at the commutator and 54° elsewhere.

TELEPHONE CARD DIRECTORY.

The accompanying illustration shows a new form of telephone directory invented by M. Holtz, of New York City. This directory is in the form of a nickeled bracket which may be clamped to the post of a portable telephone apparatus, and contains cards arranged as in a card index, permitting any classification—by business, alphabetically or in any other way to suit the convenience of the user. A card may be withdrawn and any number of names of the same general classification, up to the capacity of the card, may be seen at a glance, the card dropping back to its place by its own weight. The projecting tabs on the cards give a quick guide to the contents, and permit the ready withdrawal of any card.

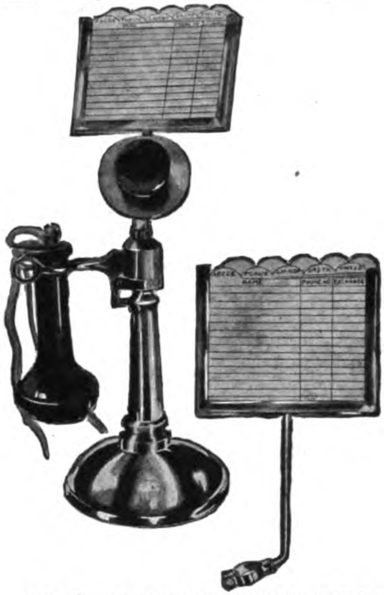

FIG. 6.—TELEPHONE CARD DIRECTORY.

IMPROVEMENTS IN ELECTRIC SIGN FLASHERS.

Some improvements have recently been made in the electric sign flashers made by the Reynolds Electric Flasher Manufacturing Company, of Chicago, which, although they might seem trivial to the layman who is not well acquainted with sign flasher work, are nevertheless important as regards the results attained. In flashers as usually constructed, the various individual switches were operated by removable cams or segments which could be adjusted to any position on the periphery of a wheel. There is one such wheel to each switch and each wheel has its cam clamped in proper position. Where several circuits of a sign were to be flashed at once, it was found difficult to adjust these cams so that they would open and close the circuit simultaneously. The new construction, which is much simpler and more substantial, consists in using a sheet steel shell instead of the cams or segments. The accompanying illustration shows a flasher built to flash two sides of a sign alternately. The eight contacts at the right-hand end flash one side of the sign and the eight contacts at the left the other side. The straight edge of the sheet steel shell insures simultaneous action of the various switches and does away with the so-called "ragged effect" on the sign. The shell being screwed directly to the flasher wheels, it cannot get loose or out of adjustment as easily as individual segments, and, furthermore, the segments require a wheels for each switch. With the shell only a few wheels are required; enough to give it stiff support. There are some combinations where it may still be necessary to use the removable segments, but by notching the steel sheet, it can be made adaptable to a large number of combinations.

FIG. 7.—REYNOLD'S SIGN FLASHER.

NEW VARIABLE SPEED MOTOR.

The Commercial Electric Company, Indianapolis, Ind., has brought out a new line of variable-speed motors for operation on a simple two-wire direct-current circuit. The general appearance of the new machine is shown by Fig. 8 herewith and Fig. 9 is a view of the "Universal" type of interlocking controller and stand built for use in conjunction with the new line of machines. The motors are of the double-commutator type, having two armature windings exactly alike connected to commutators at both ends of the armature. The controller connects the two armature windings in series or parallel, according to the speed requirements, and also modifies the field-magnet excitation of the machine in order to give intermediate speeds between zero and maximum with the armature windings in series, and between the maxima with the windings in series and in parallel. The controller is equipped with two handles; the small handle at the right is used only for starting and stopping the machine, and the handle shown on top of the stand actuates a cross-bar carrying contact brushes at its ends which travel over radial contact segments inside the case. This latter switch controls the connections of the two armature windings and also varies the field-magnet strength. The panel mounted in the frame of the controller carries a double-pole circuit-breaker and two enclosed fuses. The range of speed control is four to one, divided into twelve uniformly-graduated steps which do not overlap. As no external resistance is used in the armature circuit, the machine runs at a practically constant speed at each speed point of the controller regardless of changes in load, and is capable of exerting its maximum horse-power at each speed. The efficiency is said to be practically constant at all speeds and high at all loads. The 5-h.p. machine, for example, has an efficiency of 80 per cent. under full load at 400 r.p.m., 76 per cent. under full load at 1,000 r.p.m., 75 per cent. at 1,500 r.p.m. and 79 per cent. at 1,600 r.p.m. The efficiency under variable load at 400 r.p.m. ranges from 70 per cent. at 2 horse-power up to 80 per cent. at 6 horse-power. The results of tests for speed uniformity are also interesting. With the controller on the first step, the speed ranges from 400 r.p.m. to 360 r.p.m.; on the fifth step, the speed ranges from 840 to 800, between no load and full load; on the ninth step, the variation was from 1,260 down to 1,200, and on the twelfth step, from 1,650 to 1,610, the figures in each case being those at no load and full load, respectively. The new machines are built in sizes ranging from 2 horse-power to 20.

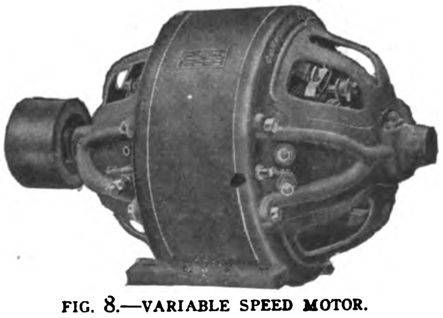

FIG. 8.—VARIABLE SPEED MOTOR.

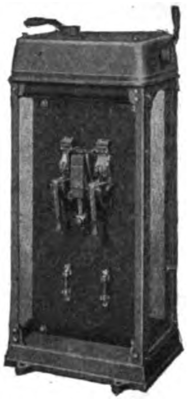

FIG. 9.—"UNIVERSAL" CONTROLLER.

THE HEANY ARC LAMP.

Since the Heany arc lamp was described in this department (July, 1902), a number of changes and improvements have been made in it which are worthy of note. The supporting stays are made of ⅜-inch tubing instead of 5-32-inch rods. The lamp has been provided with a top casting, on which is mounted a substantial switch and binding posts. The binding posts are mounted on porcelain, and have — and + signs plainly visible. They have also large binding screws and wire holes large enough to accommodate No. 6 wire. The resistance wire is wound on a porcelain ring which surrounds the supporting tubes; the porcelain ring is cut with a thread of 10 pitch, and the wire is wound in this thread. A novel vice-like clamp slides in a slot in the porcelain ring to cut in or out the resistance wire for various line voltages. The solenoid spool is held on the supporting tubes by six strap clamps, instead of screws as in the old lamp. The dash-pot in the earlier lamp was made of drawn tubing; it is now cast and reamed, increased from ½-inch to ⅝-inch, and is fastened to one of the supporting tubes with a clamp, the supporting tube being provided with a locating pin, which brings the dash-pot to the proper place. In the old lamp no provision was made for locating the dash-pot. The clutch is made entirely of stampings, instead of castings. The carbon receiving tube has been increased in diameter from ⅝-inch to ¾-inch, permitting the use of ½-inch carbon if desired, so as to interchange with the other type of Heany lamps. In fact, in improving the lamp this point has been carefully considered, and the casing, carbon receiving tube, supporting tubes, globes and all principal parts will interchange on all the types. The casings are made of copper, and are well ventilated, as well as weather-proof. The lower carbon holder has been provided with a cam to lock the carbon, instead of a screw, and has a projection which limits the weight of carbon and is of importance in trimming. The spider on the base of the lamp has been dispensed with and a projection from the base of the lamp takes its place. In the old lamp the carbon was partially exposed; in the new lamp this space is closed, making a bearing for the carbon, and preventing admission of oxygen to the inner globe, thereby prolonging the life of carbons, and at the same time simplifying the construction. The internal parts are copper and nickel-plated to prevent corrosion and oxidation. Mica and porcelain are used throughout as insulation.

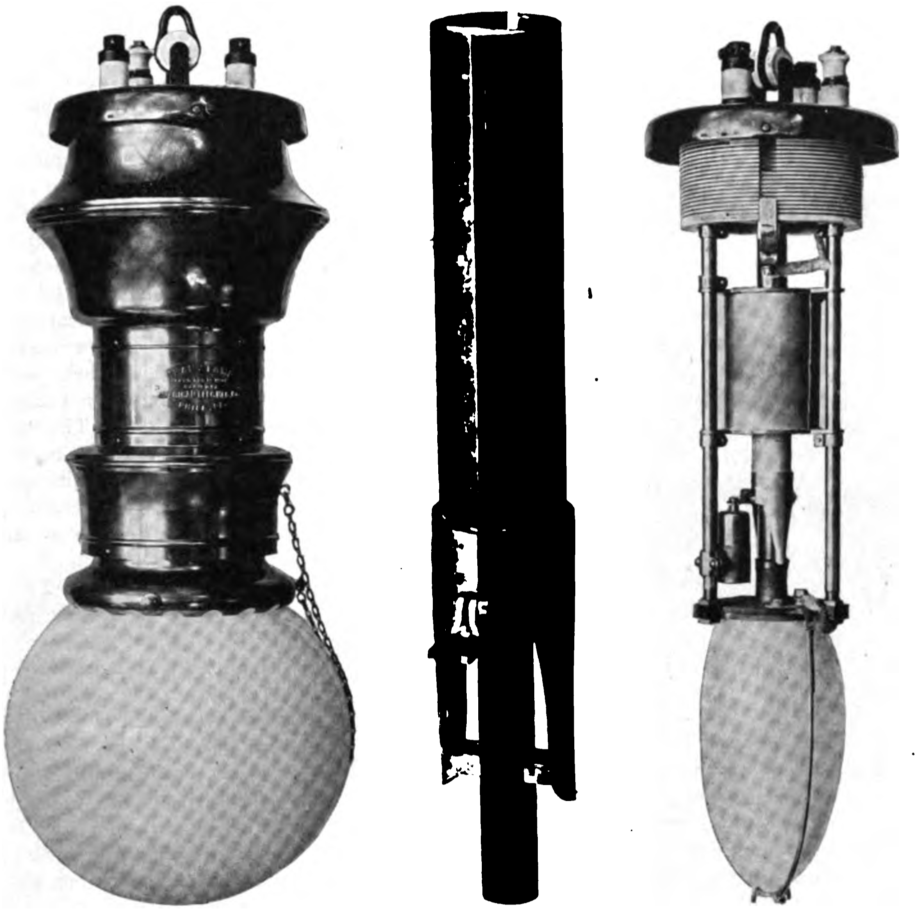

FIG. 10.—HEANY ARC LAMP AND DETAILS.

TYPE W SPRAGUE HOISTS.

Fig. 11 herewith shows one of five Sprague hoists installed in the foundry of the Brown & Sharp Manufacturing Company Providence, R. I., on cranes designed by the company. Fig. 12 shows the hoist and trolley carriage. It will be noticed that the hoist is very compact, the motor and gears being entirely enclosed, the latter running in an oil casing. An F-2 Sprague controller is mounted on the end of the bridge to the right and is operated from the floor by hanging cords. This controller is said to be especially designed for foundry work and to permit of several slow positive hoisting and lowering speeds in addition to full speed. A test made on one of the first hoists installed with the controller on the first contact gave a hoisting and lowering speed of almost 16 inches a minute, both with empty hook and with a three-ton load. 'The full speed of the hoist with five tons was about 8 feet per minute. A limit switch is provided with the hoist to prevent damage caused by jamming the rope sheaves against the gear case. This switch is shown in the engraving attached to the bottom of the gear case. A lower limit can also be furnished to prevent the rope from entirely unwinding from the drum.

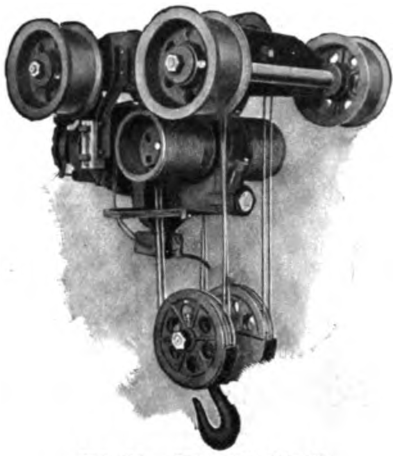

FIG. 11.—SPRAGUE HOIST.

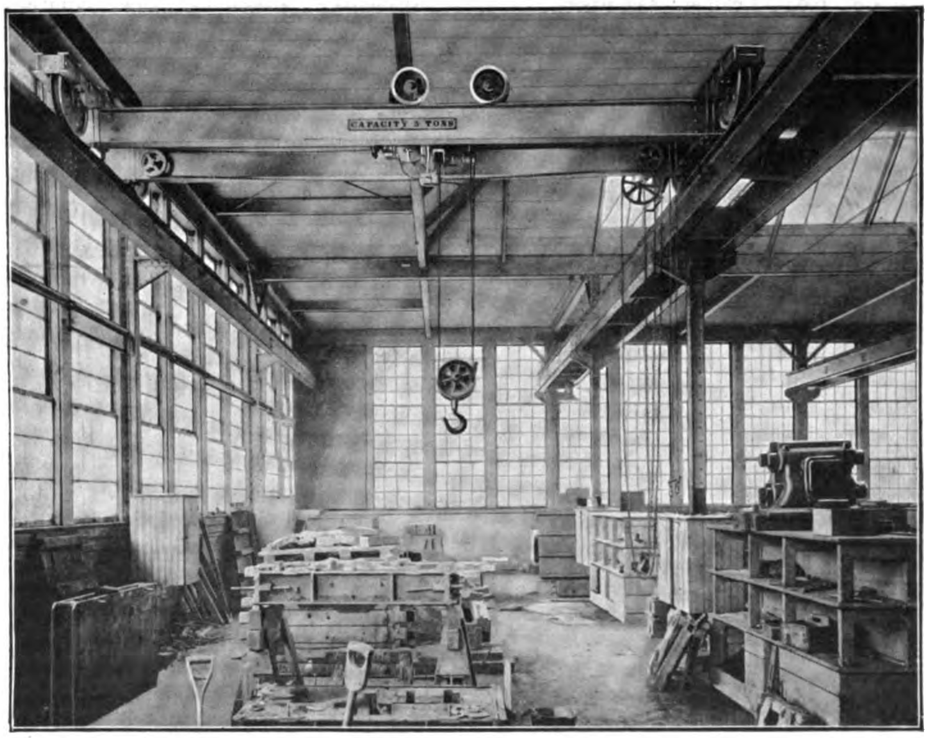

FIG. 12.—BROWN &SHARP FOUNDRY, SHOWING ELECTRIC HOIST.

NEW STAR SPEED LATHES.

The Seneca Falls Manufacturing Company, of Seneca Falls, N. Y., has brought out a new 10-inch and a new 12-inch lathe which embody in their construction several new features of interest to users of this class of machines. The head-stock is of the web pattern. Its spindle is forged from crucible steel and runs in dust-proof and self-oiling bearings of phosphor-bronze.

The cone pulley has four steps and is turned inside as well as outside. The tail-stock is of the curved or cut-out pattern. The tail spindle has a new combination screw and lever motion with a dial, graduated in sixteenths, which is valuable in drilling, counterboring, countersinking, etc., to a desired depth. To change from screw to lever motion it is only necessary to loosen the thumb-screw and the spindle sleeve is released. When not in use the long hand-lever can be lifted off. The tail stock has a long bearing on the ways and is firmly locked to the bed by a convenient lever. The hand-rest is provided with long and short T-rests. The rest-socket and saddle are locked to the bed by a cam locking device and the T-rest is held in the socket by a friction clamp. Both of these devices are operated by levers. The bed is broad and deep and well braced. The front way is flat and the back way is V-shaped. Secured to the back of the bed is a convenient shelf for the reception of tools. The countershaft has self-oiling and self-aligning bearings, a four-step cone and tight and loose pulleys. Friction clutch pulleys are furnished if desired.

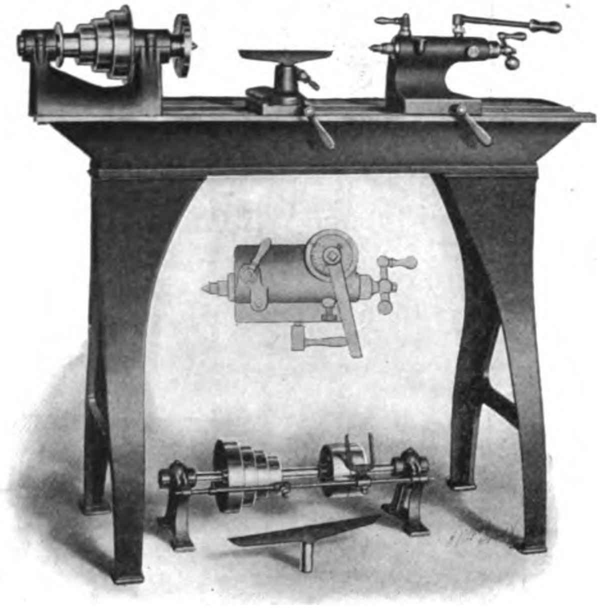

FIG. 13.—"STAR" SPEED LATHE.

NEW BOOKS.

Modern Wiring Diagrams and Descriptions. By Henry C. Horstman and Victor H. Tousley. Chicago: F. J. Drake & Co., 1904. Leather; 152 pages, 4 ins. x 6 ins.; 177 illustrations. Price, $1.50.

This little book contains an excellent collection of diagrams and a reasonably complete explanation of them in the text. The diagrams cover all classes of circuits that a wireman or other practical worker will be likely to encounter, and a considerable number that he probably never will have to deal with. One should not object, however, to more information than is required. The authors' diction is open to criticism, and the use of symbols is not always judicious; for examples: "The positive of the machine is connected to the positive of the circuit"; "leading wires," meaning individual wires; "multiphase" instead of "polyphase"; "Magnet A * * * * is almost impenetrable to rapidly alternating or intermittent currents"; "transformer," in the fourth line of page 104, referring to an autotransformer; the use of *C* to represent amperes instead of the recognized symbol *I*, and the use of a circle to represent an annunciator magnet. These little points are of more importance in a book directed to the audience for which this one is intended than they would be in a more abstruse work written for men who are less likely to accept as a guide every utterance of an author. Barring the minor lapses of the sort mentioned, the book has the merits of technical accuracy, clearness and completeness.

A Text Book of Electrical Machinery, Vol. I. By Harris J. Ryan, Henry H. Norris and George L. Hoxie. New York: John Wiley & Sons; 1903. Cloth; 265 pages, 5½ ins. x 9 ins.; 134 illustrations. Price, $2.50.

This volume is devoted to the exposition of fundamental principles and is intended to prepare the student for a thorough comprehension of Volume II, which will be devoted to the analysis of the structural and performance characteristics of electrical machinery. In the present volume the authors start at the beginning, dealing first with the basic principles of electricity and magnetism, fundamental and derived units. The treatment in the first few chapters is a rather inconsistent mixture of highly mathematical exposition and childishly simple problems. For example, after carrying the student through a chapter bristling with trigonometrical formulas, and another dealing with complex quantities, the authors propound this staggering test: "A current of 105 amperes is furnished by the armature of a railway generator that has a resistance of .15 ohm; what e.m.f. is consumed in the armature?" The next problem is one to which the answer, as expressed by the authors, is 2095 /47°8′ volts; this unusual expression is a composite one, intended to convey the information that the e.m.f. is 2059 volts and leads the current by 47° 8′. With full respect for the authors, this manner of statement impresses the reviewer as being clumsy, confusing and totally unnecessary. Barring a few mannerisms, so to speak, of this kind, the book can be recommended unqualifiedly to students who already have a fair knowledge of geometry and trigonometry. It is the only one that has thus far come under the reviewer's notice in which the exposition of the inductance and capacity of the two parallel wires of an alternating-current circuit is both accurate and unmistakably clear; it is to be regretted that the authors did not extend their discussion to three-phase circuits.

Mechanical Engineers' Reference Book. By H. H. Suplee, M.E. Philadelphia: J. B. Lippincott Company. Soft leather; 842 pages 4 ins. x 7 ins.; illustrated. Price $5.50.

This is a finely executed and well-planned member of the engineer's "pocket book" class which contains several features not found in previous books of that kind. There is a very useful multiplication table by means of which one may ascertain the product of any digit and any number of two figures by inspection, and of two numbers of any reasonable magnitude by simple addition; there is also a factor table giving the factors of all composite numbers up to 9,600, excepting those divisible by 2, 3 and 5. The table of trigonometrical functions is arranged in steps of one minute, instead of 10 or 15, as in most other similar books, and is supplemented by a table of logarithmic angular functions. The table of hyperbolic logarithms progresses in steps of .01 up to 10 and thence in units steps up to 134. There are the usual sections on mechanics, materials and strengths of materials, but these are somewhat fuller than usual, and are followed by a most useful section on machine design heretofore lacking. Cost of power and works management are also new headings, although most of the other books contain some material on the former of these two subjects. A thorough review of the book is impracticable, of course, in view of the diversity of subjects; so far as the reviewer has been able to test the merit of it by analysis or application of the contents, the author's work has been very accurately and conscientiously done. Errors will doubtless be found as one puts the book to practical use, but the first inspection has revealed very few. Probably the worst, *per se*, is the statement taken from another hand-book, that the brake horse-power of a gas engine is proportional merely to the stroke, speed and square of the cylinder diameter, without any consideration of the compression ratio. In the electrical section, the author manifests inconsistency with accepted practice by using *C* to represent current, although *P* is used to represent power; in copying the Institute table of copper wire properties he has retained the less convenient "Feet per Ohm" section and omitted the more convenient "Ohms per Foot" section. Some excellent records of tests made on motors for machine-tool drive are included, but otherwise the section consists of reprints of the A. I. E. E. table just mentioned, the Underwriters' Rules, the General Electric Company's wiring formulas and tables, the report of the A. I. E. E. Standardization Committee and some fugitive quotations from papers and articles on motor drive. The non-electrical parts of the book are far more complete and satisfactory—naturally, perhaps.

Secondary Batteries. A Practical Handbook for Owners and Attendants. By an Engineer. London: H. Alabaster Gatehouse & Co., 1903. 83 + viii pages 5¼ by 8 inches; 8 illustrations. Price 4 shillings.

This little volume has both a preface and an introduction. The preface opens thus: "The writer of this book is an Engineer, and not an Electrician. He has attempted, therefore, to write, not Electricity, but En-

American Electrician.

Vol. XVI. New York, April, 1904. No. 4.

THE STEAM TURBINE IN POWER HOUSE EXTENSIONS.

CENTRAL STATION OF THE ROCKLAND LIGHT & POWER COMPANY.

An interesting application of the steam turbine to existing conditions in central station practice may be found at the power station of the Rockland Light and Power Company, located at Orangeburg, N. Y. This company operates an alternating-current distribution system covering considerable territory in the southeastern section of New York State, including as many as twenty towns and villages. The system extends from Nyack, N. Y., on the north to Cresskill, N. J., on the south, and from the Hudson River as far inland as Spring Valley and Monsey N. Y. The power house supplies 3000-volt 2-phase current for all purposes, the power being transmitted by high-tension feeders to the various distribution centers and there stepped down by transformers to voltages suitable for commercial and private lighting and street arc lighting. For the latter, tub transformers are employed in connection with constant-current, alternating, enclosed series arcs.

A considerable motor load is carried through the day, the majority of the motors being of the polyphase constant speed induction type. These motors furnish power for operating various machine shops and factories located within the territory cov-

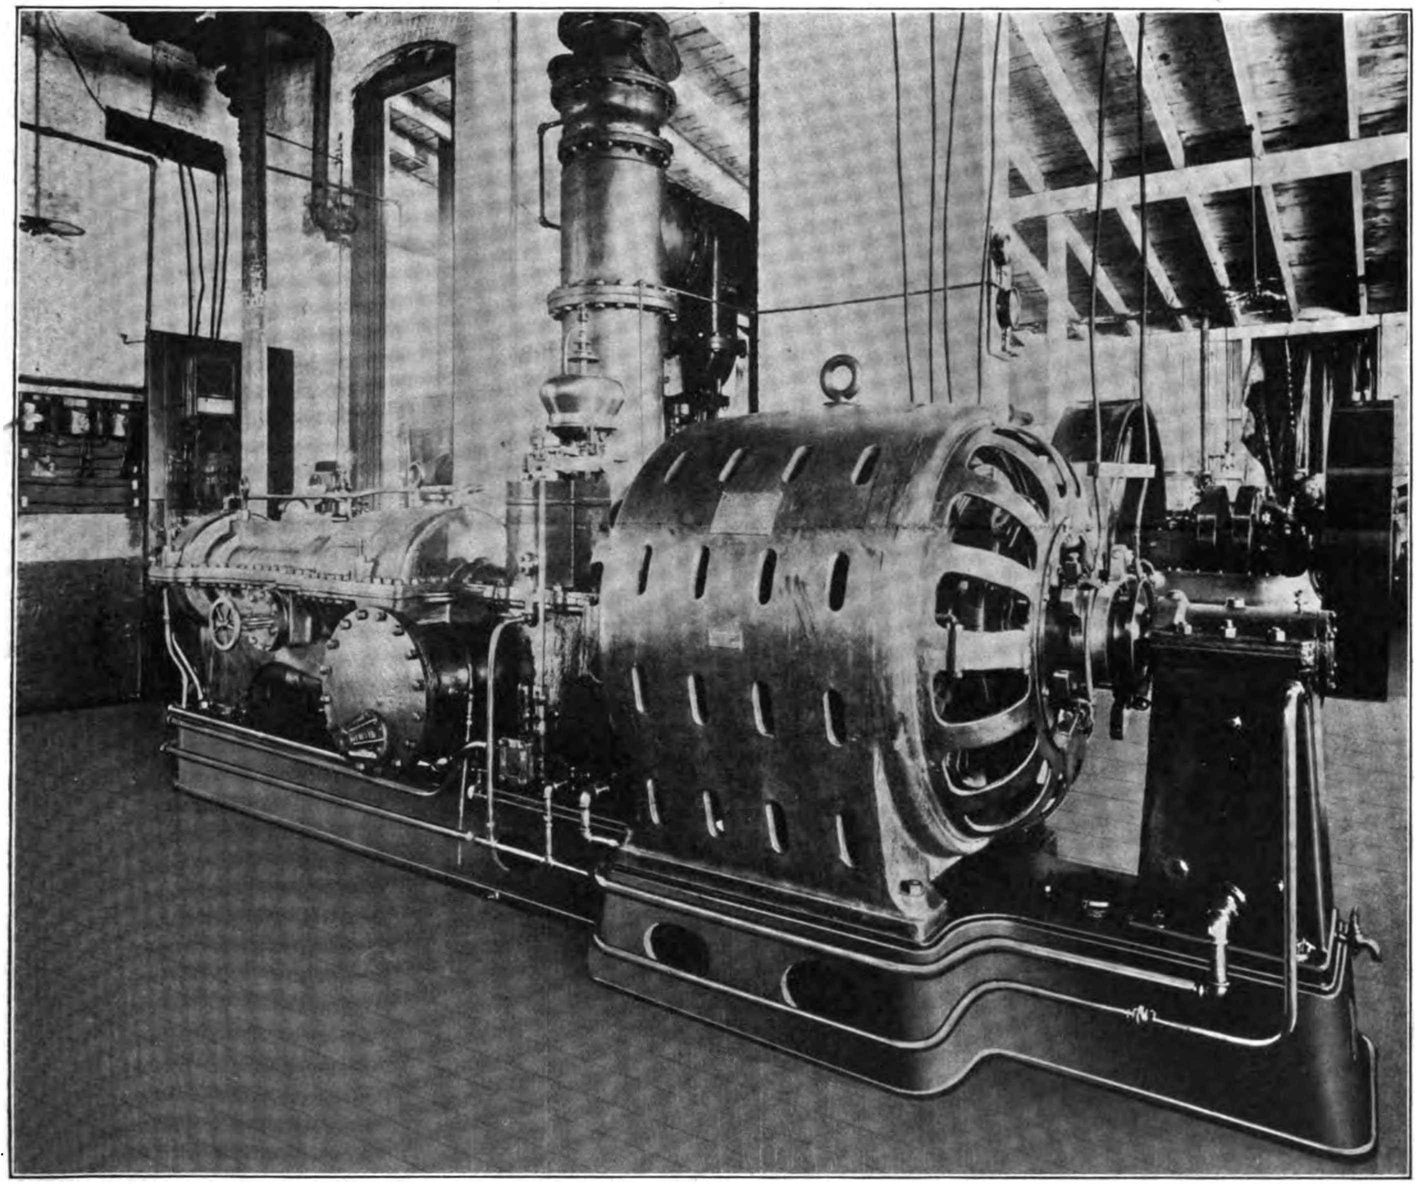

FIG. I.—TURBO-GENERATOR IN ROCKLAND LIGHT AND POWER COMPANY'S STATION.

ered by the company's distribution system.

The power station at Orangeburg contains at present about 800 kw. of generating machinery, mostly of the polyphase type. The only direct-current generator in the plant is used for supplying power for variable speed motors in an adjacent factory. At present a 400-kw. Westinghouse-Parsons turbo-generator forms the largest unit in the plant. It has been in operation for about five months and carries the entire evening and night load from 5 p. m. to 3 a. m. During the remainder of the 24-hour day's run, two Stanley inductor generators are employed, these being of 180 kw. and 125 kw. capacity respectively, the one driven by a 18-in. x 30-in. x 16-in. Westinghouse compound engine and the other by an McIntosh & Seymour tandem compound engine. Both of these outfits are of the belted type.

Steam is furnished at 125 lbs. pressure from an 875-h.p. plant located in the adjacent half of the station building. Water-tube boilers of B. & W., Heine and Caldwell types are employed; also one 70-in. horizontal return tubular boiler which supplies steam to auxiliaries. An 8-in. steam main extends from the most distant battery in the boiler room to the last unit in the engine room, where it joins the second main connecting all engines with the first three batteries of boilers. Valves in the various sections of the steam main provide a suitable flexibility in the operation of the boiler plant.

Provision has been made in the plant for the use of superheated steam in the turbine equipment. For this purpose an independently fired superheater has been installed in the boiler room and connected to the 8-in. main steam line, in such a manner that by opening and closing certain valves all steam coming from the boilers may be deflected through the superheater, where its temperature may be raised to any desirable degree, the steam then proceeding to the turbine. Or if it is not desired to use the superheater it may be by-passed and saturated steam furnished to the engine and turbine alike. The superheater is of the type supplied by the Power Specialty Company. Its construction differs somewhat from the U-pipe used in the Schmidt system and by some American boiler makers, in that the superheating surface is supplied by numerous radial ribs cast upon the periphery of a number of round cast-iron pipe sections arranged in a zigzag fashion within the superheater setting. Flat grates are used and the same grade of coal is burned in the superheater as in the regular boiler furnaces.

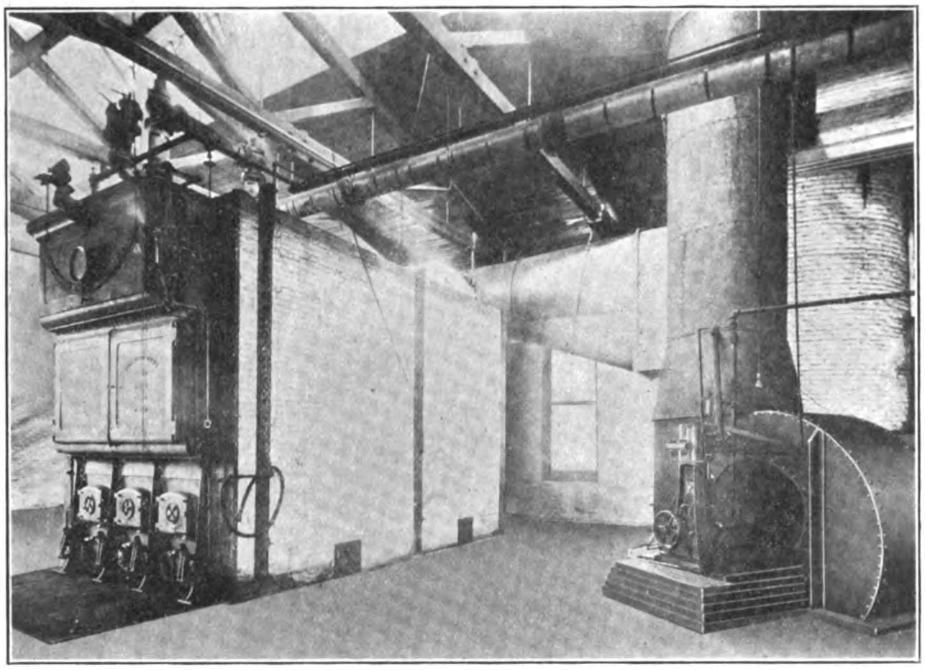

FIG. 2.—PORTION OF BOILER ROOM, SHOWING MECHANICAL DRAFT OUTFIT.

Draft is furnished by a brick stack into which lead sheet steel smoke flues from the various boiler settings. An American Blower Company mechanical draft outfit is also available for use during periods of heavy load and assists the main stack by drawing from the main flue a portion of the burned gases, discharging them into an auxiliary steel plate stack standing near the main stack. The fan intake is controlled by a butterfly damper located at its junction with the main flue. Coal is brought to the station upon an elevated track connecting with the lines of the West Shore and Erie railroads, which pass very close to the station. At present hand firing is employed.

The turbo generating unit was installed under pressure of necessity owing to the lack of sufficient floor space in the engine-room for the installation of an additional engine-generator outfit of suitable capacity. Since the plant was started the distributing system has rapidly increased both in point of area served and in aggregate load, and the plant forms an interesting example of the gradual tendency of engineering practice towards the use of more compact machinery.

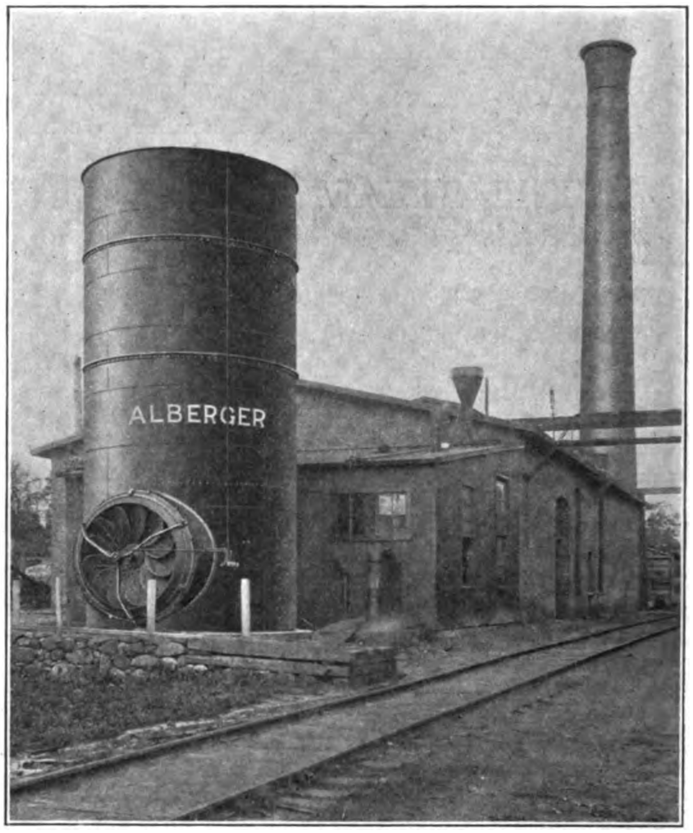

FIG. 3.—EXTERIOR OF STATION, SHOWING FAN-DRAFT COOLING TOWER.

The first outfit installed was the tandem compound horizontal engine belted to its generator; for the second outfit a vertical compound engine was installed, also belted to its generator; and for the third outfit, the direct connected turbo-unit, which occupies about one-tenth of the floor space required for the tandem compound belted unit.

The usual practice in turbine plants is to employ surface condensers in order that the condensed steam may be returned directly to the boilers, thereby avoiding the cost of water and also its purification in cases where mineral ingredients would cause boiler encrustation. At this plant, however, the feed water is drawn from a stream which passes the power house a short distance away, and as the water is comparatively pure, the condensing system operating the plant previous to the installation of the turbine was retained. This consists of an Alberger jet condenser with direct-acting air pump. The outfit is capable of maintaining a vacuum of 25 in. to 26 in. of mercury referred to a 30-in. barometer with the usual range of temperature of injection water. Outside of the engine-room is located an Alberger fan-draft cooling tower, which during normal operation of the plant serves the jet condenser. The fan shaft extends through the wall of the engine-room for the purpose of housing the belt-drive from a small Westinghouse Junior engine. This engine is also belted to a centrifugal pump set in a concrete pit just below the normal water level of the cooling tower well which supplies injection water to the condenser. In this position the pump never needs priming when being started. Exhaust steam from engines and auxiliaries is conducted to two heaters, one a primary and the other a secondary, and valves in the various exhaust lines provide complete control of the temperature of the feed. When the engine exhaust is greater than necessary for heating the feed water, a relief valve enables the excess steam to escape to the atmosphere. The turbine is also provided with an atmospheric relief in case of loss of vacuum.

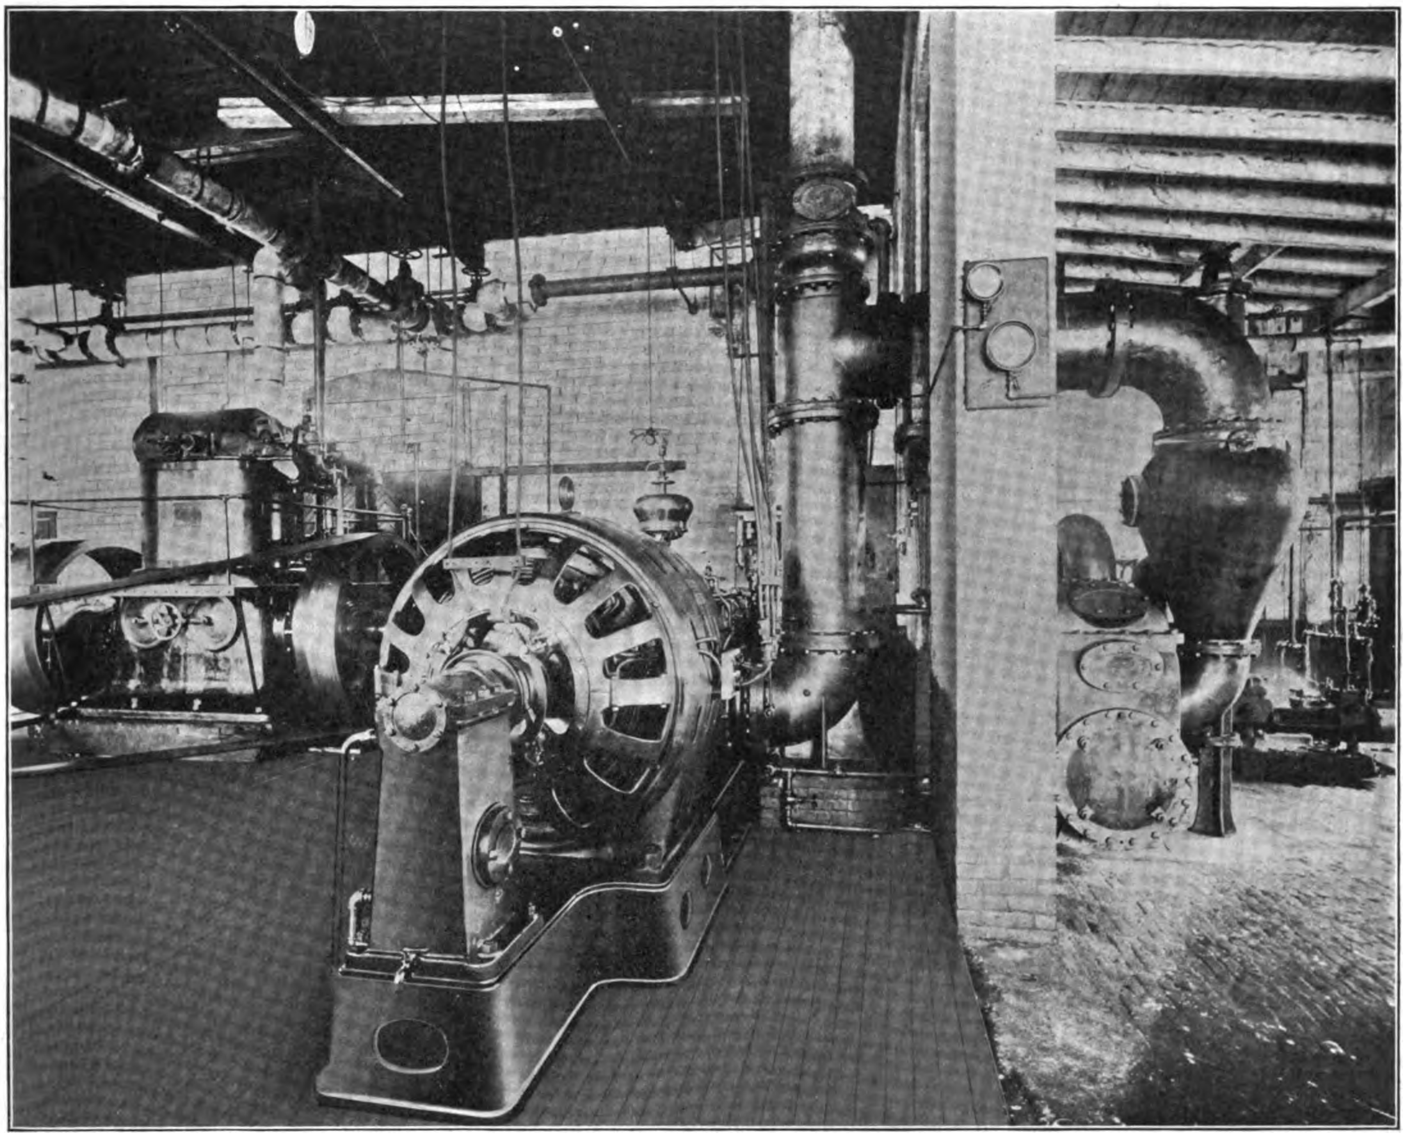

FIG. 4.—VIEW OF ENGINE ROOM, SHOWING TURBINE AND ITS CONDENSER.

The operation of the turbine up to the present time indicates in a striking manner what may be accomplished under unfavorable conditions. It is well understood that a high pressure and vacuum is desirable for use with a turbine on account of the increased economy derived therefrom. This increase of economy is greater than that which would be derived from a piston engine operating under the same conditions, and the greater investment in condensing machinery suitable for high vacuum is no doubt profitable in the case of the turbine. It is not, however, usually understood that the parallel flow type of turbine can operate with good efficiency under conditions of low vacuum and steam pressure such as obtain in this plant. Official tests conducted in the testing department of the Westinghouse Machine Company at Pittsburg indicate the general good economy of the turbine under these conditions:

Boiler Pressure, lbs.	Quality of Steam, %.	Vacuum ref. to 30-in. Bar.	R.P.M.	Brake Horsepower.	Steam Consumption, lbs. B.H.P. Hour.
126	1.0015	26	3536	580.	15.41
125	.999	26	3555	457.2	16.36
131	.999	26	3545	326.	17.89

During the test the steam was maintained approximately dry by means of the superheater installed in the testing department, in which the steam coming from the boiler plant was superheated just sufficient to re-evaporate the moisture contained. Its quality was determined by a throttling calorimeter.

The vacuum was measured by a mercury column and subsequently corrected upon a basis of 30 in. of mercury, which is used as a datum in all comparisons of turbine performances under different vacua. Brake horse power was measured by a special water absorption brake direct connected to the turbine and arranged as in the case of the ordinary Prony brake. At full load the turbine showed a steam consumption of 15.4 pounds per horse-power, which is equivalent to about 14 pounds referred to steam engine indicated performance. At a little over half-load the consumption had only increased to 17.89, or about 16 per cent, which is much lower than the corresponding increased economy in the piston engine, which amounts to more nearly 25 per cent. It should be borne in mind that this turbine although tested under low vacuum and steam pressure, was designed for 150 pounds pressure and 27 in. to 28 in. vacuum, as these conditions, it was anticipated, will ultimately prevail in the plant at Orangeburg. In view of these facts, therefore, the economy is particularly good.

In the matter of general operation, the experience with this turbine has been particularly fortunate, no troubles of a serious nature having arisen since the turbine was first placed in service. At times when the superheater has not been in use the turbine has been supplied with wet steam, which occasioned for the moment a slowing down in speed until the slug of water had passed through into the condenser, when the turbine immediately regained its speed. It is interesting to observe that no harm has resulted from this entrained water.

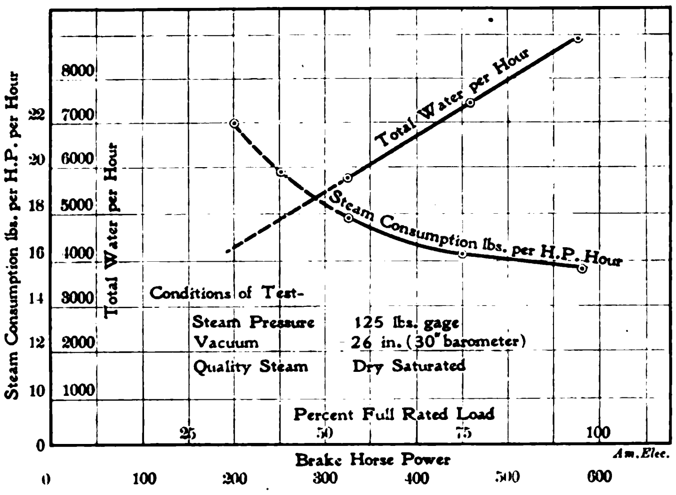

FIG. 5.—CURVE OF TURBINE PERFORMANCE.

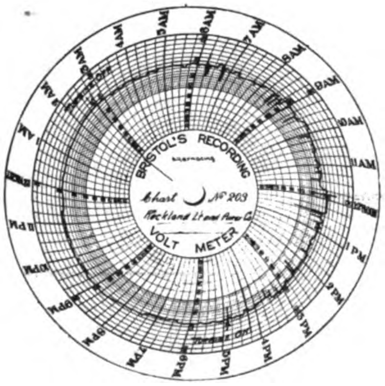

FIG. 6.—VOLTMETER CHART.

The great uniformity of rotation of the turbine is well demonstrated in the Orangeburg plant in the matter of voltage regulation. Up to the present time it has not been attempted to operate the engine and turbine units in parallel, as the switchboard is so arranged that the high voltage feeders leading to the various distributing centers may be switched over from one machine to the other, according to which machine happens to be in operation. It is, however, noticeable at distant points that the voltage regulation of the turbine is a large improvement over that of the engine equipment. This is shown in a striking manner in the accompanying recording voltmeter chart which was taken at Nyack, several miles from the power station. The turbine was put in service at 5 p. m. and continued until 3 a. m. on the following day, while the engine equipment continued through the balance of the twenty-four hours. It may be noted that the excessive fluctuations in a voltage of a more or less instantaneous character which are noticeable on the chart are largely due to induction motors which are connected to the system during the day. The gradual changes in voltage, however, may be traced directly to the regulation of the engine equipment. The circuit voltage is regulated from the switchboard through Stillwell regulators. One of these is placed on each phase of the two-phase circuits. By means of a chart, consisting of a straight line curve, the ordinates for which represent voltage and the abscissas current, the switchboard attendant is enabled to tell at a glance what voltage is required to compensate for the drop in the circuits.

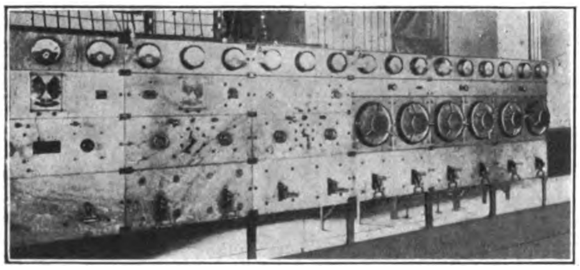

FIG. 7.—SWITCHBOARD.

The Rockland system is in charge of John S. Avery, general manager.

◆

ELECTRICITY ON STEAMSHIPS.

BY E. N. PERCY.

Lately several companies have specialized in the manufacture or design of electrical plants for steamships, but there is a larger field for progressiveness here than most electrical engineers realize, and it would seem that designers of marine machinery are not familiar with the possibilities of electricity in this field except in a general way. Some of the companies just referred to buy their dynamos ready made and couple them to cheap single-cylinder engines of more or less flimsy construction. The ship is fitted up with cheap switches and instruments, small poorly-insulated conductors, and there is no special protection against salt water or weather or the working of the ship. Moreover, this apparatus is likely to be installed by inexperienced men or the engineer's crew who have no special electrical knowledge. On the other hand, in the best passenger boats and in the United States Navy ships some very fine plants have been installed.

Applying electricity to any purpose on a ship involves many peculiar problems, some of which are as follows: Foundation or bed-plate flanges and bolts must be designed to withstand the pitching and rolling of the ship, even to the extent that they will not fall out if the ship capsizes, for many a good ship is rescued after "turning turtle."

The motions of a ship will transfer a rapidly rotating armature from one plane of gyration to another, introducing extra strains on the bearings and armature itself. This effect can be studied by whirling a weight on the end of a string and suddenly trying to change the plane of rotation.

The electric plant must be compact in all its parts, take up as little floor space as possible and at the same time be accessible. It must not be any higher than necessary and the center of gravity should be as low as possible. The engine must not throw oil and the generator must be protected from oil drips, salt water and sweat from the ceiling; it may even be placed where the main engines can throw oil or water on it. There may be lots of coal dust around, or the atmosphere may be kept damp by leaky steam joints. The steel hull of the ship or proximity of some of the beams may affect the magnets, or a hot steam pipe may touch some insulation.

Conductors of differing potential must not be run together. One of the most frequent causes of trouble is the breaking or shearing of conductors by the working of the ship. They must be given plenty of length and all armor or mouldings screwed or mortised at the ends to keep them from shearing. All connections must be carefully soldered, as corrosion is rapid in the salt air. Where lights are required in places exposed to the weather, they are covered by hermetically sealed globes. Sockets must never be exposed to weather. All outdoor switches and plugs for portables must be watertight. All conductors must be as flexible as possible and heavily insulated. Wherever conductors pass through bulkheads, there should be bushings of ebonite or rubber, never porcelain. These bushings or sleeves must in some way take hold of the armor or moulding to prevent shearing.

Grounds are more serious than in land practice. Besides the danger of fire, powder explosions or short-circuiting, the effect of electrolysis upon the ship's structure is very dangerous. A ground of a few weeks' duration may seriously weaken a spot in the ship's structure, or eat through some important pipe. Portable interior lights may be connected up with ordinary lamp cord, but no swinging lights are allowed, as they short-circuit in a few weeks at the upper end of the cord. In a metal ship it is almost impossible to prevent grounds without first-class work.

Lamps of 8 and 16 candle-power are favorites for staterooms and crew's quarters. Larger units are used on the decks and in chandeliers. Most steamships nowadays are provided with searchlights. These are often 50-volt lamps worked on a 110-volt circuit in series with resistance coils. How much better it would be to install two searchlights and run them in series. A cable runs up the forward mast to the mast-head light and to others at times for signalling purposes. These cables should be carefully armored and connected, as they often ground or shear off, especially on steel masts. Colored lights are placed on each side in accordance with law, a white light being placed inside a water-proof lantern.

Motors are in general use for ventilation and to some extent for hoisting purposes, but for little else. It is perfectly possible, and would result in many advantages, to apply them to forced-draft blowers, pumps, jacking gear, etc. Scarcely a ship comes in that does not require repairs to her forced-draft engines. These engines run from 400 to 1000 r.p.m., and one cannot escape the impression that it is the engine instead of the draft that is forced. These engines frequently go to pieces and use enormous quantities of steam. An electric motor would stop all of this waste and repair. No machine on board ship gives more trouble or is more wasteful than the pumps. Electricity has been successfully applied to the driving of every known type of pump. Lately, the wonderful success of compound turbine and propeller pumps and centrifugal pumps indicates that soon these pumps will be used for pressures of any height, and they are eminently well adapted to be driven by electric motors. These can be used for boiler feed, main air pumps, fire and bilge pumps, and all other purposes. Refrigerating machinery is easily driven by an electric motor, and the turbine principle can be applied to air and ammonia compressors in time. It can be applied to the operation of large ice cream freezers, chopping machines, baking machinery, etc. Deck motors are made watertight, as are also their controllers and switches. They are used for cargo hoisting, working boat davits, coal derricks, and opening or closing bulkhead doors.

Electrical auxiliaries present many advantages. They do away with the auxiliary steam piping now necessary; having a concentrated source of power, they are compact; the repair bill is much smaller; they can be run by current from the dock when in port; they can be started instantly without draining pipes or warming up engines. In the case of a ship provided with water-tight motors, if that ship sank and were repaired by divers she could be pumped out by her own pumps, taking current from another steamer.

Storage batteries are not of much practical good in a ship, except in very small plants. Telephones, bells and speed indicators all play a part in a vessel's make-up. The commercial efficiency of electric heaters is an open question. Their only advantage is the doing away with steam pipes.

So far, most marine plants are of the direct-current type. Alternating current offers, possibly, some advantages which the marine engineer has yet to have made clear to him. It might obviate some direct-current troubles, such as electrolysis.

Electrical engineers have lately evinced some interest in the marine plant problem, and it is hoped their efforts will bring forth good fruit.

MANUAL VS. AUTOMATIC TELEPHONE EXCHANGES.

BY HOWARD S. KNOWLTON.

In considering recent progress in telephone engineering the writer is drawn to the conclusion that a large amount of time and money has been expended in developing the so-called automatic exchange. Inventors have for several years worked hard to bring out a system which will stand the test of commercial operation, and their painstaking efforts to advance the art of communication by telephonic means deserve great credit. The operation of the new exchange at Grand Rapids, and at other cities where automatic systems have been installed, will be watched with great interest by telephone engineers and superintendents, and the test of time ought to make comparisons possible which will determine whether the new systems shall stand or fall.

At this time, however, it is important to recognize the disadvantages of any new system quite as much as its advantages. It is better to go slowly than to hasten to adopt untried systems and repent because they do not come up to the standards demanded by an exacting and not always reasonable public. It is not the purpose of this article to declare that automatic telephone exchanges have no place in the signalling world, nor is it the writer's intention to affirm the everlasting superiority of the manually operated systems. Rather, it is desired to point out the somewhat rigid requirements of service which the automatic exchange must meet if it is to hold a firm position in telephone practice of the immediate future.

It is certain that some of the automatic apparatus which has lately been brought forward is remarkably ingenious in its details, and on cursory examination appears, as far as the central office is concerned, to be able to stand up under continuous service without going to pieces. Parts are in duplicate, rugged in construction, and logically arranged. But technical success does not necessarily mean commercial success, although it is always an essential feature of the latter.

The greatest advantage claimed by the advocates of the automatic system is the elimination of subscribers or "A" operators, whose wages necessarily constitute a large factor in operating expenses. The argument that this elimination does away with the possibility of strikes and similar labor troubles among these operators does not strike one as powerful. Telephone operators are not sufficiently unionized to make this a formidable consideration.

In the strictest sense the automatic telephone exchange is not automatic after all. A telephone conversation between two subscribers involves an unavoidable process of selection in establishing a connection between them. In the manual system this selection is made by the "A" operator, and in the automatic system the work falls upon the subscriber. From the operator's standpoint, which in some ways is more important than the technical, it is a serious thing to throw upon the subscriber or casual telephone user the slightest amount of work beyond taking his receiver off its hook and asking for the required number. The whole trend of telephone practice has been toward greater simplicity in the subscriber's station and its operation; witness the replacement of the magneto generator and local battery by the common-battery central-energy exchange. The first cost of this has been very high, sometimes a thousand dollars per foot in the central office multiple switchboard alone, but the reduced maintenance charges and increased satisfaction on the part of the subscriber have gone a long way toward justifying the change. It is hard to estimate the betterment of service produced by enabling the subscriber to call the central office by simply removing the receiver from its hook, as compared with the old method of grinding out signals through a sometimes cranky magneto. One cannot imagine anything much simpler than this from the subscriber's standpoint.

The automatic system requires the subscriber at least to set up the number which he wants by means of pegs, pins or cranks, and in some cases he is obliged also to ring up the other party to the conversation. These operations are simple enough to persons accustomed to accuracy, but it is another proposition to expect the public at large to grasp the sequence of operations and correctly to manipulate the delicate apparatus of an automatic system each time it talks by telephone. It is true that the annoyances occasioned by operators' mistakes, flippancies and thoughtlessness are eliminated in local traffic by the automatic exchange, but it is possible that other vexations may occur. It is not difficult to imagine the trouble which it would be to a business man in a large city to have to put his mind upon solving the puzzle of setting up numbers himself at some crisis of his affairs when every moment is of great value and every faculty of his mind required to be at its highest efficiency. Here is a chance for the most decided annoyance to enter, and if the private branch exchange be cited as a remedy it only removes the trouble a step further. Perhaps the most important function of the telephone lies in its time-saving qualities, and in the case of a subscriber who wants a large number of numbers in sequence, the inconvenience of setting up all these numbers himself, and probably ringing them up as well, is no imaginary burden.

Again, it is doubtful if a great public service system like the telephone exchange can be entirely reduced to machine methods with the ready acquiescence of the public. Human nature is at each end of the line, and conditions are bound to arise where something more intelligent than machinery is needed to straighten matters out. Thus, in a conversation through an automatic central office the transmission may be imperfect and cannot be remedied without the delay of an appeal to the wire chief, whereas it might be possible for an operator in a manual exchange to suggest effective remedies or notify the trouble man at the very moment the difficulty was noticed. No mere machine, however intricate or wonderful, can possess intelligence, and that quality is one of the most vitally important characteristics of an efficient operator. An illustration of the public's attitude toward this is found in the antipathy which was shown to the use of the graphophone to inform a calling subscriber that the line sought was busy. This monotone repetition of the words, "The line is busy, please ring off!" became so annoying to the public that the telephone companies are lately substituting other means of imparting this unwelcome information.

Another step which at first blush looks like a backward movement is found in the increased complication of apparatus at the subscriber's station. This means increased cost of repairs, not only for labor and material, but in time expended and in money paid out in traveling from station to station when the instruments get out of order. This increase in the maintenance item must certainly be considered as an offset in some degree to the reduction in operators' wages occasioned by the installation of the automatic system. In other classes of telephone service the reduction in maintenance expenses caused by the removal of batteries and magnetos from the subscriber's station has been great indeed, and any progressive company will hesitate a long time before doing anything to increase this kind of expenditure. Again, the writer is advised that the outside wire plant in some systems requires not only a separate service from the office to each subscriber, but three wires instead of two to each station. This means heavy extra expense for overhead circuits, aerial and underground cables, conduits, etc., to be considered in its relations to the saving in operators' wages.

As far as the claim of superior secrecy in the automatic system goes, there is just about as much chance of cross-talk occurring between the outside lines of one system as the other. While it is true that an operator at a central office can "listen in" on a conversation by pressing a key on the keyboard in front of her, it is also true that in an office where business is properly proportioned between different switchboard positions an operator has very little time in which to regale herself with the conversations which pass over her cord circuits. The same claim would fall as flat when applied to the service given by a telegraph company. Any employee of a company transmitting messages as a business who divulged the nature of such messages would speedily find himself or herself in serious trouble. Complaints that telephone service is not secret in a manual system are about as trivial in actual practice as can well be imagined and almost always indicate the ignorance of the complaining party as to the real operating conditions in the exchange which serves him.

The service requirements of different communities vary widely. It is difficult to see how an automatic system can satisfy any others than flat rate, and possibly some few measured service, customers. Some communities are entirely contented with unlimited flat rate service, but others want every variety of contract which ingenuity can devise. The problem of "nickel service" would still further complicate the subscriber's station, and it certainly does not appear easy to fit it to an automatic system so as to insure successful operation without an operator at "central" to oversee the process of establishing and paying for a connection.

In the automatic systems, pay station service of the class originating in hotels, drug stores, saloons, etc., must with little doubt be handled by manual operators. Toll traffic over long-distance lines cannot be handled by mere machinery alone. It is a question whether calls from pay stations can be handled as rapidly in a system which is partly manual and partly automatic as in a purely manual system, where the pay station lines terminate in easy reach of the multiple jacks of all local subscribers connected to an office. It would appear that ceaseless vigilance is as necessary to keep an automatic system in repair as to hold a manual board up to the work of good operation, and outside the central office there is little room to doubt that it is a much harder task to maintain the automatic system in first-class condition.

A strong point of automatic telephony is said to lie in its freedom from interruption. The mechanism is designed to allow absolutely no interference while two subscribers are talking. This, however, is by no means an unmitigated blessing. Occasions often arise when it is most important that a conversation be temporarily discontinued. For instance, a long-distance call for a local subscriber may enter the office while that subscriber is talking with another local line. After a reasonable time of waiting, it is desirable that the called local subscriber be informed that a long-distance connection wants him, and if it is impossible for a courteous interruption to be made the service will be rendered poorer all around for that reason.

Great inconvenience arises at times in an automatic system from the fact that numbers have to be set up visually. It is difficult to use such a telephone in the dark. Even if the subscriber knows the required number without consulting the directory, it cannot be rapidly and accurately set up without some sort of illumination on the instrument.

It will be a satisfaction to the writer if the advocates of automatic telephony in large exchanges will publish the results of operation in the cities which have been bold enough to try the new systems. Every telephone engineer would appreciate full information as to first cost, maintenance, depreciation, and the method of overcoming the obstacles specified herein. The telephone world naturally wants the best apparatus which can be produced, and if the automatic systems prove superior to the manual, it will not be through concealing their data. In few branches of engineering would the publication of reliable data be productive of greater good. It may as yet be too early to determine the future status of automatic telephony, but it is certain that until the difficulties here suggested are overcome there is little chance of the manual systems being superseded. That the best system may ultimately triumph is the desire of every broad-minded student of telephone engineering.

CLEANING STEAM BOILER SURFACES.

BY R. T. STROHM.

The effect of scale in lowering the efficiency of heat transmission through the plates and tubes of steam boilers seems to be grossly exaggerated, if one may judge by the statements made concerning this point. According to some writers, the presence of scale to a depth of one-sixteenth of an inch causes an increase of 15 per cent. in fuel consumption. This means that if scale should collect to a depth of seven-sixteenths of an inch, the fuel consumption would be doubled. Unfortunately, these figures cannot be substantiated by actual experience, and a reasonable doubt prevails as to whether the loss due to scale is anywhere nearly as great as some writers would make it.

However, while opinions may differ markedly as to the exact amount of loss occasioned by unclean heating surfaces, steam boiler users are unanimous in declaring that scale does lower the boiler efficiency. And further than that, it endangers the safety and shortens the life of the boiler because of the overheating of the plates at those points where the scale lodges thickest.

In order to clean the shell of a return tubular boiler which is badly scaled, it is necessary to remove the manhole covers and enter the boiler with hammer and chisel, or with wire brush and scrapers, to remove the incrustation to the best advantage. This is always a tedious and disagreeable piece of work, and it is small wonder that it is so often neglected. The usual method of procedure in cleaning a boiler of this type is to open the blow-off and start the feed-pump, maintaining a fairly constant water level until the boiler is cooled down considerably. Then all water is drawn off and the manhole and hand-hole plates removed. After air is once admitted to the boiler, the cleaning should be carried on as rapidly as possible, for most scale solidifies quickly upon exposure to the air. If the boiler has a manhole at the top, it is often found convenient to remove it and to enter the boiler at this point, scraping the scale from the shell by using stiff wire brushes and lowering the water level slowly at the same time. This prevents any contact of the air with the scale, and thus prevents the hardening referred to previously.

The above method is mechanical only in so far as it requires the use of mechanical appliances. A novel form of mechanical cleaning, obviating all manual labor in chipping off the scale, was brought out and patented in England some years ago. This method was simply to use a small refrigerating system, producing inside the boiler a very low temperature, which served to render the scale brittle and caused it to chip or flake off, owing to the difference in coefficients of expansion of iron and of scale. The refrigerating apparatus consists of a small ammonia compressor, and a number of expansion coils which are placed within the boiler. The interior is then subjected to a temperature close to zero. The expansion following the removal of the coils, as the boiler returns to the normal temperature, assists in removing particles of scale which the contraction has only loosened. This process, however, would scarcely be a very practical one except in refrigerating plants.

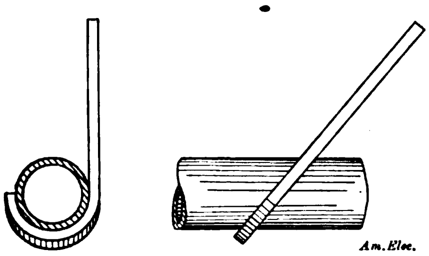

FIG. 1.

While it is comparatively easy to clean the plates of a return tubular boiler, the matter of removing incrustation from the fire-tubes is not so easy, unless the proper tools are at hand. Scrapers made of rectangular bar iron bent into a U at one end, as shown in Figs. 1 and 2, have been improvised, but they are not easily used, and do not remove the scale as perfectly as it should be done. As a consequence, a large number of boiler-tube cleaners have been placed on the market, their object being to lessen the labor and the time required to clean tubes satisfactorily.

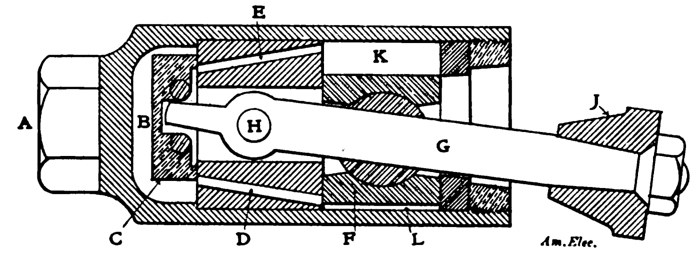

FIG. 3.

The principles of construction of these cleaners vary widely, according to the types of boilers in which they are to be used, and depend also upon the nature of the cleaning which they must perform. Consider first the cleaner required to remove scale from the water surface of a fire-tube, as in a return tubular boiler. Such a cleaner is illustrated by Fig. 3. It consists of an outer cylindrical casing having a nozzle at *A* for the admission of either compressed air or steam, whichever is the more easily obtainable. Inside the nozzle is a chamber, *B*, in which is a small slide-valve, *C*, without lap, which moves diametrically across the seat containing the ports *D, E*, alternately opening and closing them. These ports lead to opposite sides of a piston, *F*, which also moves diametrically back and forth across the cylinder under the pressure of the fluid admitted through the ports. A lever *G*, carrying at its outer end a hammer *J*, is pivoted on a pin *H*, fixed in the casting containing the ports. The other end of this lever moves the slide-valve *C*, while at the middle it passes loosely through a steel sphere which makes a ball joint in the piston *F*.

The action of the device is very simple. Supposing steam to be admitted to the chamber *B* with the parts in the position shown, the steam would pass through the port *D* into the clearance space *L* and force the piston *F* to the other side of the cylinder. This motion would be very swift and would cause the hammer *J* to deliver a quick, sharp blow against the inner surface of the tube. However, the motion of the piston *F* in the direction of clearance *K* causes the slide-valve *C* to move in the opposite direction. This closes the port *D* to the live steam and opens it to the central exhaust passage, and at the same time opens the port *E*, admitting live steam to the chamber *K*; the piston *F* and the hammer *J* are thereby forced back to their original positions, the latter striking a blow against the tube opposite the previous point of impact. The rapid motion of the hammer, which may reach 1500 vibrations per minute, subjects the tube to repeated shocks, the blows being at no time of sufficient strength to hurt the tube, provided it is sound, and yet capable of cracking the brittle scale and jarring it loose from the water surface of the tube. If, on the other hand, the tube is thin owing to corrosion, or burned, so as to be weak and unsafe, then the blows of the hammer are likely to reveal the defect, which should be known.

This cleaner-head is attached to the end of a pipe of sufficient length to enable it to be pushed from one tube-sheet to the other, the pipe serving also to convey the steam required for operating the device. Owing to the inaccessibility of the tubes in a return tubular boiler, with the exception of the upper and lower rows, the hammer cleaner offers practically the only solution to the problem of removing scale formations from the water surfaces of fire-tubes. The use of acid solutions to clean all interior surfaces has been advocated, but has gained little favor owing to the fact that the boiler materials may be corroded by the acid.

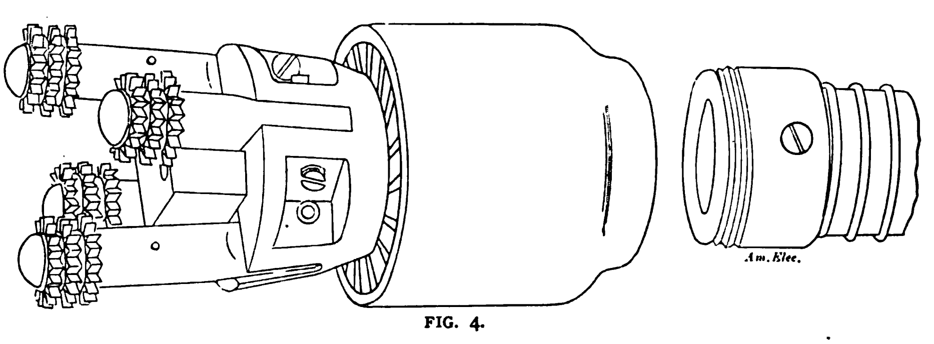

FIG. 4.

In the case of water-tube boilers, the scale formation occurs inside the tubes, and consequently a different style of cleaner must be used. It becomes necessary not only to remove it from the tube surfaces, but also to get it out of the way of the cleaner. The scale met with in water-tubes is frequently of a very hard and tenacious character and requires no small amount of force for its removal. As a result, three distinct methods of operating the cleaner have come into use. These are steam or air, water, and electricity. The principles upon which tube-cleaners act may be divided into two general classes—a cutting action and a hammering action. In the former, the tool is furnished with a number of cutter wheels, which are given a rotary motion inside the tube, or are forced along the tube in a longitudinal direction, while in the latter a hammering action is employed to break up and loosen the scale.

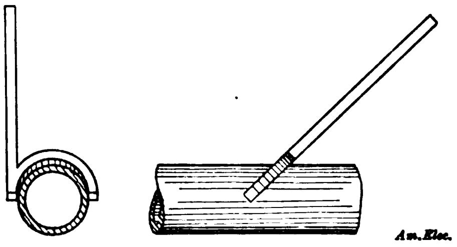

FIG. 2.

A good example of the class using a rotary cutter is shown in Fig. 4. It consists of a cylindrical outer casing in which is a small turbine, operated by water under 150 pounds pressure, or higher, the water being supplied through a hose connected to the coupling shown on the right. The turbine has ball bearings to reduce friction to a minimum, and rotates very rapidly. To it is fastened a spider of phosphor bronze, into which four steel arms are pivoted, these steel arms carrying hardened steel cutter-wheels. As the turbine revolves, the arms carrying the cutters are thrown outward by centrifugal force, and the sharp-toothed wheels cut the scale loose from the tube surface. The water discharged from the turbine flows out past the spider and the cutter-wheels and serves to carry away the scale as fast as it is loosened. Different styles of cutter-wheels are furnished with each cleaner so as to adapt the device to all kinds of scale formations.

Very often the scale is of such thickness and tenacity as to require more than ordinary efforts in its removal. In such cases an electric or a hydraulic motor or a small steam engine supplies the power necessary to operate the cleaner. A motor cleaner of this kind is illustrated by Fig. 5. The cutter-head consists of a steel casting having several recesses, into which are fitted a number of steel toothed wheels, free to revolve on their shafts. The rotation of the shaft to which the cutter-head is fastened throws the wheels outward, and they cut the scale loose, at the same time polishing the inner surface of the tube.

If the scale formation is thin, and the tubes are straight, it is possible to remove it by the use of hand cleaners such as those illustrated by Figs. 6 and 7. The former consists of four pairs of cutter-wheels set at the ends of four spring arms. This head is fastened to a rod, and is pushed from one end of the tube to the other by muscular effort. The latter form of cleaner, from which one arm is omitted to show more clearly the construction, has a sliding wedge which forces the cutter-wheels against the scale. It is evident that these two types require not only a large amount of manual labor, but that they are much slower than the turbine and motor types.

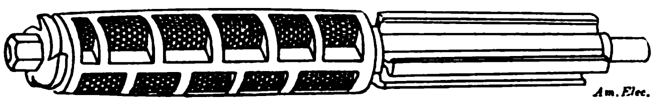

FIG. 5.

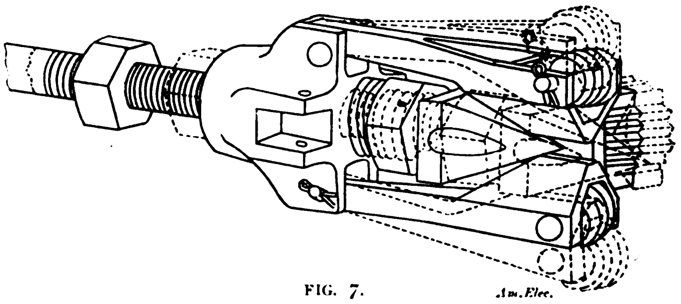

FIG. 7.

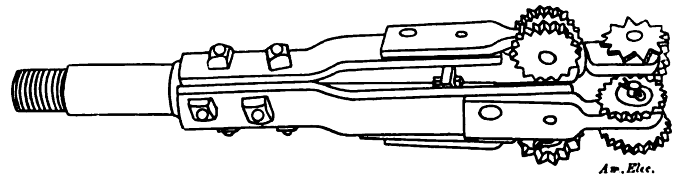

FIG. 6.

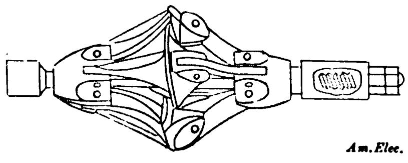

FIG. 9.

The second class of cleaners for water-tubes, using the hammer action, does not differ essentially from the one shown in Fig. 3. All that is necessary is to change the hammer-head on the vibrating shaft, using a sharper edge to cut the scale.

Incrustation on the water surfaces of tubes is not the only retarder of heat. The interior of fire-tubes and the exterior of water-tubes frequently become coated with soot and cinder, which are likewise poor conductors of heat. Consequently, any such accumulations should be removed as often as necessary to facilitate the transmission of heat and to increase the boiler efficiency.

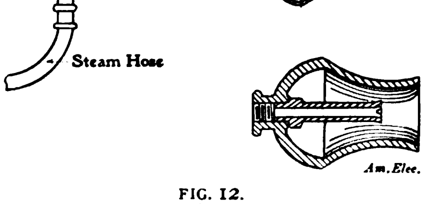

FIG. 12.

The cleaners in use at present for this purpose may be divided into four classes, viz., scrapers, brushes, blowers and suckers.

A very good idea of the scraper tube-cleaner may be obtained from Fig. 8, which shows a well-known make. It has four tempered steel blades, curved to a circular form so as to fit the tube, against the inner surface of which their cutting edges are held by the elasticity of the shanks. This scraper is attached to a long rod and is pushed from end to end of the flue. Fig. 9 illustrates another type of scraper, which possesses the advantage of being adjustable to fit tubes of different diameters. Adjustment is accomplished by turning the nuts at the end of the head, moving the blades further apart or closer together.

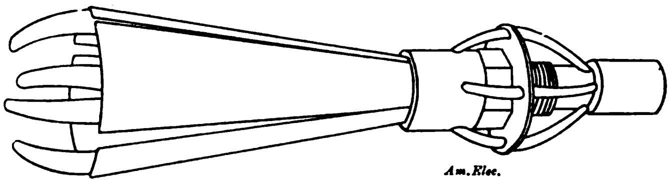

FIG. 8.

The common form of flue-brush is shown in Fig. 10, consisting simply of a helix of stiff wires interwoven with a heavy wire or iron center. This style of cleaner can be used to advantage only where the soot is dry and does not adhere strongly to the tubes. More often, therefore, it is customary to combine the brush and the scraper in one cleaner, as illustrated by Fig. 11. The scraper goes into the tube first, cutting loose the accumulations of soot and dust, while the brush follows and sweeps the surfaces clean. This combination of brush and scraper is made in a large variety of forms. The great objection to all cleaners of the scraper class is that their use entails a large amount of labor when the coating of dust is heavy.

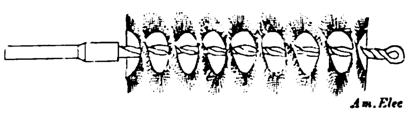

FIG. 10.

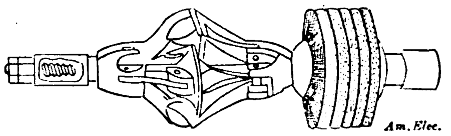

FIG. 11.

One form of blower cleaner for fire-tubes is illustrated by Fig. 12. It has a central steam nozzle of small diameter opening into a hollow head, which in turn is placed in the end of the tube. The steam blast, divided by the partitions at the tip of the nozzle, draws with it a large amount of air and this current of air and steam at high velocity is intended to clean the tube of all soot and dust. Another form of blower cleaner is shown in section in Fig. 13. It also uses a steam blast from a central pipe, which draws in an air current through a small conical nozzle, on the principle of the ejector. This ejector action is compounded by a series of converging nozzles and a large volume of air thus entrained with a small steam current. This blast of air is caused to impinge against the sides of the tube by an inverted cone placed at the outlet. The air thus issues in a thin annular stream, giving it a sort of knife-like action in removing the dirt. This cleaner may be pushed to any distance in the tube, assuring a clean surface throughout.

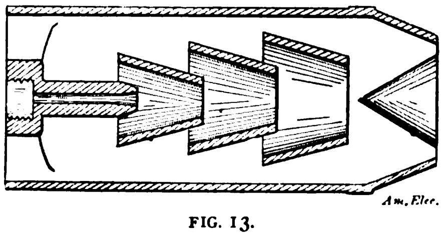

FIG. 13.

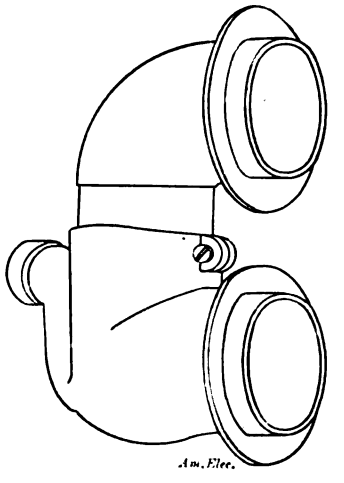

FIG. 14.

Some engineers object to admitting steam and air into the tubes. They complain that the steam condenses, making the soot and dust sticky, and causing it to adhere so tightly that a scraper is necessary to remove it properly. In order to overcome this difficulty, the blower shown in Fig. 14 was designed. It has two nozzles, one of which fits into each of two adjacent tubes. A steam jet in the lower nozzle draws the hot gases from the tube in which the upper nozzle is placed. These hot gases superheat the steam and prevent its condensation and at the same time furnish the volume of the blast necessary to clean the tube.

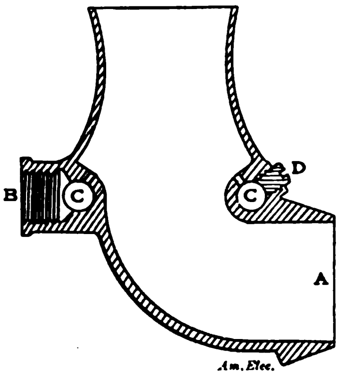

FIG. 15.

The fourth type of cleaner, working on the suction principle, is represented by Fig. 15. It is a cast-iron elbow having one end, *A*, tapered so as to fit into the tube to be cleaned, the other end, bell-mouthed, being pointed toward the chimney flue. Steam is then admitted, through a pipe connected at *B*, into the annular chamber *C*, which is pierced with numerous small holes pointing toward the outlet. In escaping through these apertures, the steam is wire-drawn to such an extent as to be superheated slightly, and its escape from the bell-mouth orifice induces a strong current through the tube into which the tapered end *A* is placed; this current of hot gases sweeps the tube clean of the accumulations of dust and soot. The soot thus sucked out of the tube is discharged at a high velocity into the chimney. The small plug shown at *D* is removed when it is desired to clean out the chamber *C* by blowing through a current of high-pressure steam.

The tubes of a water-tube boiler are cleaned externally by means of a steam blast. A cheap but effective form of cleaner for the Heine boiler is shown in Fig. 16, consisting merely of a round bar bent into a handle and attached to a long piece of wrought-iron pipe by a tee, the branch of which admits the steam supply. The end of the pipe is plugged, and eight small holes are drilled in the wall near the end. The water legs of the Heine boiler are fitted with a large number of hollow stay-bolts, through which the pipe is pushed, cleaning the tubes from end to end.

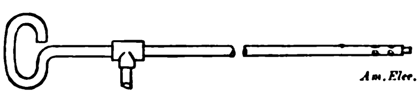

FIG. 16.

The tubes of many water-tube boilers are bent, and consequently their cleaning, internally, becomes considerably more difficult than the cleaning of straight tubes. In such cases it is necessary to use a boring head which will pass easily around a bend, and this means a short cleaner. Also, it must have a flexible connection with the operator. Several cleaners using motors as their source of power are provided with flexible shafts to transmit the power to the cleaner-head.

TELEPHONE ENGINEERING.

Cable Terminals.

BY F. J. DOMMERQUE.

All cables must be provided with terminals at both ends. The terminals may be at the exchange building, in a subscriber's building, or upon a pole line. At this juncture the pole line terminal is of interest only. The older method of terminating the cable in a cable-head, consisting of an iron box screwed to the rear wall of a wooden box, is still in favor in many places. The construction of iron cable-heads differs in detail only. In general the cable-head is a rectangular cast-iron box with a removable front, as illustrated in Fig. 1. The cable enters the box from the bottom, the pot-head end of the cable being attached to a metal bushing in the bottom of the cast-iron head. Inside the head the conductors lead each to one end of a connector-pin, a row of which is inserted along both sides of the head, each pin being insulated from the metal by a hard rubber bushing. The outside end of the connector-pin is attached to or forms part of the lightning arrester and fuse, mounted upon the outside of the box. This kind of terminal is nearly always provided with lightning arresters and fuses, because it is used upon cable poles that form the transfer point from underground to aerial construction; in that case always a considerable quantity of open wire enters into each line, requiring protection against lightning and strong currents. These heads are built for 25 to 100-pair cables. The protective devices will be described in detail subsequently. The heads are encased in a terminal box attached to the pole.

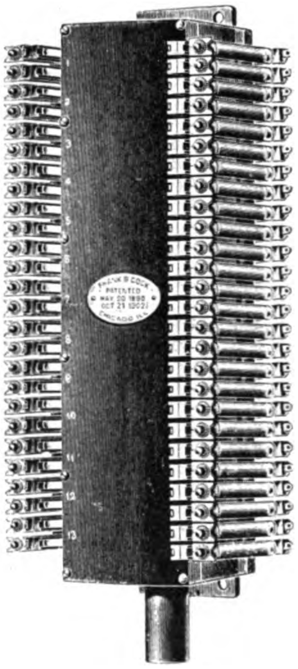

FIG. 1.—CABLE HEAD.

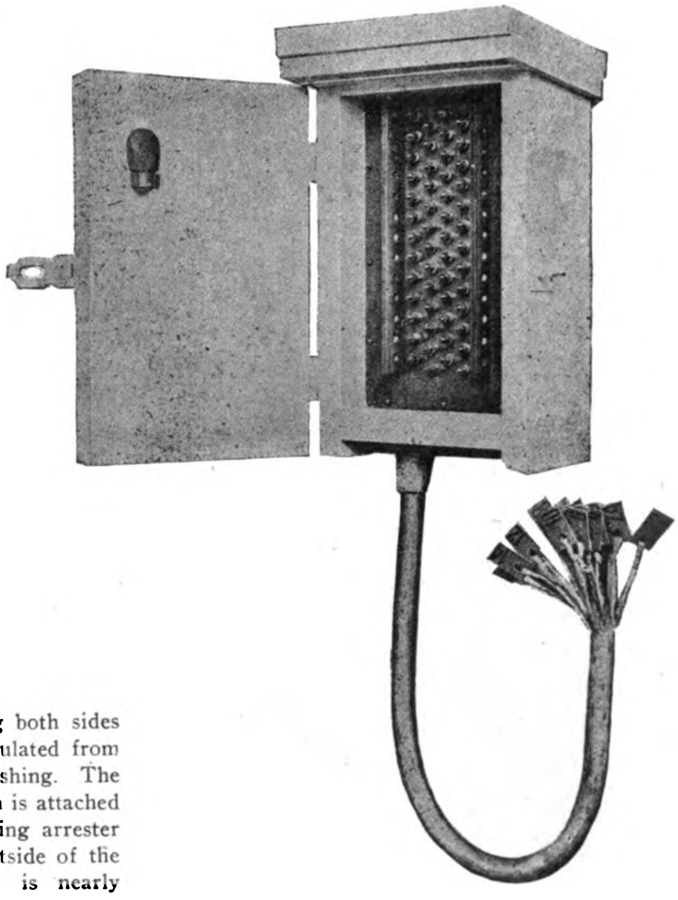

FIG. 2.—25-PAIR CABLE BOX.

In modern line-work open wires are mostly used for distribution only, except in very small plants and for toll and long-distance lines. When the cable terminates upon a distributing pole, which means when the cable is not continued in open line wires but opened in the terminal box and each pair of conductors connected to drop wires that lead directly to the subscriber's premises, the cable-box required can be of comparatively small dimensions, as such a cable will as a rule not contain more than 25 pairs and very often 10 pairs only. Not all 25 pairs will be used at this distributing pole, but all 25 will terminate there. In fact, at the beginning there should be quite a number of spare lines, in order to enable the telephone company to fill future orders for connection without disturbing the rest of the plant and on short notice. Just in this direction the economy of aerial cables with respect to open wires will be appreciated most. Not only that for the same first investment a greater number of lines can be provided in a cable than in open wires, but that any extension up to the full capacity of the cable is so very much cheaper. As the drop or service wires from the distributing pole to the subscriber's premises are short and not exposed to atmospheric discharges and high-tension currents, lightning arresters may be dispensed with altogether at this end of the line, provided there are arresters at the switchboard end of the line. In this case, the cable terminates in a pothead which is held in the bottom of a wooden box, the rubber-covered wires from the pothead extending to binding posts inside the box. Fig. 2 illustrates such a box for a 25-pair cable. It will be noticed that there are 26 pairs of binding posts provided; the twenty-sixth pair is for the extra pair in the cable. The box itself is made of 1¼-inch dressed kiln-dried lumber (cypress), sides, top, bottom and door, each made out of one piece; the top is made double, or single and covered by a piece of well-painted galvanized sheet iron. The box must be painted inside and outside with two coats of pure white lead and oil; the inside may also be treated with a flame-proof insulating compound for the protection of the cable, or lined with asbestos. The top should be projecting and slanting for the rain to run off. On each side of the binding posts is a fibre or wood panel with holes for the jumper-wires which are run down in a hand-made cable through holes in the bottom of the box and thence to the insulators upon the distributing fixture, which may be a cross-arm or a ring. Fig. 2 shows the box fitted with a flange funnel and a short piece of cable for connection to the main cable; this piece of cable is furnished with the box and saves time and trouble for the lineman. When this short piece of cable is connected to the main cable by a Y-splice, it should be given a dip in which any moisture that may come in from the terminal box may collect. Fig. 3 shows a connection of a terminal box to a main cable. The binding posts in the box should always be numbered; the numbers may also be located upon the jumper panels, and it is recommended to have a record card attached to the inside of the door on which a record is kept of all changes in the jumpering.

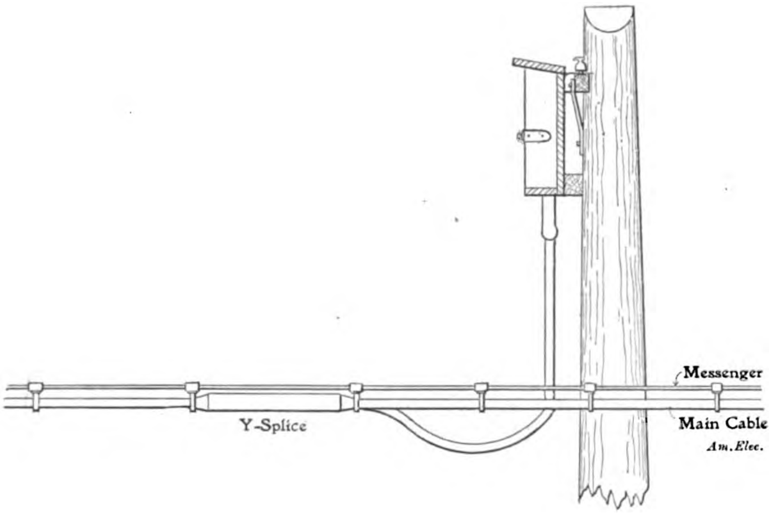

FIG. 3.—MAIN CABLE CONNECTION TO TERMINAL BOX.

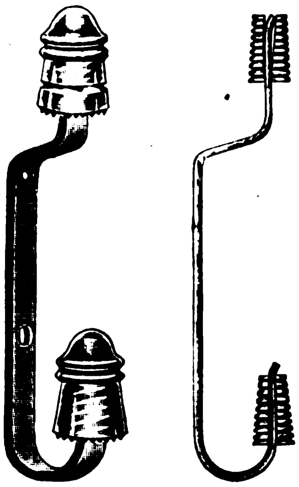

FIG. 6.—BRACKET.

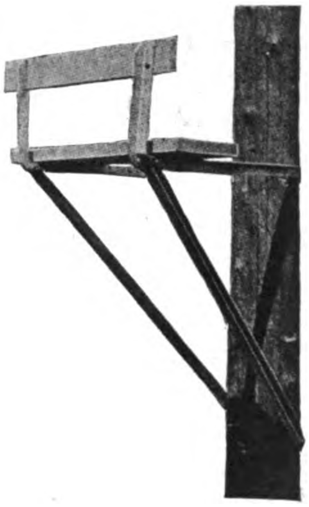

FIG. 8.

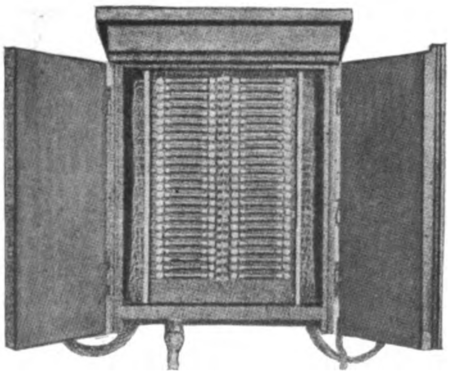

FIG. 4.—TERMINAL BOX.

Where long aerial lines are connected to the cable, lightning arresters and strong current protectors or fuses are required, the same as in the old iron cable-heads. Nowadays mostly wooden boxes, similar to the one just described, onlv larger, are used. Fig. 4 shows such a box wired up. The lightning arresters are in the center, the tubular fuses on each side of them, and the jumper-wire panels at the two sides.

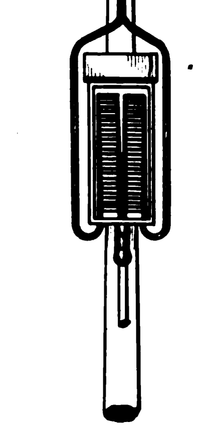

FIG. 5.

In all terminal boxes the cables enter and leave from the bottom. The jumper-wires for 25-pair and larger cables are usually divided into two hand-made cables and run outside the terminal box to the cross-arms in the manner shown in Fig. 5. In this figure the pins on the cross-arms are numbered consecutively; they may be numbered also from 1 to 25, giving two adjacent pins the same number in correspondence with the numbering of the pairs of conductors in the cable.

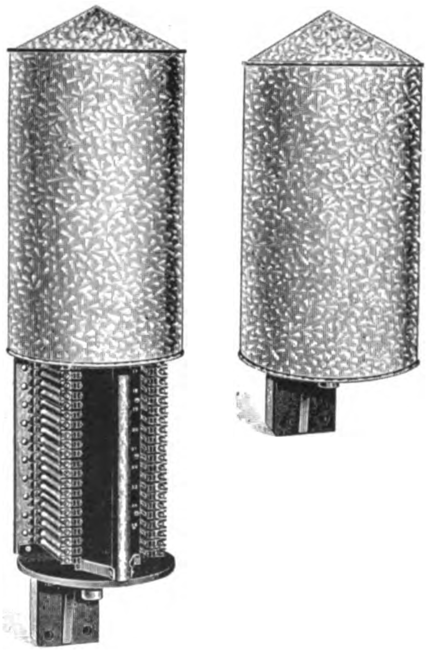

FIG. 7.—TERMINAL BOX.

In the illustration last mentioned, distribution from the terminal box by means of cross-arms is shown; such distribution would be justified or practicable with alley distribution, which means when the cable pole is located at the entrance to the alley and a short pole line or spur is run through the alley for distribution. In places where a number of subscribers can be reached from one pole, such a pole is used as a distributing pole, and preferably a distributing fixture is used which consists of a number of metal brackets attached to two rings supported by four braces. Fig. 6 shows such a bracket with and without insulators. This one is made of ¼ x 1¼-inch Bessemer steel. The ends of the bar are slightly bent and act as wedges to spread the split pins when these are drawn up by screwing the insulators on. The use of a distributing ring with porcelain knobs, instead of insulators, is a cheap and objectionable method. In fact, knob insulators should be strictly kept out of all outside construction work.

With the tendency to use more cable, particularly aerial cable, and in some cases all cable, as where the streets are full of large trees and no alleys are available, the number of terminal boxes becomes very great; as there was need of much small cable, small terminals grew plentiful, particularly for 10 pairs, and the great call for terminal boxes brought new designs upon the market.

The iron cable box particularly marks an advance in the right direction. This cable box has a circular cast-iron base-plate upon which is securely fastened (or cast in one piece with the base) an iron frame holding one or more hard rubber plates provided with binding posts, 5 pairs or 10 pairs or 25 pairs to a plate. A cylindrical galvanized-iron cover sets over the frame and rests upon the circular base. Such a box may be fastened with its base on the top of the pole, or it may be provided with a cast-iron bracket by means of which the box may be fastened with lag screws to the side of the pole. The cable enters and leaves the box through a hole in the base. This kind of terminal box is also made with lightning arresters and fuses, as shown in Fig. 7.

Wooden terminal boxes are usually attached to the pole; very small boxes, however, may also be attached to two cross-arms. For small boxes, no special platform need be provided, as there will not be much for the linemen to do on such poles. But distributing poles should always be provided with some kind of a platform. Where much work is to be done, a regular seat may be provided of the kind illustrated in Fig. 8. Where more than one man is to work upon a pole, for testing or frequent jumpering, a balcony like the one in Fig. 9 would answer the purpose.

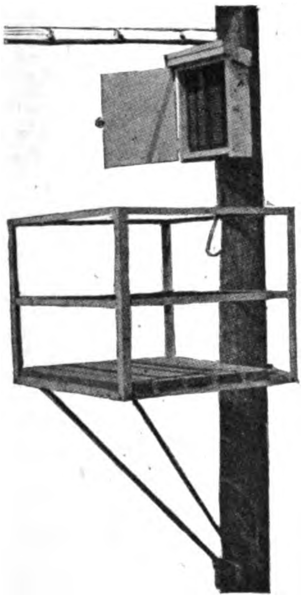

FIG. 9.

PREDETERMINING SOLENOID CHARACTERISTICS.

BY WM. A. DEL MAR.

The design of a solenoid for tractive work is a subject which is foreign to most text-books on electromagnetism. Why this should be so it is difficult to understand, as it is a simple matter to find a formula which will connect the three fundamental quantities which appear in the theory of solenoids. These three quantities are ampere-turns, flux and mechanical pull. The mechanical action of any solenoid or magnet depends on the fact that a magnetic circuit has a tendency to decrease its reluctance. Any iron or other highly permeable substance placed in a magnetic field will therefore tend to move towards where the field is strongest, as it is there that it is most effective in decreasing the reluctance. A piece of iron placed in a magnetic field so that no possible motion of the iron can decrease the reluctance of the magnetic circuit is not subject to any mechanical force due to the magnetism. The pull or force exerted by the field is thus dependent, not on the flux, but on the *flux gradient* of line differential of the flux.

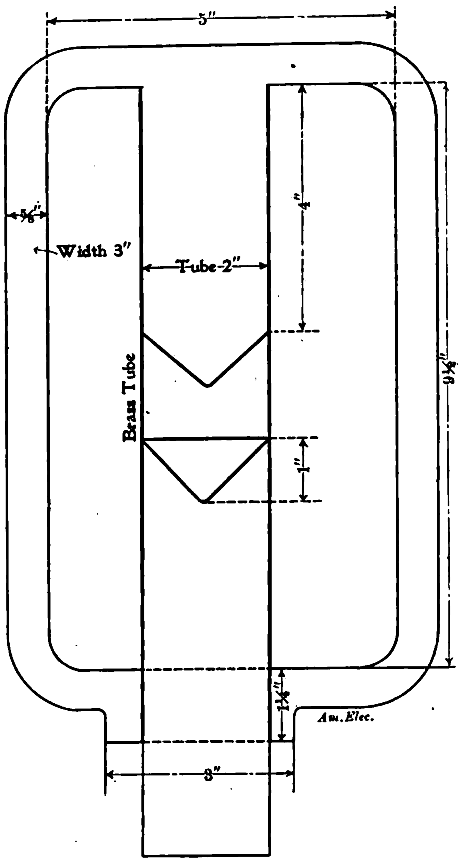

FIG. 1.—SECTIONAL ELEVATION OF SOLENOID.

When the core of a solenoid is moving so as to decrease the magnetic reluctance, the increasing flux gives rise to a back electromotive force in the windings. If

V = back electromotive force,
S = number of turns in the winding,
F = magnetic flux in maxwells,
t = seconds,
D = distance moved through (feet),

$$V = \frac{S}{10^8} \cdot \frac{dF}{dt},$$

watts expended usefully =

$$VI = \frac{IS}{10^8} \cdot \frac{dF}{dt},$$

$$\text{foot-lbs. per min.} = \frac{33{,}000}{746} \cdot \frac{IS}{10^8} \cdot \frac{dF}{dt}.$$

Now foot-lbs. per min. ÷ ft. per min. = lbs.; so that

$$\text{lbs.} = \frac{33{,}000}{746 \times 60} \times \frac{IS}{10^8} \times \frac{dF}{dt} \times \frac{dt}{dD}, \text{ or}$$

$$\text{lbs.} = \frac{738}{10^{11}} \times \textit{ampere-turns} \times \frac{dF}{dD}$$

where $\frac{dF}{dD}$ is the magnetic gradient in lines of force per linear foot.

If applicable to working conditions, this formula should be extremely useful in the design of solenoids, so that it is interesting to find how results obtained by the formula agree with experimental data. Three examples are given here in order to show that the gradient formula does give results which agree fairly well with practice.

Fig. 1 gives the sectional elevation of a solenoid which exerts a pull varying from 75 lbs. to 300 lbs. over a range of 1¼ inches. The actual curve of pull obtained by direct measurement is given in Fig. 2. There were 46,000 turns of No. 27 wire on this solenoid and the current taken was 0.234 ampere, so that the ampere turns amounted to about 10,800. Putting this in the "gradient" formula and inserting the necessary constants, curve 3 was obtained showing the gradient for different lengths of air-gap. The curve of flux may be derived from the gradient curve in the following way: Let G = flux gradient, F = flux increase,

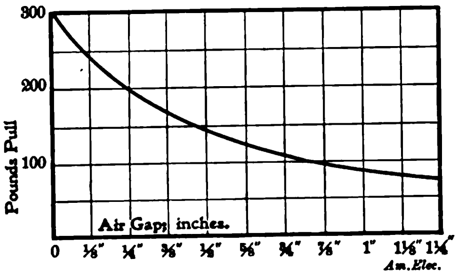

FIG. 2.—CURVE OF PULL.

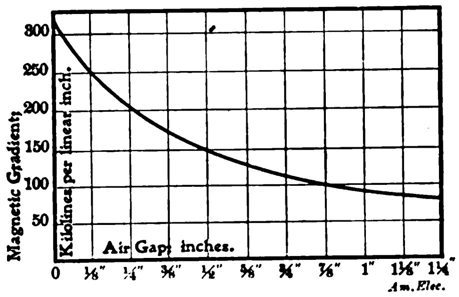

FIG. 3.—CURVE OF PULL.

and D = distance across the gap; then

$$G = -\frac{dF}{dD},$$

the sign being negative because as D increases, F decreases. Hence,

$$F = -\int_a^b G \,.\, dD + K$$

$$= K - \int_a^b G \,.\, dD$$

where $G.\ dD$ represents the change of flux between the limits a and b, and K, the constant of integration, is the flux when D is zero. In actual calculations the limits should be taken fairly close so that between them the curve does not depart very much from a straight line. In the case under consideration, if the limits be taken ⅛ inch apart the error will be very small, so that a sufficiently close approach to accurate integration may be effected by finding the areas of sections of the gradient curve for every ⅛ inch of air-gap. Thus in the section corresponding to an air-gap varying from 1⅛ in. to 1¼ in., the gradient is about 80,000 lines per linear inch. This average ordinate multiplied by the base gives the area of the section. Thus, 80,000 × ⅛ = 10,000 is the increase of flux, while the air-gap varies from 1¼ in. to 1⅛ in. This should be done for each of the ⅛-in. sections, so as to get the change of flux in each. The total flux for any position of the plunger is obtained by adding the proper increments to the original flux, or flux with no air-gap. This latter quantity must be found from the ampere-turns and the known dimensions of the magnetic circuit, and must be obtained by successive trials. In the case under consideration, a flux of 235,000 lines was found. The final trial is given below in order to illustrate the method.

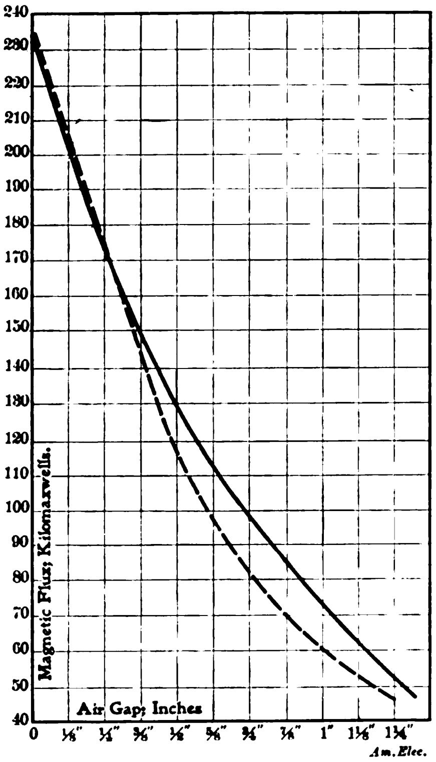

FIG. 4.

Wrought iron core:
Length = 24 cms.
Area = 12 sq. cms.
Assumed density, 19,600 lines; $\mu = 70$;
Total flux = 235,000 lines;

$$\text{Reluctance} = \frac{24}{12 \times 70} = 0.0288\ .$$

Wrought iron frame:
Area = 24 sq. cms.
Length along magnetic path, 40 cms.;

$$\text{Density} = \frac{235{,}000}{24} = 9800;\ \mu = 1200;$$

$$\text{Reluctance} = \frac{40}{24 \times 1200} = 0.0139\ .$$

Ring air-gap (the gap through which the plunger slides):
Height = 1¼ in.
Diameter = 2 in.
Area = $1\tfrac{1}{4} \times 2\pi \times 2.54^2 = 50$ sq. cms.
Length or thickness = 0.2 cm.

$$\text{Reluctance} = \frac{0.2}{50}\ 0.004\ .$$

Inside air-gap:
Owing to the existence of a stop the coned surface never approaches closer than 0.13 cm., so that the minimum reluctance is 0.011.

Summing the reluctances:

Core	0.0288
Frame	0.0139
Ring gap	0.0040
Inside gap	0.0110
Total	0.0577

$$\text{Flux} = \frac{4\pi}{10} \times \frac{\textit{ampere-turns}}{\textit{reluctance}}$$

$$= \frac{1.256 \times 10{,}800}{0.0577} = 235{,}000\ .$$

This agrees with the assumed flux and should therefore be correct.

A table can now be constructed on the following plan:

TABLE I.

Air-gap length. (Inches.)	Change of flux.	Flux.
Minimum	......	235,000
Min. to ⅛	34,400	200,600
⅛ to ¼	27,500	173,100
¼ to ⅜	22,800	150,300
⅜ to ½	19,400	130,900

The curve derived in this way is shown by the full line in Fig. 4. The dotted curve is not derived from the measured pull, but merely from the ampere-turns and reluctance, just as the flux of 235,000 lines was obtained above. The assumption was made that the ends of the core were flat instead of coned. It is interesting to note how closely the two curves shown in Fig. 4 agree, although where the air-gap is long the slope of the dotted curve is less than that of the full curve, while the opposite is the case where the air-gap is short. As the slope of the flux curve is really the magnetic gradient, it is seen that coning the ends of the core has a perceptible tendency toward equalizing the pull at different parts of the stroke. The curve shown in Fig. 5 is interesting as it gives the rise of current in the solenoid just considered.

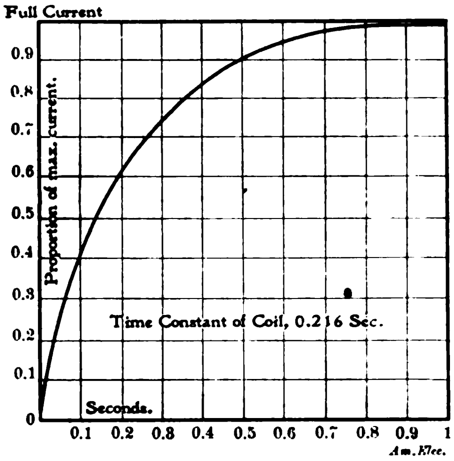

FIG. 5.

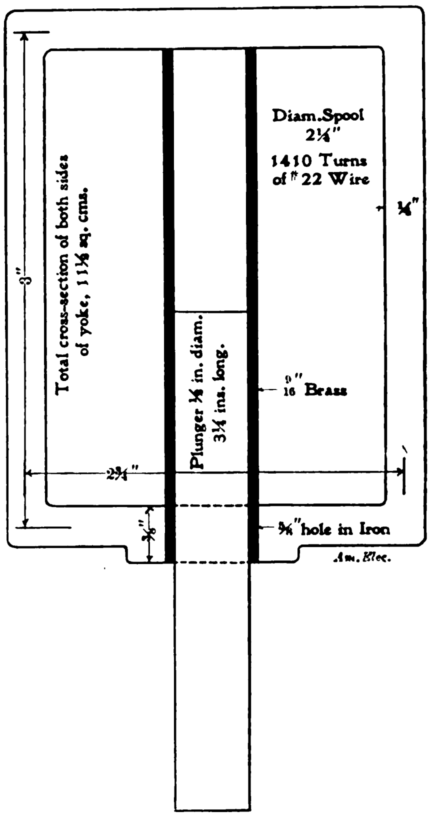
In the above example, a comparison was made of two curves of flux, one obtained directly by the law of the magnetic circuit, *i. e.*, from the ampere-turns and reluctance, and the other derived by means of the gradient formula from the measured mechanical pull. In the following examples, the flux will be calculated by the ordinary magnetic circuit formula, the gradient derived from that, and the pull calculated



Diam. Spool 2¼"

⅝" hole in Iron
Am. Elec.

FIG. 6.

from the gradient. This is the most important application of the theory here set forth. A comparison will then be made between the curve of pull derived from the formula and that obtained by actual mechanical measurement.

Fig. 6 gives the general dimensions of the next solenoid to be considered. As the air-gap varies between ¾ in. and 1¾ in., it is evident that the only reluctances that amount to anything are those of the air-gaps. The area of the ring air-gap, through which the plunger slides, is 4.72 cms. and its length about 0.159 cm. The reluctance is therefore $\frac{0.159}{4.72} = 0.034$, and this is the only one that need be added to the reluctance of the main air-gap. It is now possible to make up Table II., as shown, in which the headings explain themselves. The curve of pull plotted from this table is shown in Fig. 7 with the curve plotted from measurements.

It may be observed that the actual or observed pull is somewhat greater than that calculated, but they agree sufficiently well for most practical purposes. A perfect agreement between theory and fact cannot be expected because the quality of iron may not be exactly as assumed and because with small solenoids like this the observed pull may be greatly influenced by friction. As a matter of fact, the errors of observation in measuring the pull of the solenoid in question were so great that the curve could not be repeated so as to agree with the first observations any better than the theoretical curve does.

The next solenoid to be considered is intermediate in size between the two just discussed. Its general dimensions are shown in Fig. 8, but some are also given below. After trying four different flux densities in the wrought-iron core, a density of 17,200 lines per sq. cm. was found to fulfil the requirements as shown below:

Condition: Core all the way in, *i. e.*, with only a ⅛-in. air-gap.

Core:

Area = 9.65 sq. cms.

Density = 17,200 (assumed); $\mu = 172$.

Length = 17.78 cms.

$$\text{Reluctance} = \frac{17.78}{9.65 \times 172} = 0.01071.$$

Flux = 166,000 .

Cast-iron frame:

Area = 36 sq. cms.

$$\text{Density} = \frac{166{,}000}{36} = 4600;\ \mu = 383.$$

Length = 30.48.

$$\text{Reluctance} = \frac{30.48}{36 \times 383} = 0.00221\ .$$

Ring air-gap:

Area = 26 sq. cms.

Length = 0.318 cm.

$$\text{Reluctance} = \frac{0.318}{26} = 0.0122\ .$$

Inside air-gap (brass stop):

Area = 9.65 sq. cms.

Length = 0.318 cm.

$$\text{Reluctance} = \frac{0.318}{9.65} = 0.033\ .$$

The total reluctance is obtained by adding these:

Wrought-iron core	0.01071
Cast-iron frame	0.00221
Ring gap	0.01220
Brass stop, gap	0.03300
Total	0.05812

TABLE II.

Length of Air-gap.		Reluctance.					
Ins.	Cms.	Inside Gap.	Total or inside gap + 0.034.	Flux = (4π × Amp.-turns) ÷ (10 × total reluctance).	Flux change in ¼ in. (Differences from last column.)	Gradient in lines per linear foot (last column) × 48.	Pull in ounces. (By gradient formula).
½	1.25	.635	0.669	3,950			
¾	1.90	.950	0.984	2,680	1,270	61,000	15.1
1	2.54	1.270	1.304	2,020	660	31,700	8.0
1¼	3.17	1.580	1.614	1,630	390	18,700	4.6
1½	3.81	1.905	1.939	1,360	270	13,000	3.2
1¾	4.44	2.220	2.254	1,170	190	9,100	2.2

$$\text{Ampere-turns} = \frac{\textit{Flux} \times \textit{Reluctance}}{4\pi \div 10}$$

$$= \frac{166{,}000 \times 0.058}{1.256}$$

$$= 76{,}000 \text{ approximately.}$$

This is very near to 75,000, the number of ampere-turns actually on the solenoid, so that the assumption of a flux of 166,000 lines is about correct.

When the core is "out," the main air-gap is ½ inch, or 1.27 cms. long. The reluctance of the iron core and frame is then almost negligible.

$$\text{Reluctance of main air-gap} = \frac{1.27}{9.65} = 0.132$$

Reluctance of ring air-gap = as before =	0.012
Iron reluctances, about	0.004
Total	0.148

$$\text{Hence, flux} = \frac{1.256 \times 7550}{0.148} = 64{,}000\ .$$

Thus the change of flux in ⅜ inch = 166,000 — 64,000 = 102,000. This is equivalent to a change of 272,000 lines per inch, or about 3,264,000 lines per foot. Now, applying the gradient formula,

Pull lbs. =

$$\frac{738}{10^{11}} \times 7550 \times 3{,}264{,}000 = 181\ \textit{lbs.}$$

as the average over the ⅜ inch, which is what was found by direct measurement.

These three examples were the first with which the writer had occasion to test the gradient formula, but they afford good evidence that the formula is a useful one. There can be no doubt that if the data were worked out more carefully the discrepancy between theoretical and actual results would be less, not only because of the elimination of errors in applying the theory, but also of errors of observation in measuring the dimensions and the pull of the solenoid.

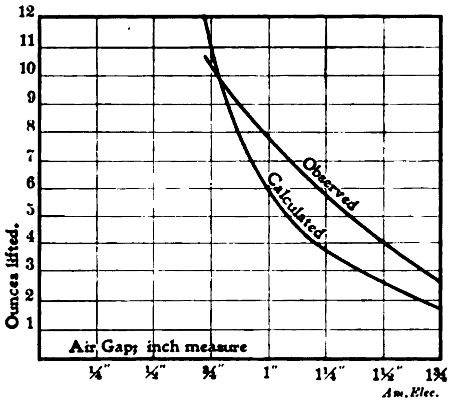

FIG. 7.

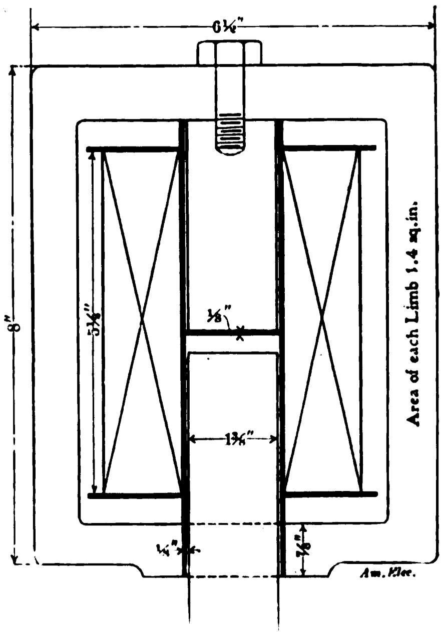

FIG. 8.

A modification of the gradient formula is useful in calculating the torque exerted by any solenoid or electromagnet with rotating parts. As before,

$$V = \frac{S}{10^8} \times \frac{dF}{dt},$$

where F is the flux, V the back electromotive force induced in the windings of the electromagnet or solenoid, and S the total number of turns of wire on the field and rotor, whether or not both have windings. The horse-power exerted at any moment

$$= \frac{VI}{746} = \frac{IS}{746 \times 10^8} \cdot \frac{dF}{dt}$$

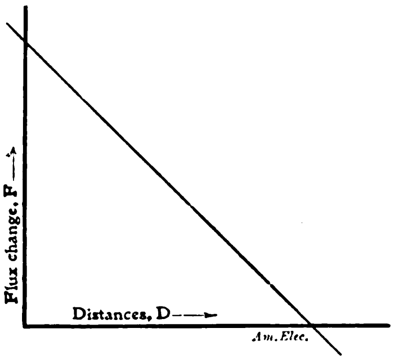

FIG. 9.

foot-lbs. per min. =

$$\frac{33{,}000}{746 \times 10^8} \cdot IS \cdot \frac{dF}{dt}.$$

Now, foot-lbs. per minute ÷ revolutions per minute = foot-lbs. per revolution, hence Foot-lbs. per rev. =

$$\frac{33{,}000}{746 \times 10^8} \cdot \frac{IS}{r.p.m.} \cdot \frac{dF}{dt}.$$

But radians per second, or $\frac{d\Theta}{dt}$, $= \frac{r.p.m.}{9.55}$

Foot-lbs. per rev. =

$$\frac{33{,}000 \times IS}{9.55 \times 746 \times 10^8} \cdot \frac{dF}{dt} \cdot \frac{dt}{d\Theta}$$

$$= \frac{33{,}000 \times IS}{9.55 \times 746 \times 10^8} \cdot \frac{dF}{d\Theta}.$$

Hence, Torque (lbs. at 1 foot radius) =

$$\frac{33{,}000}{9.55 \times 746 \times 10^8 \times 2\pi} \times IS \times \frac{dF}{d\Theta}$$

$$= 0.000{,}000{,}007{,}372 \times IS \times \frac{dF}{d\Theta},$$

where IS = ampere-turns and $\frac{dF}{d\Theta}$ = magnetic gradient in lines per radian.

This formula is especially applicable to such mechanisms as a commutatorless shuttle-wound motor or an equivalent device for obtaining rotation through a right angle.

It is interesting to consider some general deductions from the gradient formula:

$$\text{Pull in lbs.} = \frac{738}{10^{11}} \times IS \times G.$$

This may be written $P = kG$,

$$\text{where } k = \frac{738}{10^{11}} \times \textit{ampere-turns}.$$

As stated before,

$$F = -\int_a^b G \,.\, dD + K.$$

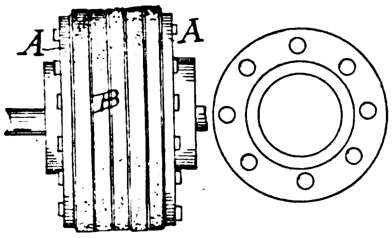

FIG. 1.—RAWHIDE WHEEL AND DISC—FIG. 2.

In order to get a uniform pull, it appears from the formula, $P = kG$, that G must be a constant. Hence,

$$\int_a^b G \,.\, dD = GD,$$

so that $F = -GD + K, = K - GD$ and the curve of flux is as shown in Fig. 9. This is very difficult to obtain in practice. A much more usual case is where the iron reluctances are negligible and the total reluctance is proportional to the air-gap length. In this case,

$$\text{Flux} = \frac{4\pi \times \textit{amp.-turns} \times \textit{area}}{10 \times \textit{length}}, \text{ or}$$

$$F = \frac{CA}{D},$$

$$\text{where } C = \frac{4\pi}{10} \times \textit{ampere-turns}.$$

Hence,

$$\frac{dF}{dD} = CA \frac{dD^{-1}}{dD}.$$

$$= -\frac{CA}{D^2}.$$

Thus the equation

$$G = -\frac{CA}{D^2}$$

represents the gradient curve when the iron reluctances are negligible. The actual gradient curves approximate to this form where the air-gap is considerable.

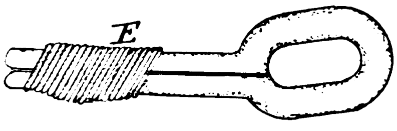

FIG. 4.—RAWHIDE BOUND TOOL.

SOME USES OF RAWHIDE IN THE FAR EAST.

(BY OUR MANILA CORRESPONDENT.)

I have been interested in observing the different applications of rawhide in connection with modern electrical apparatus and machinery, electrical wiring, etc. Rawhide is one of those commodities that one does not hear very much about in shop or mill, but it is a useful material to the electrical machinist, the wireman, the telegrapher, and others. The accompanying illustrations will give the reader an idea of some of the services to which the rawhide is put in the every-day electrical construction shop.

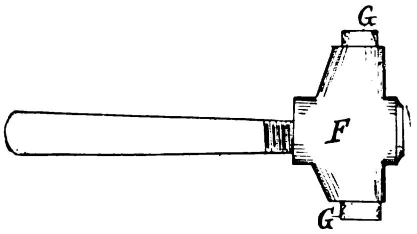

FIG. 5.—RAWHIDE FACED HAMMER.

I have noticed a number of wheels made for frictional contact purpose, designed on the pattern indicated in Fig. 1. The rawhide portion consists of the series of discs B, which may be almost any sizes from 2 to 12 inches in diameter. I have seen a number of little frictional wheels thus made for electrical machinery. The discs are clamped tightly between the flanges, A, which are secured to the shaft with proper set screws or keys. One of the discs in readiness for use is shown in Fig. 2. I have seen in some shops lagged wheels, in which a surfacing of rawhide, C, was applied to the rim, D, as shown in Fig. 3. The sheeting of rawhide is applied just as a leather lagging would be; it is fastened to the rim of the wheel by rivets.

The writer observed some odd-shaped tools in use, the handles of which appeared to be wound, as represented in Fig. 4 at E, with some material which close observation showed to be strands of rawhide. The binding enables the workman to grip the handle of the tool more securely. The strands are strong and reliable. Fig. 5 illustrates a type of rawhide-faced hammer employed in some of the electrical workshops. The erecting department is furnished with these hammers, for it is possible to deliver quite a telling blow upon painted metal with the rawhide-faced hammer and not damage the painting or finish. The hammer body, F, is

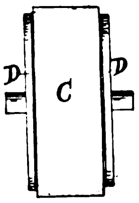

FIG. 3.

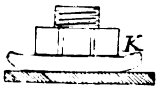

FIG. 7.

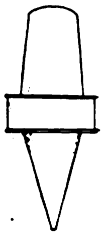

FIG. 8.

frequently made of a pipe tee, in each end of which is set a plug of rawhide, *G*. The handle may be a section of pipe threaded into the tee as shown. These hammers are usually made to order by the local machinists.

I have also noticed that rawhide stock is being utilized in connection with journals of electrical apparatus. The surface of sheet rawhide, when properly fitted as a sleeve or lining for a bearing, makes a yielding bed for the revolving shaft. It is not considered workman-like to use rawhide extensively for this purpose, but worn bearings, bearings made undersize, and refractory bearings have been refitted with rawhide linings and made to run indefinitely.

I saw a journal bushed with a rawhide sleeve about ⅛ inch thick. On the other hand, I noticed some electrical machinery in which the workman had used a rawhide sleeve (Fig. 6) bushed with a split metal liner. The object of this odd arrangement was to get an elastic support for the journal sleeve. The tough yet flexible rawhide eased the shaft just enough to give the special conditions sought by the machinist.

I found that rawhide washers on electrical devices were a failure except when thin metal washers were used on the upper side of the rawhide. Fig. 7 indicates what occurs when rawhide washers are used without the proper protecting washers of metal. The rawhide washer is represented at *K*. Shrinkage and various conditions of wear, tear and exposure, would tend to impair the solidity and uniformity of the rawhide washer on any machine, unless there were a proper capping washer of metal at least as large in diameter as the rawhide washer itself.

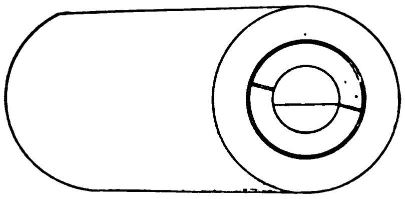

FIG. 6.—RAWHIDE SLEEVE BUSHED WITH SPLIT METAL LINER.

I have seen rawhide pins in use in the wood-working department of some electrical wood frame construction shops. The pins are about an inch in diameter and are calculated to take the place of wood pins in securing parts of wood frames; the pins are tapered and serve their purpose quite well.

Fig. 8 shows a form of stud made of rawhide. The pointed part is sunk into a hole and screws through the flange or shoulder to secure the pin in position. The slightly tapered projecting stud can be used for several purposes. Link chains of rawhide are made by riveting several ticknesses of the appropriately cut rawhide together. Each link is looped with its corresponding link, of course, before the rivets are put in. After the parts are riveted, the rivets are smoothed down with a file and the chain finished off.

Abstracts from Foreign Contemporaries

Small Gas Engines vs. Electric Motors. Gas engines operated under favorable conditions are certainly economical as a source of power, and it is often very difficult to persuade users to abandon them in favor of an electric motor. The power represented by such engines would constitute a very desirable load for any central station capable of supplying it, since the average result would be a fairly steady load which would be worth a considerable amount of trouble to get. A writer in a recent issue of the London *Electrical Review*, who is endeavoring to replace a large number of small gas engines by electric motors, has carefully inquired into a considerable number of cases with some remarkable results. He cites this typical example: A 14-brake-horse-power gas engine in a joiner's shop, stated to work at an average of half-load for 48 hours a week, which is equivalent to 7 brake-horsepower for 624 hours per quarter. The actual gas bill for the quarter was $26.70. A brief calculation shows that for the load and hours stated current at $0.03 per unit would cost $121.50. Illuminating gas is used at $0.60 per 1000. Taking the consumption of gas at an average of half-load as 30 cu. ft. per brake-horse-power-hour, for the load and hours given the gas bill should amount to $79.44. It is therefore evident that the engine does not do one-third of the work with which it is credited. The brake-horse-power-hours equivalent to a gas bill of $26.70 are 1467 instead of 4368 as stated, so that the actual performance of the engine may be stated as a first approximation as 7 brake-horse-power for 209 hours per quarter. The engine is however running for 624 hours per quarter, so it must be running for 415 hours per quarter without load. Such an engine would consume 50 cu. ft. of gas per hour when running empty which would amount to 20.75 thousand cu. ft. per quarter or $12.60 out of a total bill of $26.70. But this amount of gas has done no useful work and the equivalent must therefore be deducted from the brake-horse-power-hours above arrived at. $27.60 per quarter is equal to 44,000 cu. ft. less 20,750 cu. ft. or 23,250 cu. ft.; which is equivalent to only 775 brake-horse-power-hours of useful work per quarter. The total cost of running the gas engine per quatter including wages, repairs, etc. is $43.74 or $.057 per brake-horse-power-hour of useful work. Taking the case of electricity, in this case to be supplied at say $.03 per unit to a polyphase induction motor with 82 per cent efficiency, and assuming that care is exercised in switching off the motor when not required, he finds that the total cost of running the motor per quarter is $24.42 or $.031 per brake-horse-power-hour. The saving due to electric power is therefore $78.24 per annum or 44½ per cent. Interest, depreciation, etc., are neglected in both cases, as it is a question of exchange and not of first choice, and, therefore, does not appeal much to the consumer. The inclusion of these items would, of coures, make the comparison still more favorable to the motor. It may be noted also that 30 cb. ft. of gas per brake-horse-power-hour, with gas at $0.60 per 1000, works out to $0.18 per brake-horse-power-hour, which does not at first sight look like an easy figure to beat. The above calculation might be worked out in many different ways, but to assume that the engine really does average half-power, as stated by the owner, appears as fair a basis as any. It is probable that in practice the comparison will, in many cases, be even more favorable than the above. Gas engines have usually small overload capacity, so that an engine of rated power, at least equal to the maximum load expected, must be installed. Thus in the above case the 14-brake-horse-power engine works at an average of half load (probably much less), and the efficiency would not be above 76 per cent. On the other hand, standard polyphase induction motors can be obtained with a guaranteed overload capacity of 50 per cent for one hour, or 25 per cent for 10 hours, and for intermittent work in such a case as that given a 10-h.p motor might be safely installed to deal with the load. Such a motor would then operate at an average of about three-quarter load, with an efficiency of at least 82 per cent, and at lighter loads the advantage would be still more marked.

Notes on Dielectric Losses.—Dr. Paul Holitscher, in a recent contribution to the *Elektrotechnische Zeitschrift*, communicates the results of measurements on dieletric hysteresis in the micanite tubes used for insulating the conductors in high-voltage machines. The dielectric losses between the magnet frame (which was earthed) and the armature copper of a 10,000-volt 500-h.p., three-phase synchronous motor were first determined. At a constant frequency of 53.3 cycles per second the losses given in Table I. were observed, and it will be seen that the increase is—for the higher pressures—approximately proportional to the third power of the voltage. The capacities derived from the measurements with the aid of the transformer diagram, are also given in the table, and it will be seen that they increase with the pressure:

TABLE I.

Secondary of Testing Transformer. Volts.	Amps.	Dielectric losses. Watts.	Capacity. Mfd.
9,000	0.115	354	0.0365
13,150	0.174	785	0.04233
15,130	0.213	1,265	0.0458
18,000	0.293	2,290	0.0538

21,550	0.43	4,860	0.0700

When the machine is in service, the neutral point of the phases is connected to the frame, and only the extreme end of each winding has, therefore, the maximum potential of 5,770 volts. If, from about 6,000 volts downwards, the dielectric losses are assumed to be proportional to the square of the pressure, the lost energy through dielectric hysteresis will amount in the above case to 40 watts—*i.e.*, 0.013 per cent. of the full load output. Some results obtained with a second machine, designed for 400 kilowatts at 10,000 volts, are tabulated below (Tables II. and III.):

TABLE II.

Frequency per sec.	Secondary of Testing Transformer.		Dielectric losses.	Capacity.
	Volts.	Amps.	Watts.	Mfd.
40	15,500	0.101	572	0.0282
45	15,500	0.114	648	0.0281
50	15,500	0.127	726	0.0280
55	15,500	0.135	767	0.0272
60	15,500	0.147	820	0.0270
65	15,500	0.155	880	0.0265

TABLE III. (50 Cycles per Sec.)

Impressed volts.	Dielectric losses. Watts.	Capacity. Mfd.
12,000	290	0.0213
15,500	726	0.0280
19,200	1,145	0.0332

To complete the tests, the insulation resistance of the second machine was measured and found to be 21 megohms. At a voltage of 15,500 volts, therefore, the I^2R losses ($R=21$ megohms) would be about 12 watts, which does not materially affect the result of the tests.

Gutta Gentzsch.—This is the name of a new insulating substance recently introduced into England, and which, if accounts be true, has already achieved a remarkable measure of success on the Continent. Judging from the account published in a recent issue of the London *Electrical Review* "Gutta Gentzsch" should in the near future play an important part in the insulation of submarine cables particularly as the growing scarcity of gutta-percha and the consequent enhancement of its price have rendered the use of unadulterated gutta-percha almost prohibitive. Various mixtures are employed, none of which are however given, according to whether it is designed as a substitute for gutta-percha in the insulation of submarine cable cores, or whether as an insulator for electric light wires and cables for use on land. The material has been used for some time in Germany so that it is not by any means a mushroom growth. A few of the physical and electrical properties of this material are of interest. The dielectric resistance is equal to that of natural gutta of similar quality. The softening point is considerably higher than that of natural gutta-percha ("Gutta Gentzsch," about 130°; real gutta, about 100°). In the case of submarine cores the capacity rises for some weeks after immersion, but attains a constant value which compares well with the inductive capacity of similar sized real gutta-percha cables. The price is very much lower than that of real gutta-percha. The specific gravity is about the same as that of water. "Gutta Gentzsch" cools more rapidly than real gutta-percha, this being an important advantage from a practical standpoint in the covering of wires with the material. The resistance of "Gutta Gentzsch" to the influence of oxidation and of the effect of light is remarkably great, as compared with natural gutta, which, as is well known, soon becomes hard and brittle, and entirely loses its valuable properties when exposed to light and air, particularly in dry positions. With regard to this latter property, two experiments may be mentioned: Dr. Weber exposed thin sheets of "Gutta Gentzsch" and of natural gutta-percha to the action of oxygen at a temperature of 86° Fahr. for eight days and nights at the end of which time the gutta-percha had become so oxidized as to fall to pieces on handling, whereas the "Gutta Gentzsch" was very little oxidized and was practically unchanged as regards suppleness. A corroboration of this is found in the behavior of a coil of wire covered with "Gutta Gentzsch" and exposed to the atmosphere and sun for two years. This could be twisted until the copper conductor broke without breaking the "Gutta Gentzsch" covering. Mr. James Swinburne also attests to this peculiar characteristic of the material. The field for "Gutta Gentzsch" is not limited to its being used as a substitute for natural gutta-percha, as its name would seem to imply. It has already been determined that it can be employed successfully, both electrically and commercially, as an insulating medium for electric light wires and cables, which are now insulated with vulcanized india-rubber, and the reason is not far to seek. It is well known that vulcanized india-rubber cables do not stand well in damp places, whereas damp does not appear to effect "Gutta Gentzsch" at all. In this regard it behaves more like the natural gutta-percha. Further, the specific gravity of the rubber mixtures which are used for the good quality of insulated wires and cables, ranges from the minimum of 1.5 to 1.7 and even higher; whereas the specific gravity of "Gutta Gentzsch" is very little higher than that of water. "Gutta Gentzsch" floats when it is warm and gradually sinks when cold, the specific gravity being about 1.03, but varying slightly with the various qualities. These two circumstances, taken in conjunction with the comparative hardness of the material as compared with gutta-percha, and its high dielectric resistance, should render it eminently suitable for the insulation of wires and cables and for a wide variety of other purposes.

Water-Tube vs. Flue Boilers.—At a recent meeting of the Manchester Association of Engineers, Mr. A. Hobbs read a paper on water-tube boilers for stationary work. Mr. Hobbs, in his paper, after describing in detail the respective types of tube boilers now principally in use, said that the Lancashire boiler was still the most popular steam generator for mill and factory purposes, and, properly worked, it was certainly an efficient tool, but probably its most ardent admirers would admit that it was not perfect as a steam generator. He thought they would agree that the heat efficiency of a boiler and the rapidity of its water circulation were almost inseparable. The circulation in a Lancashire boiler was due to convection currents alone. In a water-tube boiler the circulation was due not only to convection, but to the actual difference in density of two columns of water of different temperature separated from each other. Other factors, all tending to give the water-tube boiler a higher heat efficiency than the Lancashire boiler, were the splitting up of the gases into smaller streams, the thin envelope separating the hot gases from the water, in comparison with the thickness of flue plating in a Lancashire; and the fact that the external surfaces of the water-tube boiler could be cleaned or scraped, through the access doors in the sides of the setting whilst the boiler was under steam, whereas access to the external flues of a Lancashire boiler could only be obtained during a stoppage, usually at rare intervals. It was a significant fact that water-tube boilers were now being largely used in collieries, ironworks, and other places, where, only a few years ago, they were seldom heard of. The most important questions from a steam user's point of view were, whether by using water-tube boilers he could reduce his coal consumption, running and maintenance costs, and obtain increased reliability for approximately the same outlay as would be incurred by installing shell or fire-tube boilers? The cost of the water-tube boiler installation could be taken at 3 per cent lower than for the Lancashire boiler installation, and, at the same time, it occupied 30 per cent less floor space. As regarded efficiency or coal consumption, makers of any of the leading types of water-tube boilers would guarantee an efficiency of not less than 70 per cent of the heating value of the fuel, under ordinary conditions, say, 10 lb. of water per pound of coal, and if they took what was a high figue, *i.e.*, 9 lb. for the Lancashire boiler, the reduction in coal consumption was still 10 per cent in favor of the water-tube boiler. Mr. S. Boswell contended that if a large surface for liberation of steam bubbles was of importance, the Lancashire or shell boiler had a very great advantage over any other type. He did not think so much need be made out of the scale and deposit question. Only a few days ago he had taken out a flue boiler after thirty years' work night and day, and during the whole of that time a tool had never been used on it by way of repair. So far as economy was concerned, he might give two trials in America of water-tube *vs.* flue boilers, the results of which were: Galloway, 12.012 lb., water per pound of combustible; Babcock, 11.88 lb., of water per pound of combustible; water in steam, Galloway, 0.57 per cent; water in steam, Babock, 3.24 per cent. Mr. Piggott said it had been claimed that in some of the best tube-type of boilers it was almost impossible for these to become scaled. All he could say was that no amount of rapid circulation of water etc., would stop scaling, and that where water contained scale-forming properties the latter would be deposited. He had seen scale under all conditions and in almost every type of boiler, and no theory would convince him that scaling was an impossibility in a water-tube boiler. He agreed that the Lancashire type of boiler was not good for high-pressure steam. The boiler had to be held together by what he called "brute force," the strains on the structure being enormous. There was too much made of the capacity of the Lancashire boiler. The water-tube boiler could do just as well with sudden demands of steam as the Lancashire boiler and the American used, comparatively speaking, nothing else but the water-tube boiler. There was, however, one certain thing with a Lancashire boiler, unless it had its economizer behind it, it was a very uneconomical type of steam-raiser.

Governing Engines Driving Electric Generators.— When the load on an engine driving a dynamo varies suddenly, the governor must be moved quickly in order to alter the rate of admission of the working medium to the proper amount. This quick movement, however, involves a corresponding expenditure of energy which is not obtained from the governor until considerable variations have taken place in the number of revolutions of the engine. It follows therefrom that the governing of the engine lags behind variations of load, and the fluctuations of the potential of the dynamo, driven by the engine, are not compensated for, and the increase of speed of the engine altered, until a corresponding current impulse has passed. The London *Mechanical Engineer* describes an invention of the German firm of W. Lahmeyer & Co., the object of which is to provide in connection with the governors of engines employed for driving electric generators an electrical device for accelerating or retarding the governor in its controlling action. The centrifugal governor of the driving engine is controlled in its action by a solenoid traversed by the working current, the core of the solenoid acting either directly or indirectly on the sliding sleeve of the governor, the controlling of the governor magnet being effected, without the intervention of any intermediate members, by the main current of the dynamo. Any variation of the load on the dynamo affects the working of the engine governor before the speed of the engine has undergone any important variation. The equalization of the load and energy supply are thereby effected earlier and the fluctuations decreased both as regards time and magnitude. Fig. 1 is a diagrammatic view of the device proposed. *R* is the centrifugal governor, the sleeve *M* of which can be shifted by the force exerted by the core *K* of the solenoid *S*, which is included in the circuit of the dynamo *D*, so that the magnetic pull acting on the core *K* varies according to the load on the line *N*. A sudden rise of the current that flows through the solenoid *S* will therefore assist the governor in its action.

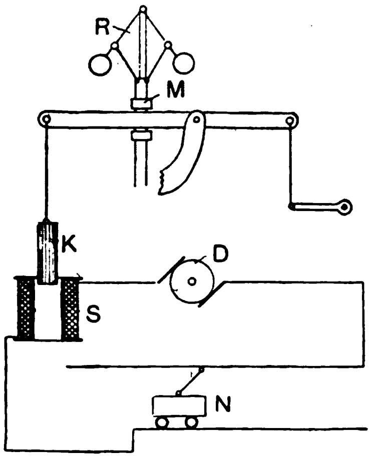

FIG. 1.—ENGINE GOVERNOR.

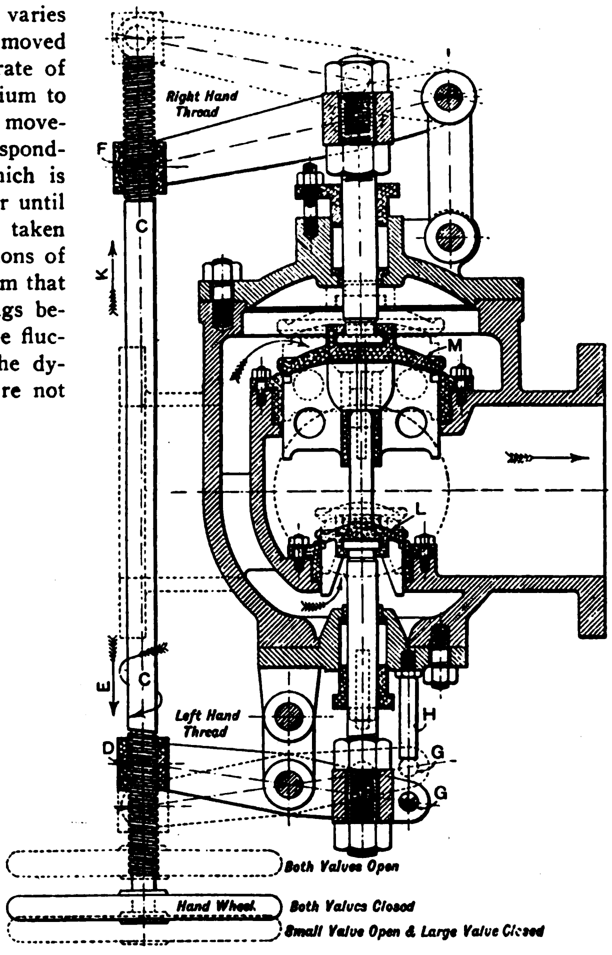

FIG. 2.—BALANCED STOP VALVE.

A New Balanced Stop Valve.—In order to overcome the difficulty of leakage and want of easy control experienced with single-seat and double-beat valves of the ordinary type, Holden & Brooke of Manchester, England, have introducted a new balanced stop-valve, the design of which will be clearly understood by reference to Fig. 2. The two valves are to a certain extent independent in their movement on one another. The smaller valve *L* has the pressure on its under side, the admission steam pressing on the larger valve *M* from above. It is evident that, when opening the valve, the small valve *L* will be the first to open and will continue to do so until the pin *G* comes into contact with the stop *H*. By this time the pressure has become equal on both sides of the larger valve, and, if the turning of the handwheel be continued, the large valve will now be lifted. The spindle *C* has a left and a right-hand thread. Although each valve is closed positively and independently, no force is required to open them, since the opening movement is assisted by the steam pressure on the under side of the small valve. It is said that the time required to open or close the valve is very short, only 12 turns of the handwheel being required, for example, to fully open or shut the 10 in. size of valve. In the standard pattern, the valves and seatings are made of phosphor bronze, the bodies being of cast-iron, steel or gunmetal according to steam pressure. The valve can also be made to operate by direct lever action instead of by screw. We are indebted to the London *Electrician* for the foregoing illustration and data.

Losses in Porcelain Insulators.—In an article on this subject by R. M. Triese in the *Elektrotechnische Zeitschrift*, it is stated that porcelain insulators may be regarded as small capacities, the two sides of which are formed by the holder (earth) and the wires respectively, the dielectric being the porcelain. In certain tests, a large number of insulators connected in parallel were suspended head downwards in a bath of water connected to one terminal of the testing transformer, the surface of the water being level with the neck of the insulator. The

holes in the insulator, provided for the iron supports were filled with water, and electrical contact with the other pole of the transformer was made by means of metallic chains dropping in the holes. In Tables I and II are recorded the results of the tests. Table I refers to an insulator of an older type, possessing a double petticoat and weighing 3.44 lbs., while Table II concerns a modern type of insulator with four petticoats and weighing 2 lbs. Both types withstood approximately the same disruptive tension. The frequency of the testing current was 50 cycles per second.

SOME RECENT ELECTRICAL PATENTS

Lamp Receptacle for Conduit Mounting.—Figs. 1 and 2 illustrate a compact lamp receptacle intended to be mounted directly on the side of a conduit pipe, as shown clearly by Fig. 2; the pipe to have a rectangular hole cut in the side, as indicated at *a*, Fig. 1, to receive the downward projection of the receptacle base. This projection, b_2, carries the connecting lugs, b_3, and b_4, of the socket, and the wires in the conduit are clamped to the lugs without being cut. In applying the receptacle to a piece of conduit pipe, the wires are pulled through the hole *a* in bights, the insulation cleaned off for a suitable distance, and the conductors clamped under the binding screws of the socket; then the wires are drawn taut in the conduit and the receptacle base set into the hole. The receptacle base is screwed to the wall of the conduit pipe, and the shell *C*, which entirely encloses the base as well as the lamp socket, is held in place by the springs *c* and *c*, Fig. 1. Patent No. 752,834.

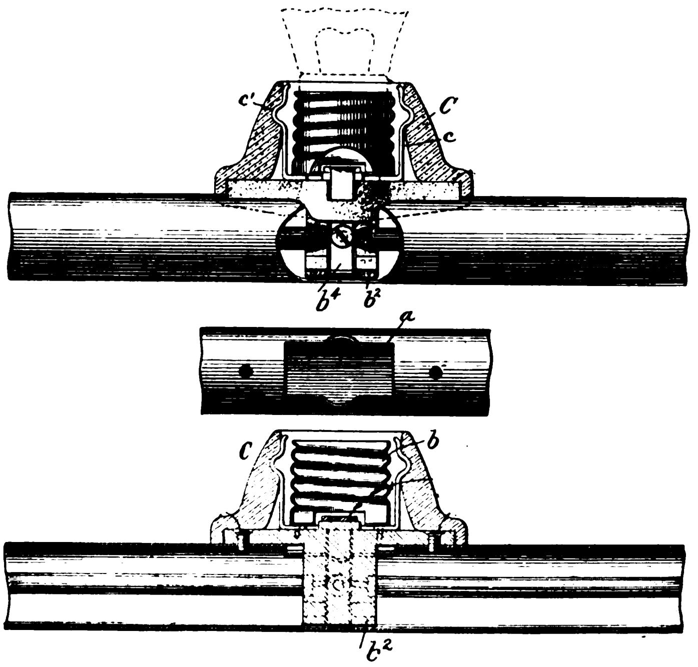

FIG. 1.—LAMP RECEPTACLE FOR CONDUIT MOUNTING.

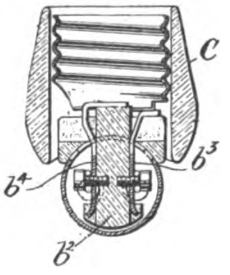

FIG. 2.

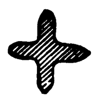

FIG. 3.

Insulator Pin.—With the view of producing a pin for supporting the large, heavy porcelain insulators now used for high tension transmission lines without involving the location on the cross-arms of an undue weight of material, James H. Bullard, of Springfield, Mass., has devised the form of pin shown by Figs. 3 and 4. The pin is to be made of cast metal, presumably steel, and the upper portion of it is of the cross-shaped cross-section shown by Fig. 3, which is taken on the line *2—2*. The four vertical webs separate toward the bottom end of the pin, and their lower ends are united in a disc or plate, *c*, from the under side of which projects a hollow shank, *d*. Making this shank hollow confers two advantages: the pin is lightened and there is space for the retaining bolt, *P*, without having to drill through the shank. The bolt passes through the base plate, *c*, and is provided with the usual nut and washer at the lower end. The upper part of the pin is notched, as shown at *g*, but not necessarily in the form of a screw thread; it is contemplated to serrate the interior of the insulator at *i*, and to pour cement or molten metal into the insulator while the pin is in it, this cement or metal being intended to fill in the spaces between the webs and take hold of them and the insulator by filling also the serrations and notches. The inner "petticoat" of the insulator is indicated, of course, by the dotted figure, *h*. Patent No. 754,123.

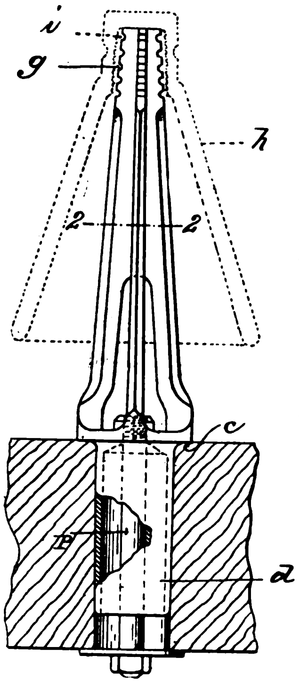

FIG. 4.—INSULATOR PIN.

Machine Tool Motors.

To the Editor American Electrician:

I have read with interest an editorial which appeared under the above heading in your March issue, and which I consider a timely warning against the indiscriminate use of any given system of motor speed control.

In the first paragraph, I noticed the sentence, "It is not often, however, that individual motor drive is economical in very small units; it is also frequently inadvisable to obtain variable speed by means of complex systems of supply." Doubtless no one could be found to question the truth of these statements; and if any criticism were made, it would be on the ground that the reader is left with the impression that variable speed is to be secured only at the sacrifice of efficiency or by use of complex systems.

In the third division of the editorial referred to, a comparison is drawn between the multiple voltage and double commutator method of speed control. Here again I should be inclined to criticise this paragraph, not on account of any statement contained therein, but on account of what was left unsaid. I think that the uninformed reader would naturally arrive at the conclusion that there were just two methods of variable speed control, the multiple voltage and the double commutator method; and that if he doesn't like either one, there is no alternative. The fact is that those who have had occasion to investigate the various methods of speed control are aware of the fact that there is upon the market at least one type of variable speed motor in which, without sacrificing other desirable features, the limit of simplicity appears to have been reached. I refer to the motors known to the trade as Stow multi-speed motors, built by the Stow Manufacturing Company, Binghamton, N. Y.

As in nearly all other motors, the pole-pieces of the Stow machine are stationary, the speed variation being accomplished by the simultaneous adjustment of cylindrical iron cores within the pole-pieces; this arrangement permits a wide variation in field strength without detriment to commutation. These motors furnish their full rated output at the lowest speed or at the highest, or at any desired speed between these limits and with a high and practically uniform efficiency over their entire range. In moderate sizes, these motors have a range of speed in ratio of 1 to 2.25 when operated on a two-wire circuit, 1 to 4.5 on a three-wire system, or 1 to 9 when furnished with double commutator and fed from a three-wire system.

It would appear that a motor having these characteristics is entitled to mention in an article purporting to compare the available methods of speed control. If the general use of this motor is questioned it may be mentioned that hundreds of them are in actual use in this country and in Europe, and that the makers will gladly refer to plants in which scores of these motors are in operation.

If the editorial referred to was written with a desire to inform, which I do not question in the least, it seems hardly consistent for comment to be directed against this and that complex method without calling attention to improvements in the art by which complexity is avoided.

G. F. PACKARD.

Binghamton, N. Y.

[We are glad to give publicity to the foregoing views. We may say, however, that our remarks were entirely general and not intended as a criticism of multiple speed *per se*, nor as a discussion of the merits or demerits of any particular system; the aim was merely to indicate in a broad way conditions under which a few well-known classes of speed control would probably make the best showing. As intimated in these remarks, it would not be practicable, within the limited space of our editorial pages, even to refer to, much less to discuss adequately, all of the specific methods of obtaining a multiplicity of motor speeds.—EDITOR.]

◆◆◆

NOTES.

Iowa Electrical Association will hold its convention this year at Des Moines, Ia., April 13 and 14.

A Correction.—In the annual fan motor article which appeared in our last issue, it was stated on page 130 (31st line of the first column) that the Eck oscillating fan motor is tilted forward and back by the oscillating mechanism. This statement was erroneous; the oscillating mechanism causes the motor to swing from side to side like the others of its class.

James Watt Memorial.—A memorial statue is to be erected in Greenock, Scotland, on the site of the cottage in which James Watt was born. For the purpose of obtaining American subscriptions to this memorial, an American committee, of which Mr. Andrew Carnegie is chairman, has been appointed. The committee consists of the presidents of the Electrical, Mechanical, Mining and Civil Engineers' national organizations, together with men prominent in the industrial world. Contributions to the memorial fund should be sent to Mr. Theodore Dwight, secretary and treasurer of the American committee, whose headquarters are at 99 John Street, New York.

A Flourishing Municipal Lighting Plant.—The eleventh annual report of the Board of Electrical Commissioners of South Norwalk, Conn., for 1903 makes a very favorable showing for the municipal plant of that city. It is obvious from the financial results, the personnel of those directly responsible for these results, and the municipal policy which determines this personnel, that the success of the plant is due primarily to the absence of politics in its control. The system is in the immediate charge of Mr. Albert E. Winchester, who is allowed to operate it on a purely business and engineering basis, and he deserves hearty congratulations upon the results of his efforts.

Safety Precautions for the Berlin Underground Railway.—Shortly after the Paris disaster, a commission was appointed to determine such precautionary measures as would be likely to increase the safety of service on the Berlin underground railway. The recommended precautions have now for the greater part been carried out. To the lighting circuits of the tunnel has been added an extra independent wire, so that in the case of one-half of the circuits being injured, the second half will not be affected. The conductors' stands on the underground railway stations are so designed as to be readily pushed aside. The number of fire hydrants has been increased, and each car has been fitted with a sand box. There are bucket fire engines in each car, as well as in the tunnel at distances apart of 100 meters (328 feet). Each station has been connected to the fire brigade alarm line. The emergency lamps in the cars are prevented from coming into contact with the curtains, and the latter are of a heavy impregnated wool stuff. Each motorman's stand is provided with devices which may be operated, even within the car, serving to cut the current off the line.

The Allis-Chalmers—Bullock Amalgamation.—One of the most important industrial deals that has been consummated since the formation of the General Electrical Company was put through recently by the practical amalgamation of the Allis-Chalmers and the Bullock Electric Manufacturing Companies. The contract made by these companies provides for the organization of a new Bullock Company with a paid-up capital of $500,000, all common stock, to lease the plant of the present Bullock Electric Manufacturing Company, which company will remain intact. The lease will be for a term of twenty-five years, with the privilege of renewal. Mr. George Bullock, president, and Mr. Joseph Neave, vice-president, of the present Bullock Company will be president and vice-president of the new company, and these two gentlemen together with three officers of the Allis-Chalmers Company will form the board of directors of the new Bullock Company. The plants of the Allis-Chalmers and Bullock Electric Manufacturing Companies will be, of course, operated as though they were absolutely owned by a single organization. The combination is a strong one. As is well known, the Allis-Chalmers Company is prepared to build, in addition to its well-known steam engines, the Nurnberg gas engine and has also arranged with an English syndicate for the manufacture of horizontal turbines. Arrangements have been made also with the Swiss firm of Escher, Wyss & Company for the manufacture of the water turbines and other hydraulic machinery controlled by the patents of that company. The Bullock Company has facilities for manufacturing complete lines of electrical apparatus for every class of lighting and power service. This company built for the Cincinnati Gas & Electric Company the largest direct-connected 60-cycle alternator that has ever been manufactured, and is also said to have built the largest synchronous motor sets in the world, which are in operation in Canada. The alliance with the Allis-Chalmers Company will result in very large additions to the manufacturing facilities of the Bullock plant.

Union Engineering Building.—It is well known to our readers that Mr. Andrew Carnegie offered to furnish the money to erect a union building for the Electrical, Mechanical, Mining and Civil Engineers' national organizations and the Engineers' Club of New York, and the prospect appeared favorable for the consummation of this plan until the American Society of Civil Engineers, on March 2, voted against the acceptance of Mr. Carnegie's offer, the vote standing 1139 to 662. This action, of course, cancelled the original offer, but Mr. Carnegie immediately renewed his offer to the other organizations in the following letter:—

ANDREW CARNEGIE,
2 East 91st Street, New York.
March 14th, 1904.

GENTLEMEN OF THE MECHANICAL ENGINEERS; INSTITUTE OF MINING ENGINEERS; INSTITUTE OF ELECTRICAL ENGINEERS; ENGINEERS' CLUB OF NEW YORK:

It will give me great pleasure to devote, say, one and a half million of dollars for the erection of a suitable Union Home for you all in New York City. With best wishes, truly yours,

(Signed) ANDREW CARNEGIE.

The Union Engineering Building, therefore, is assured. In addition to the $1,500,000 contributed by Mr. Carnegie for the erection of the building, the four societies named have invested over half a million dollars in land for the site of the building. The Union Engineering Building will probably be twelve stories high and will contain four or five auditoriums of different sizes, one of which will contain a seating capacity of 1500. All of them will be appropriately equipped for scientific meetings, lectures and demonstrations. There will be an engineering museum and a magnificent library hall where the libraries of the several organizations will be grouped and consolidated, each section being administered by the librarian of the society owning it. The societies, of course, will in no way be consolidated; each will maintain its identity and autonomy and will have individual quarters in the building. The representatives of the four bodies which have been made the beneficiaries of Mr. Carnegie's splendid gift, are as follows: F. R. Hutton, C. W. Hunt and J. M. Dodge, from the American Society of Mechanical Engineers; Dr. A. R. Ledoux, Theodore Dwight and C. Kirchhoff, from the American Institute of Mining Engineers; Charles F. Scott, Dr. S. S. Wheeler and Bion J. Arnold from the American Institute of Electrical Engineers; J. C. Kafer, W. H. Fletcher and T. C. Martin, from the Engineers' Club.

Predetermining Solenoid Performance.

Anyone who has ever attempted to make a solenoid to do a predetermined amount of work, using the familiar traction law as the basis, has made the unpleasant discovery that the traction law does not apply even remotely when there is an air-gap of appreciable length. Of course, this fact is well known to those versed in electromagnetic theory, and it has also been well understood that the pull of a solenoid or electromagnet at any given position of the armature or plunger is directly proportional to the increment of flux increase per increment of movement that would result from such movement. The application of this latter principle to actual practice, so far as we are aware, is explained in print for the first time in Mr. Del Mar's article in this issue. In order to make his deductions conform perfectly with the fundamental laws governing the case, Mr. Del Mar has used the calculus in presenting the analysis of his reasoning, but it is not at all necessary to use calculus in applying his method to practical work, as he himself indicates by taking arithmetical averages over small distances instead. Where a close approach to accuracy is essential, the distances should be very small, of course.

The method of obtaining the flux gradient by calculating the individual reluctances of the different parts of the magnetic circuit for each position of the plunger might be somewhat simplified by using suitable constants instead of reducing the dimensions of the circuit to metric measure, or by making the solenoid parts all to standard metric measure, as one prefers; but probably the most practical method would be to work in terms of ampere-turns per inch length of path required at given densities. The whole procedure is necessarily of the cut-and-try character, so that it would be as expeditious to work from curves showing the exciting force per inch of length required at different magnetic densities as to use permeability curves and reduce from English to metric measure to ascertain the reluctances. The "gradient" method has the disadvantage of being non-reversible; one cannot assume the pull desired and solve the gradient formula for ampere-turns. Nevertheless, it is far superior to the guess-work that is entailed by attempting to predetermine solenoid characteristics without applying this method.

It should not be overlooked that the success of the gradient method depends on the practicability of calculating the magnetic flux that will be produced by a given excitation with the movable member of the system in a given position. The longer the air-gap, the more spreading of magnetic lines there will be, even when the air-gap is entirely enclosed in the exciting coil, as in the type of solenoid considered in Mr. Del Mar's article. If the apparatus is an ordinary electromagnet, the spreading will be very much greater, and it is practically impossible to estimate the reluctance of the air-gap with any approach to accuracy; moreover, magnetic leakage around the outside of the magnet coil or coils, which cannot be even approximated by computation, would vitiate any calculations based on the theoretical flux in the air-gap. The method, therefore, does not appear to be applicable to any case except that of a solenoid in which the exciting coil completely encloses the air-gap and the length of the latter is small in comparison with the length of the coil along its axis. Since most modern solenoids are of exactly this type, however, for the reason that it is the most efficient, the gradient method should be of much practical value, notwithstanding its shortcomings when applied to other types of electromagnet.

The Union Engineering Building.

As noted in another column, Mr. Andrew Carnegie just before his departure for Europe completed the details of his splendid donation to the engineering profession. While the electrical, mechanical and mining national engineering associations are the direct beneficiaries of Mr. Carnegie's generosity, all engineering and scientific organizations that may desire to establish headquarters in the new building will share the benefits with the societies mentioned. In fact, one of the reasons for the delay in putting the terms of the benefaction in final form was Mr. Carnegie's desire to learn whether or not the proposed establishment would be a union engineering building in reality as well as in name. The result of an investigation on this point has been extremely gratifying, numerous representative engineering and scientific bodies having made formal application for quarters in the proposed building.

In addition to furnishing a suitable home for the principal engineering societies whose headquarters are in New York, Mr. Carnegie's gift will undoubtedly have the effect of promoting closer affiliation and co-operation between these bodies by reason of the intimacy of association which will result from joint occupancy of the Union Building. Moreover, this intimacy of association will not only tend to strengthen the cordial relations already existing between the several organizations and facilitate the furthering of interests which they have in common, but it will undoubtedly develop and enhance personal friendliness between individual members of the societies. These latter features alone will more than justify Mr. Carnegie in his latest benefaction to science and engineering.

Manual vs. Automatic Telephone Exchanges.

The article on this subject which we print elsewhere in this issue can scarcely fail to impress the unbiased reader as a very clean-cut, impartial discussion. There are many points of advantage on both sides, and while Mr. Knowlton seems to think that the preponderance thus far is on the side of the manually-operated exchange, it cannot be said that his argument is at all partisan. The fact that the automatic class of exchange has made conspicuous headway during the past few years, and the lively interest in that type of apparatus which the Bell organization is manifesting, are strong evidence that the automatic exchange is entitled to very serious consideration. On the other hand, as Mr. Knowlton points out in detail, one must "go slow" in adding to the routine which a subscriber has to follow in obtaining a connection with another subscriber. The present central energy systems are marvelously simple so far as the amount of effort imposed on the calling subscriber is concerned; in compensation, of course, there are the too familiar annoyances incident to conferences between irascible subscribers in a hurry and pert telephone operators laboring under an exaggerated sense of their own importance.

It would seem that the most serious obstacle to be overcome in automatic exchanges is the difficulty in obtaining long-distance connections promptly. A mixed automatic and manual system would, of course, be necessary to a solution of this problem, and while such a mixed system might develop some extremely troublesome features at first, there seems to be no good reason why these cannot be eventually eliminated. The drawback of imposing upon the subscriber the work of setting up the number he wants to call might be serious in very large exchanges, but it could be reduced to practical insignificance in those of moderate and small sizes. However, the question cannot be discussed satisfactorily in the absence of complete reports of the results obtained with automatic exchanges in practice; many difficulties apprehended from theoretical considerations may never develop at all, and many "snags" which could never be predicted or even suspected will certainly crop out under conditions of daily practice. This is true of all classes of invention.

Power Factor.

Although the meaning of the term "power factor" has been explained in this part of the paper two or three times and was briefly discussed in the Lessons Department last month, the receipt of many letters asking for information on the subject moves us to explain once more than the "power factor" of an alternating-current circuit is the number by which the apparent power in the circuit must be multiplied in order to ascertain the actual or true power, in the absence of an instrument which will indicate the true power. The power factor is always a number less than unity; when the apparent power and the true power are identical, the circuit is commonly said to have a "power factor of unity," but logically it has no power factor for the reason that there is no need for the use of one except when there is a discrepancy between the apparent and the true power.

When an alternating-current circuit contains inductance, the current lags behind the e.m.f., and when it contains capacity the current rises ahead of the e.m.f.; in each case the current and e.m.f. reach their maximum values at different instants, and the product of e.m.f. and current ($E \times I$) at any instant is less than it would be if the two were in phase with each other. If the e.m.f. and current be measured separately, the voltmeter and ammeter will give the individual mean effective values; if they are measured by a wattmeter, the instrument indicates the combined effect of the two synchronously, not the product of their mean effective values, which occur at different instants. Consequently, the wattmeter indication is less than the product of the separate voltmeter and ammeter readings; the ratio of the former to the latter is the power factor of the circuit.

Assume, for example, that a voltmeter and an ammeter connected up at the terminals of an induction motor indicated 200 volts and 120 amperes, and a wattmeter connected at the same point indicated simultaneously 21.12 kilowatts. The product of the voltmeter and ammeter readings would be 24 volt-amperes, and the power factor of the motor, with the load then being carried, would be $21.12 \div 24 = 0.88$, or 88 per cent. This would mean that the current lagged behind the e.m.f. to such an extent that when the latter was at maximum, the current was only 88 per cent of its maximum value; or, when the e.m.f. was actually at its mean effective value, the current had reached only 88 per cent of its mean effective value. On the assumption that the current wave follows the sine law, this would indicate that the current lagged almost exactly 0.08 of a cycle behind the e.m.f.

Lighting Electric Cars.

It is a matter of common knowledge, of course, that the lights in an electric car operated on a sub-surface conduit system are extinguished momentarily whenever the car passes a switch or a crossing. This is one of the minor disadvantages of such a system which are not worth the expense of correction. The momentary disconnection of the car circuit from the working conductors in the conduit is due to the necessary break in the conductors where they meet other conductors of opposite polarity, and there is no practical method of avoiding this break when a track separates into two curves turning in opposite directions to enter another track at right angles to the first one. At almost all other points the disconnection could be avoided by using two plows on each car, so that one of them would always be in contact with the conductors; but such an arrangement would cause a short-circuit on the system when the car passed the Y junction between two tracks at right angles, just mentioned.

In view of these well-known facts, it is somewhat difficult to identify the system of "wiring" an electric car to which the *New York Times* referred recently as affording a simple cure for the blinking of the lights under the conditions named. According to this technical authority, such a system has been in use in Europe for some time and has been "installed, after a careful test, on the electric street railway system of Scranton, Penn." The Scranton Railway Company states that it is all news to them, and we confess it would be a revelation to us to find that any method of wiring a car could prevent the lamps from going out when the car circuit is disconnected from the supply source. Some genius may have "invented" a system of small storage battery cells to be carried by each car for the purpose of keeping the lamps bright during breaks in the supply connections, but of course an authority of the *Times'* standing could not confuse a storage battery with a system of wiring.

CONSTRUCTION OF A 2-H. P. MOTOR OR 25-LIGHT INCANDESCENT DYNAMO.

BY F. C. MASON.

The accompanying drawings are for a direct-current motor of which the writer has built several; all of these run smoothly, without any sparking or overheating whatever. Fig. 1 is a sectional elevation showing practically the whole construction, and Fig. 2 is an end elevation with the journal bracket partly broken away and the field magnet partly sectioned to show the other view of the pole-piece and armature core.

The field magnet yoke ring is of cast steel, with the magnet poles or cores cast integral; the pole-pieces are also of cast steel and are held in place by bolts extending through the centers of the cores from the outside of the yoke ring. The four pole-pieces are intended to be cast together with thin webs, say ¼-inch, connecting them; this will give a circular casting with four circular "bosses" equidistant around the outside, these "bosses" being the magnet core extensions. In machining the pole-piece casting, it should be chucked by the polar extensions in a four-jaw chuck, the "bosses" turned to a light driving fit in the 9-inch bore of the cores cast with the yoke ring, and the pole-faces bored to 7 inches diameter. Then the connecting webs must be cut away and the corners of each pole-piece rounded to ¼ inch radius. Next, the hole for the retaining bolt should be drilled precisely in the center of each pole-piece and tapped for a ⅝-in. cap screw.

The machine work on the field magnet frame is simple. The frame is first strapped to the face-plate, the magnet core ends bored to 9 inches diameter, and the exposed edge of the yoke ring faced off and recessed for the journal bracket ring; then a supplementary face-plate must be made which fits snugly in the recess for the bracket-ring, this plate bolted to the face-plate of the lathe so that its center coincides precisely with the lathe center, and the magnet frame again strapped to the lathe face-plate with the unfinished edge outward this time, the supplementary face-plate entering the bracket-ring recess in the finished edge and thereby centering the magnet frame with its former position. Then the exposed edge of the yoke ring is faced off and the recess cut for the other journal bracket ring. The holes for the ⅝-in. cap screws which retain the magnet pole-piece in place should be ¾ inch in diameter, so as to allow ample clearance for adjusting the pole-pieces to equidistant positions in case the magnet cores of the yoke ring are not precisely equidistant. These holes should be laid out with extreme care, so that their centers will be precisely 90 degrees apart and all of the holes will be absolutely radial to the machine frame. After this is done the feet may be faced off on a planer or milling machine to fit in the base shoe, Fig. 3. The fit should not be too snug; the machine should slide freely in the shoes.

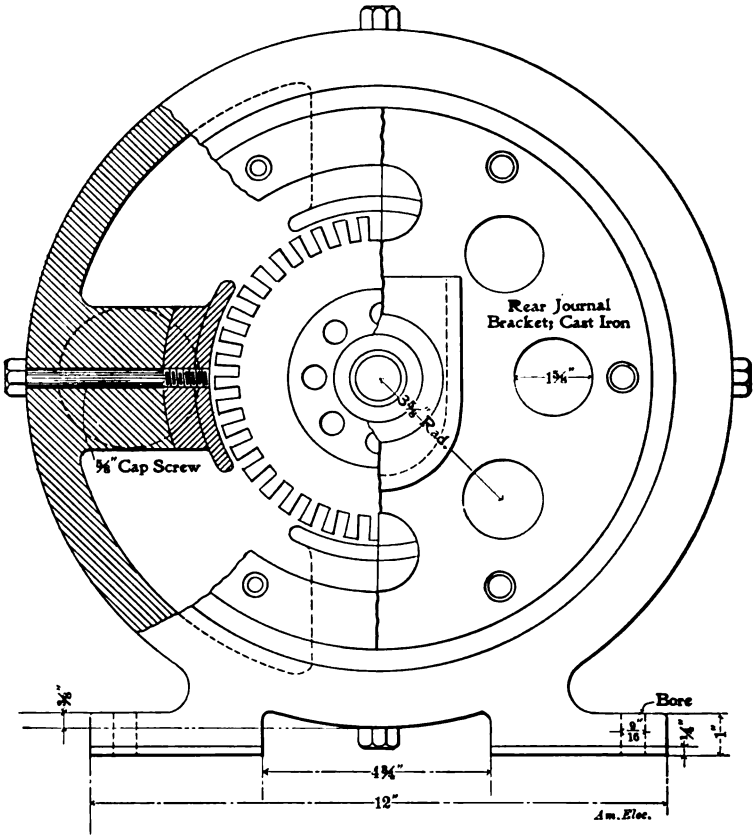

FIG. 2.—SEMI-SECTIONAL END ELEVATION OF MOTOR.

The journal bracket-ring for the commutator end of the machine is shown by Fig. 4. The design is quite simple, so that explanation is unnecessary. The bracket-ring for the pulley end of the machine is shown with sufficient completeness in Figs. 1 and 2. It is practically a dished disc with eight 1⅝-in. holes cored in it for ventilation; the centers of these holes should be 3⅝ inches from the center of the shaft hole. In machining the brackets probably the best plan would be to drill the hole for the shaft bushing first and mount the bracket on a mandrel, bracing it from the inside by means of a disc of cast iron about 8½ inches in diameter, also mounted on the mandrel and pushed up against the curved portions of the bracket

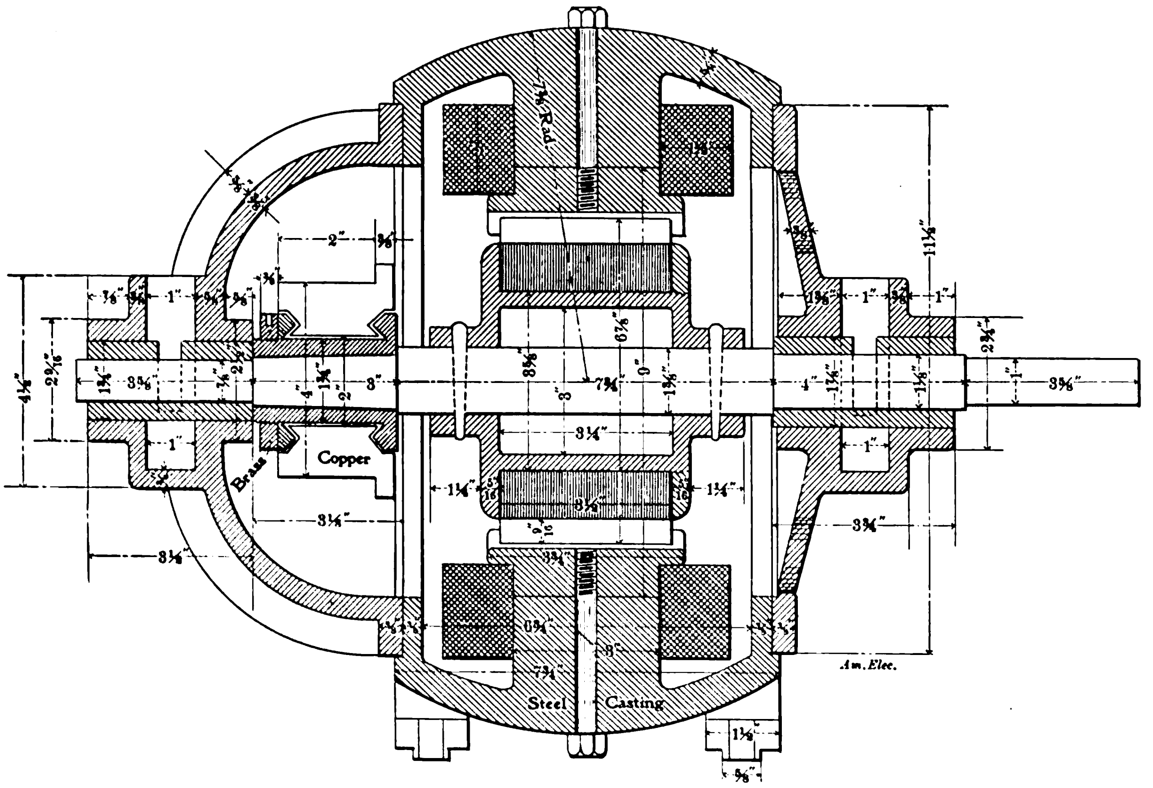

FIG. 1.—SECTIONAL ELEVATION OF 2-H.P. MOTOR.

yoke. The internal circular edge of the bracket ring does not need to be finished off, but it is better to take a little cut off that edge for the sake of appearance.

The bearing bushings (see Fig. 5) may be made either of hard brass or phosphor-bronze, preferably the latter. Each bushing should be bored out first and then mounted on a mandrel and finished on the outside. The oil groove at each end may be tooled out when the bushing is bored or afterwards, as may be most convenient for the builder. The oil ring slot is preferably cored out and cleaned up with a fine file afterwards, but if the builder finds the pattern making troublesome the bushing may be made solid and the oil ring slot cut out after the bushing has been trued up inside and out. Fig. 6 shows the oil ring dimensions.

It will be noticed from Fig. 1 that the shaft is ⅞ inch in diameter in the bearing at the commutator end and 1⅛ inches in diameter in the bearing at the pulley end. On this account, and also because of the greater side thrust at the pulley end, the two bushings are not identical, the one in the bearing at the pulley end being longer as well as larger in diameter than the other. The shaft can be made of machinery steel, but it is preferable to make it of low-carbon tool steel. If the latter material is used, the shaft should be rough-turned first to within 1-16 inch of the final diameter. It should then be heated to a dark red and allowed to cool; after cooling, it should be turned down to the required size. This process leaves the shaft straight in a semi-annealed state without any internal stresses, and it will always remain so.

The armature is of the usual slotted drum type and the discs are mounted on a cast-iron spider, which is pinned to the shaft as shown in Fig. 1. The discs must be of the very best grade of electrical steel and should be about No. 20 gauge. If the builder has no facilities for stamping out the discs, the core may be made by cutting sheet steel into squares about 7⅛ inches each way, having the center holes punched out at some shop where proper facilities are available, and mounting the square sheets on a mandrel, clamping them between two cast-iron or wrought-iron discs 6⅞ inches in diameter.

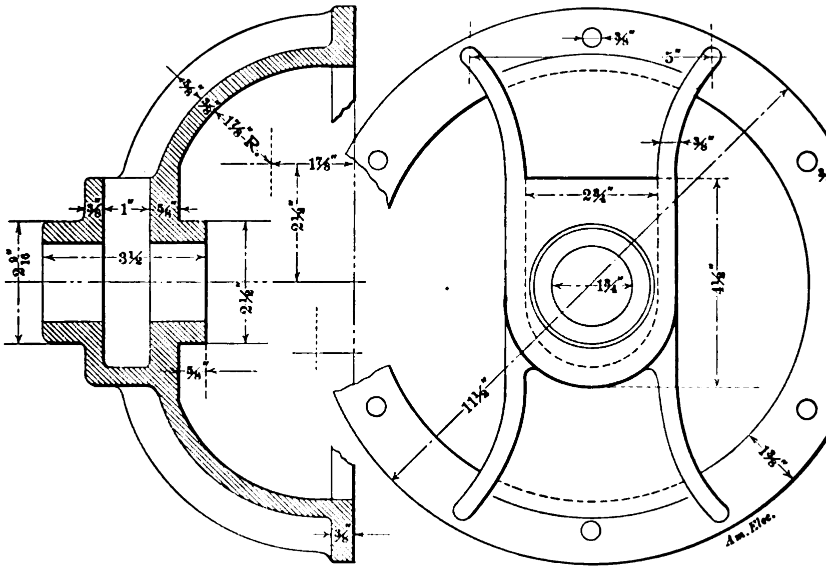

FIG. 4.—JOURNAL BRACKET RING; COMMUTATOR END.

The sheets can then be turned down to circular form of the proper diameter, starting the tool in the flat face of the mass and not attempting to turn off the corners with a radial tool. The center hole in each plate should be punched out with a keyway, so as to avoid the possibility of the discs turning on the mandrel or on the armature spider, as well as to facilitate assembling them accurately on the spider.

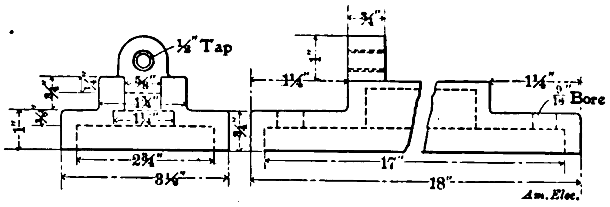

FIG. 3.—BASE SHOE.

After the core is turned to its circular form, the slots may be cut on a milling machine. If oil is used in order to expedite the work of milling out the slots, the discs must be thoroughly cleansed from the oil afterwards. This may be done by the use of gasoline, or better still, by a hot potash solution. After cleaning off the oil, the discs should be varnished with shellac or some armature insulating compound on each side.

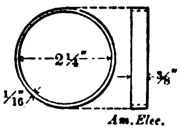

FIG. 6.

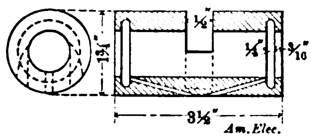

FIG. 5.—BEARING BUSHING.

They are assembled on the armature spider with a disc of hard fibre 1-16 inch thick at each end of the core. These discs should extend to the outer diameter of the core discs, and it is advisable to that end that they should be assembled with the core discs when these are put on the milling machine for cutting the slots, so that the slots will be cut in the fibre discs also. The armature spider or drum is fastened to the shaft by No. 6 standard taper pins. The writer has found this method easier and more satisfactory than the use of keys.

The armature slots must be provided with troughs of material 1-64 inch thick; the material may be hard fibre, press board, mica or flexible micanite. Mica is, of course, the best material so far as insulation is concerned, but micanite is preferable from all-round considerations as it withstands mechanical strains better than the pure mica.

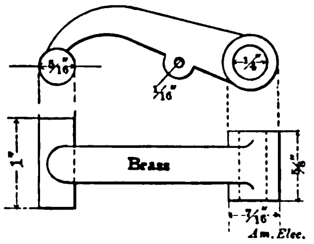

FIG. 9.—BRUSH HOLDER FINGER.

If the troughs are made of flexible micanite, the builder can very easily shape these to fit the slots by means of a simple former of hardwood, consisting of a block with a slot exactly the size of the armature slot and a strip of wood the thickness of which is 1-32 inch less than the width of the armature slot. The strip constitutes a male die to press the micanite into the slot in the block.

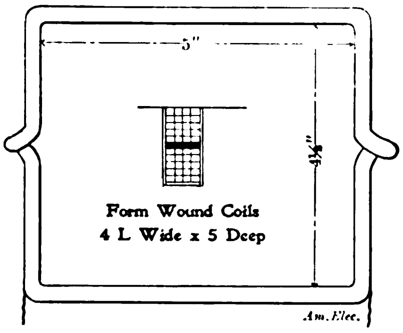

FIG. 7.—ARMATURE COIL.

The armature coils are intended to be form-wound and the dimensions of the former are given in Fig. 7. The armature coils for 110 volts consist of 20 turns of No. 16 double cotton-covered wire; for 230 volts, each coil has 40 turns of No. 19 wire. The ends of each coil should be left about 8 inches long for connection to the commutator, and these should be covered with cotton sleeving just large enough to slip over the wire comfortably and long enough to extend into the coil about ½ inch. After putting on the sleeves the coils should be taped with a single wrapping of German linen tape, half lapped. After painting the coils with fairly thick shellac or armature insulating compound, they should be allowed to dry just enough to allow ready handling, but it will be found easier to assemble them on the core if they are put in before they are entirely dry. There are forty-seven coils and forty-seven slots, and each coil should embrace twelve core teeth. The terminals of each coil are connected to commutator segments between which there are twenty-two other segments, or in the armature winder's parlance, each coil is connected up "1 and 24." If the builder has had no experience in armature winding and connecting, it will pay him to secure the services of an armature winder to assist in this work.

The commutator is the most difficult part of the motor to build successfully. Copper segments suitable for this machine can be obtained from any one of several manufacturers. Drop-forged segments are the best, but cast copper may be used. The dovetail part of each segment does not need to be precisely as the drawing shows it. The best method is to obtain catalogues from the various makers of commutator segments and commutators and select the stock segment which comes nearest to the shape and dimensions shown in the drawing. The commutator core or shell and clamping collar will, of course, have to be made to suit the size and shape of the segment selected. The micanite strips between the commutator segments should be 30 mils thick, and the rings insulating the dovetail part from the beveled collars should be at least 1-16 inch thick, and preferably 75 mils. For assembling the commutator a drawing-down ring should be made of machine steel about ½ inch larger in inside diameter than the external diameter of the commutator barrel. Two rows of set screws should be tapped into this ring so that the screws will point to the center of the ring, and the two rows should not be staggered. As many screws should be put in each row as space will allow. The commutator segments and mica strips are assembled inside this ring, each segment and strip being shellacked as it is put in place. Then the set screws should be tightened up evenly all around, each screw being given only a part of a turn at a time until all of the screws are tight and the commutator segments have been forced into an approximately cylindrical shape. Then the commutator should be baked until the shellac is thoroughly hard, after which the inside circle of the segments should be trued up and the circular beveled end faces machined to size. Then the segments, with the clamping ring still in place, are transferred to the commutator shell or core and clamped tightly between the beveled collars, the core, of course, having been previously machined to size. The final work consists merely in turning off the outside of the commutator barrel and the lugs, which may be done by mounting the commutator structure on a mandrel and driving the mandrel by a lathe dog. The slots in the commutator lugs for the armature wires should then be cut either by a thin saw on the milling machine or by means of a hack saw, preferably the former.

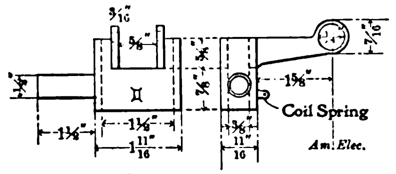

FIG. 8.—BRUSH HOLDER.

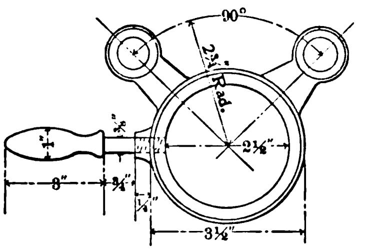

FIG. 10.—BRUSH YOKE.

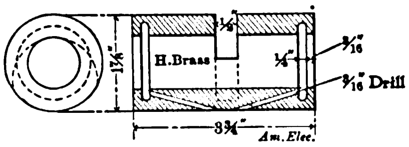

FIG. 11.—BEARING BUSHING.

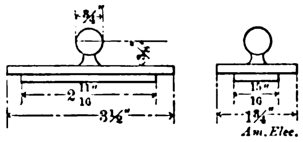

FIG. 12.—OIL WELL CAP.

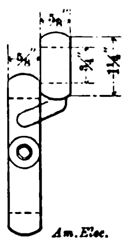

After testing up the winding and commutator for grounds or other defects and clearing out any troubles which develop, the binding wires may be put on the armature. This should be of No. 18 hard brass wire and should be wound over a layer of pure mica. Three sets of binding wires about ½ inch wide should be used, one around the middle of the core and one near each end.

The field-magnet coils should be wound on spools of either fibre or mica, and the coils should all have exactly the same number of turns of wire. The magnet coils for the 110-volt machine are of No. 12 wire, and those for the 230-volt machine are of No. 27 wire. The dimensions shown in Fig. 1 indicate the inside dimensions of the spools. If the winding is carefully done the builder will be able to get from 3000 to 3100 turns of No. 23 wire in each coil. It will be impossible to wind the No. 27 wire in smooth layers, but this should be approximated as closely as possible. The starting end of each coil should be marked by a tag or other means, and when the coils are put in place they should be assembled with the ends of the spools through which the inner ends enter all turned toward the armature. It will then only be necessary to remember that the inner end of any coil must be connected to the outer end of the neighboring coil in order to magnetize the cores properly.

The brush-holders are of the simple box type, as shown by Fig. 8; Fig. 9 shows the feeding finger which presses the carbon brush on the commutator. The holders must, of course, be insulated from the quadrant or yoke by means of fibre washers.

The speed of the machine is approximately 950 r.p.m. It may be used either as a 2-h.p. motor or as a shunt-wound dynamo; it will have a capacity of about 25 16-c.p. lamps when driven as a dynamo. The speed, of course, will need to be a good deal higher than the motor speed; 1000 to 1025 r.p.m. will be sufficient. The starting box for the motor should be purchased from one of the standard manufacturers, and this is also true of the field rheostat if the machine is used as a dynamo.

THAWING FROZEN WATER PIPES ELECTRICALLY.

BY WALTER M. PETTY.

The thawing out of frozen water pipes by means of electricity was first suggested in 1900, but not until this year has the idea been put to practical use, so far as the writer is aware. The winter being so very severe in the vicinity of New York, an unusual number of house-holders have been the sufferers by reason of the freezing up of the service pipes, and in the suburban towns this has been particularly noticeable. The writer found in one instance that the frost was in the ground to the depth of 3 ft. 9 ins. As all, or nearly all the pipes do not lay in the ground much below this depth, it is easily understood why so many have been frozen.

To Mr. Walter P. Schwabe, Superintendent of the Rutherford District of the Gas & Electric Company, of Bergen County, N. J., should be given the credit of first employing on an extensive scale the heating effect of the current for the purpose of thawing out frozen pipes. Mr. Schwabe used two 10-kw. oil insulated transformers, connected in multiple, and stepping down from about 2400 volts to about 55 volts. A water rheostat was used to control the primary current and an ammeter was put in the primary circuit. The whole outfit was mounted on a wagon drawn by one horse, and three men were employed to do the necessary work. As all the wires in Rutherford are overhead it was a simple matter to connect the primaries of the transformers to the commercial lines by sending a man up the nearest pole. Heavy leads composed of No. 0 cable were then clamped on to the water service pipe requiring thawing, in the cellar of the affected house, and the other to the service pipe in the nearest cellar. The circuit through the primary was closed by means of the water rheostat, and in about one minute a perceptible heating was noticed in the pipes. This increased until water flowed. The time required from the closing of the circuit until the water flows varies from three to twenty minutes, the average being about ten.

The average length of the service pipes thawed out was 50 feet. As nearly all these services are made of lead pipe, the resistance in all cases is about the same, namely, 0.15 ohm. Occasionally, however, an iron service pipe was encountered, and the effect of the increased impedance was felt. At such times the ammeter in the primary registered about 5 amperes, and the melting took longer. The rusty joints of iron pipe also increased the resistance somewhat. Even under these circumstances not a single failure has been experienced.

The average current in the primary circuit was 9½ amperes; this would mean in the secondary about 460 amperes. The amount of power required is obviously in the neighborhood of 20 kilowatts, in round figures.

This method is so far superior to that of excavating the street and is so sure that the electric light company has been overwhelmed with orders. One gang of men can do about twenty jobs in a day. Whenever two houses in the same neighborhood are frozen, as often happens, they can be thawed out at the same time.

One of the peculiar facts noted is that whenever it takes longer than the average the first flow of water brings with it a quantity of sand sediment, which must act as a plug. The thawing serves as a cleansing agent as well.

In taking bridge measurements in order to ascertain the resistance of the house services, the writer found at times that he was unable to get a balance. Upon testing with a low reading voltmeter it was found that there existed a difference of potential of 0.133 of a volt between adjacent houses. There being no trolley line within a distance of half a mile, it cannot be caused by leakage from the trolley circuits. Possibly the fact that the street mains are of iron and the services of lead may account for this flow of current.

[In addition to the foregoing, Mr. Schwabe informs us that he found it advisable to disconnect the service pipes from the consumer's house piping and let out the ice and sand before discontinuing the application of the thawing current. When this was not done, the sand and ice in the pipe choked the flow of water so that it froze again. In one case a run of 525 feet of galvanized iron pipe was thawed out; this required the transformer secondaries to be connected in series so as to obtain 110 volts in the secondary circuit. The current required for this case was about 260 amperes and the thawing took 45 minutes; the secondary leads were clamped to the service pipe in the consumer's cellar and to the nearest fire hydrant.—EDITOR.]

HINTS FOR WIREMEN.

BY ELMER E. WARNER.

Every age and trade has its superstitions. From time immemorial the left hind foot of a rabbit has been regarded by some persons as an infallible charm against all evils. Like the rabbit's foot, sheet asbestos has become a sort of fetish with some electrical wiremen, who seem to think that any electrical appliance backed up by a piece of this mysterious substance immediately becomes immune.

Taking a thirty-ampere Edison plug cut-out as an illustration—as perfect an appliance as is used in the trade—the cautious wireman will nail up against the wall a scrap of flooring and over this carefully double a sheet of 1-32 inch asbestos, upon which he screws his cut-out block. Any kind of rheostat, switch or controller is considered safe with a backing of this sort.

Tracing back, one finds these traditional observances originating in the early days of rules and regulations for installation work, when appliances were imperfectly insulated, which is rarely the case now. Rheostats have metal frames and backs and projecting feet, giving air space behind. The rules require it. What is needed is intelligent discrimination.

But after all there may be method in the madness of the wireman, for asbestos is cheap and may cover the roughest sort of wood butchery. It is indeed, in many cases, a sort of electrical upholstery. The writer has more than once found panel boards, made from rough scrap lumber gathered on the premises, clothed to a semblance of respectability by a layer of this material—even raisin and fig boxes thus transformed and doing duty as panel boxes. However neat in appearance at first, asbestos readily absorbs dust and is likely to become ragged as well as discolored. It is, in short, fragile and impermanent. Small fireproofed boards for assembling cut-outs, switches, etc., neatly molded with extra separable batons, could be furnished to small contractors, if made up in quantity, at less than their makeshift backings cost them now. Two or three sizes would cover the bulk of their work and give an appearance of finish lacking now.

Every wireman owes it to his employer to make himself as little of a nuisance as possible. The customer need not be an expert to appreciate neatness in workmanship or politeness in manner or quickness and care in cutting through floors and walls and getting up his wires. And just here it is not amiss to mention floor bushings. The ordinary porcelain tubes in many cases are not set close to walls or do not meet the moldings. Whereat the wily wiremen who does not carry a lumber yard with him, hunts around in the cellar for some remnant of a packing case and laboriously builds up around them a box which is not only a disgrace to himself but literally a stumbling block in the path of others. Now, a piece of conduit, or plain iron pipe even, is cheaper and better.

Pending the time when all risers will be allowed only in conduit, such a bushing of pipe carried at least to the top of the baseboard and strapped to it, with each conductor encased in loom projecting from the pipe and extending continuously from molding to molding, makes a first-class and neat job. Pipe is particularly desirable where walls are stepped off or partitions are not directly on line, because it can be curved in the floor spaces, avoiding offsets or projections above the surface of the floor.

The best of things may be run into the ground, and it may be well to remember that such an excellent protector as circular loom and similar conduit has its abuses as well as its uses. As a passageway for concealed wires in finished buildings of the cheaper class, it is excellent if continuous between outlet boxes and well secured in the boxes. As an extra insulation for use on open wires where pipes are crossed or branches are taken off and wires of opposite polarities cross, it also has a legitimate function. But when inserted in molding work to have mitering or neatly fitting the molding around projections and corners, it makes a piebald, discontinuous, disreputable job. As many as ten breaks of this sort may often be seen in a hundred-foot run of what would otherwise be very creditable work. Even when dropping down from the ceiling past a very elaborate wood or metal cornice, it is better to go through and *behind* in circular loom projected into the gouged ends of the molding than it is to break around outside, and in many such cases it is possible to cross cheaply by using molding with a stout backing strip fitted at the ends into the cornice. One should be consistent above all things, and whatever the system of wiring adopted, stick to it throughout.

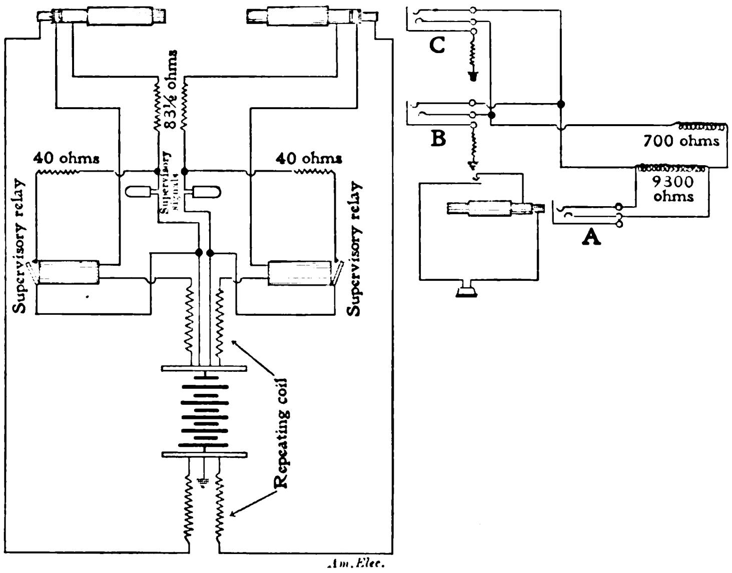
SOME AIDS IN THE MAINTENANCE OF COMMON-BATTERY CENTRAL OFFICES.

BY A. DALLAM O'BRIEN.

In the modern common-battery central office, with its multitude of more or less complex circuits and its great number of delicately adjusted relays, the problem of satisfactory maintenance is far from being a simple one, and the engineer is called upon to exercise considerable ingenuity in order to overcome the numerous troubles to which the equipment is subject. It is of the greatest importance in central-energy systems that the line insulation resistance should be maintained as high as possible, as with lines of this kind a leakage that would probably not prove serious in a local-battery or magneto system will in common-battery installations be sufficient to operate the line signal and thus, so far as the connected subscriber is concerned, render the line inoperative. It is the customary practice in central-energy exchanges to make an insulation test on all the lines connected to the exchange at least once every twenty-four hours and to note all cases which show defective insulation and have each case of trouble followed up and cleared by linemen at the earliest possible moment.

There is one class of trouble to which the three-wire, and indeed the two-wire, common-battery system is especially subject and which is the cause of considerable annoyance to subscribers and no inconsiderable expense to the telephone company. The trouble referred to is that due to defects in the connecting cords at the switchboard. The defect may be a short-circuit, an open conductor in the cord, or an intermittent make and break of the circuit usually termed a "cut-out." This last-mentioned form of trouble is probably the most aggravating defect in the service that the subscriber comes in contact with, and it forms the basis of almost an infinite number of complaints.

It is a difficult if not an impossible feat to entirely eliminate defects in the connecting cords, even though every possible precaution is taken. In order that connections may be handled with a reasonable amount of rapidity by the operators, the cords must necessarily be flexible, and with the present switchboards the plug in which the cord conductors terminate must be rigid in order that it may make contact properly with the springs of the jack. It is at the point where the flexible cord enters the base of the plug that the defects referred to show up and they are directly due to the handling of the cords by the operators. If it were possible to train operators so that when placing a plug in a jack they would hold the plug firmly without allowing the hand to come in contact with the cord, it is probable that troubles of this nature would be very largely decreased. The tendency, however, during busy periods is for the operator to insert the plug part way in the jack and then push it in the rest of the way by pressing on the end where the cord enters, in this way straining the conductors and in time damaging them.



Am. Elec.

FIG. I.—DIAGRAM OF CONNECTIONS FOR LOCATING CORD CIRCUIT TROUBLES.

In addition to the troubles already mentioned, there is another fault to which the cord circuit is subject, namely, the false operation of the supervisory signals, this being due to the improper adjustment of the supervisory relay. The relay may stick, due to low insulation resistance on the line; or the armature, not being properly adjusted, may fail to fall upon disconnection of the circuit and thus necessitate supervision on the part of the operator. A thorough test of all the cord circuits for cut-outs, opens and short-circuits, and for relay adjustment is made once every twenty-four hours. In addition to this, cases of trouble which show up before the test are at once taken up and cleared by the maintenance force.

The diagram in Fig. 1 shows a very common arrangement in use for testing and locating cord circuit troubles. For this arrangement it is necessary to use three of the multiple jacks throughout the switchboard, the third wire or sleeve strand of two of these jacks being connected to ground through a 30-ohm resistance coil; the sleeve strand of the third jack is left unconnected. The jacks are located so that *A*, as shown in the diagram, appears as near the center of each switchboard section as possible, while jacks *B* and *C* are located one at either end of the section. A 9300-ohm resistance coil is connected across the line terminals of the jack *A*, and in series with this coil is connected a 700-ohm resistance, the free end of which is connected to the tip springs of the jacks *B* and *C;* the ring springs of the three jacks are connected together, as shown in the diagram. The cross connections of the jacks and the connections to the resistance coils are usually made at the intermediate distributing frame. The tester is equipped with a head receiver wired in series with a strap key or push button and connected to the tip and ring contacts of a switchboard plug, the normal position of the strap key being that in which the circuit is broken.

In the operation of testing cord circuits, the cord to be tested is inserted in either of the jacks *B* and *C*, depending upon the position of the cord, and the tester's plug inserted in the jack *A*. The strap key being closed, current flows from the cord circuit battery through the supervisory relay to the ring of the test jack, thence through the tester's receiver and strap key and back through the 700-ohm resistance coil and tip of the plug to the cord circuit battery. If the supervisory relay is in proper adjustment, sufficient current will flow through the testing receiver and the 700-ohm resistance to operate it and thus close the 40-ohm shunt around the supervisory signal and extinguish the lamp; this, of course, should have lighted when the plug was placed in the test jack, its circuit being closed through the 30-ohm resistance coil to the ground. If now the strap key be closed, the current flowing through the supervisory relay of the cord under test can only return to battery by passing through the 9300-ohm and 700-ohm coils in series, and if the adjustment of the relay be properly made the current flowing in this last case will be so small that the relay will release its armature and the supervisory lamp will again light up.

By working the strap key and alternately throwing in the 700-ohm resistance and the combination of the 9300-ohm and the 700-ohm coils, the rapidity with which the relay armature responds can be ascertained and satisfactory adjustment made.

From the foregoing it will be evident that the supervisory relays are adjusted so as to attract their armatures when a resistance of approximately 750 ohms is in series with the relay winding and to release their armatures when the external resistance is increased to 10,000 ohms. The value of the external resistance through which the relay should operate will depend largely upon local conditions, as it is of course necessary that the supervisory signals be made to operate when the cord is connected to the longest line entering the exchange. If the relays are adjusted, as has been assumed in the case described, to operate through an external resistance of 750 ohms and an allowance of 650 ohms is made for the line resistance, assuming that the cable conductors are No. 18 B. & S. wire, the supervisory signals will operate satisfactorily over a line five miles in length, which is probably considerably longer than any line connected to the average central office. In using this test to discover defects in the cord conductors, the strap key is closed and the cord to be tested is manipulated and worked by the tester throughout its length. Should there be a "cut-out," it will at once be detected by the clicking in the receiver, and an open or short-circuited cord will show up by the absence of a click when the strap key is closed. With this method of testing, a large switchboard can be very thoroughly gone over in a comparatively short time, and where two men are employed, one to operate the strap key and receiver and plug up the cords and the other to remove defective cords and adjust relays, the time can be reduced considerably.

There are a number of troubles that occur on subscribers' lines, which are intermittent in their nature and are usually designated by telephone men as "swinging troubles." They are particularly frequent on lines which run for some part of their length overhead and which are consequently subjected to possible grounds, short-circuits and crosses with other wires. The swinging of a wire on a pole line during a wind storm may serve to ground it sufficiently well, by contact with some other conductor, to operate the line signal at the central office; the same effect may result from a cross between the wires of a metallic circuit, the resulting short-circuit operating the signal. In cases of this kind, where the signal is displayed at the switchboard and the operator upon answering the line receives no response, a report of "Signal In" is made to the wire chief and the work of clearing the trouble is left to him.

The wire chief's testing desk is provided with a number of jacks which are wired to plugs located at a switchboard position, these lines being termed "plugging-up lines." An operator is stationed at this position and is connected to the wire chief by means of a calling circuit so that the wire chief can at any time communicate with the plugging-up position. These lines are numbered at both ends, and upon receipt of a report of trouble on any subscriber's line the wire chief requests the operator at the plugging-up position to connect cord No. 1, for instance, to the line in question. This the operator does through the multiple jack, and thus the connection is completed through to the testing desk. The diagram in Fig. 2 shows the arrangement of the plugging-up line and its connection to a subscriber's line. By following up this circuit the operation will be made clear.

The operator at the plugging-up position, having been requested by the wire chief to connect cord No. 1 to line 400, for instance, places the plug of the cord in the multiple jack of the line and presses the button *A*. Current then flows from the battery through the winding of the relay *B* and the button *A* to ground, thus operating the relay and closing the circuit from the battery through the relay armature, the wire chief's signal lamp which is located under its jack on the test desk, the winding of relay *C*, through the wire chief's cut-out button to the sleeve of the plug, and thence through the line cut-off relay to ground. The relay *C* and the line cut-off relay are now both operated and the signal of the line in trouble extinguished; at the same time, the lighting of the wire chief's signal lamp notifies him that his request has been complied with and the line is ready to test. As the button *A* is only momentarily depressed in order to operate the relay *B*, this relay is kept in operative condition by means of a contact on the armature of the relay *C*, and current flows from the battery through the relay *B*, the contacts on the relay *C*, to the ring of the plug and thence over the line to the fault, thus keeping the relay *B* operated. At the same time an interrupted battery current through a repeating coil flows to the sleeve of the plug and thence to the jack sleeves of the line in trouble, so that an operator at any section of the board testing the line in question is notified of the fact that it is in trouble. When the wire chief tests the inner contacts of the jack springs at the testing desk are opened and a clear test circuit is obtained. By pressing the cut-out button, the wire chief can cause the line signal to light at the answering position and can ascertain from the subscriber's operator if the line shows clear. Upon the removal of the fault, the circuit of the relay, *B*, is opened, its armature released, the relay *C* rendered inoperative, and the line cut-off relay restored to its normal condition. In cases where the fault consists of a short-circuit, the current flowing through the relay *B* returns over the line and through the contact of the relay *C* to ground.

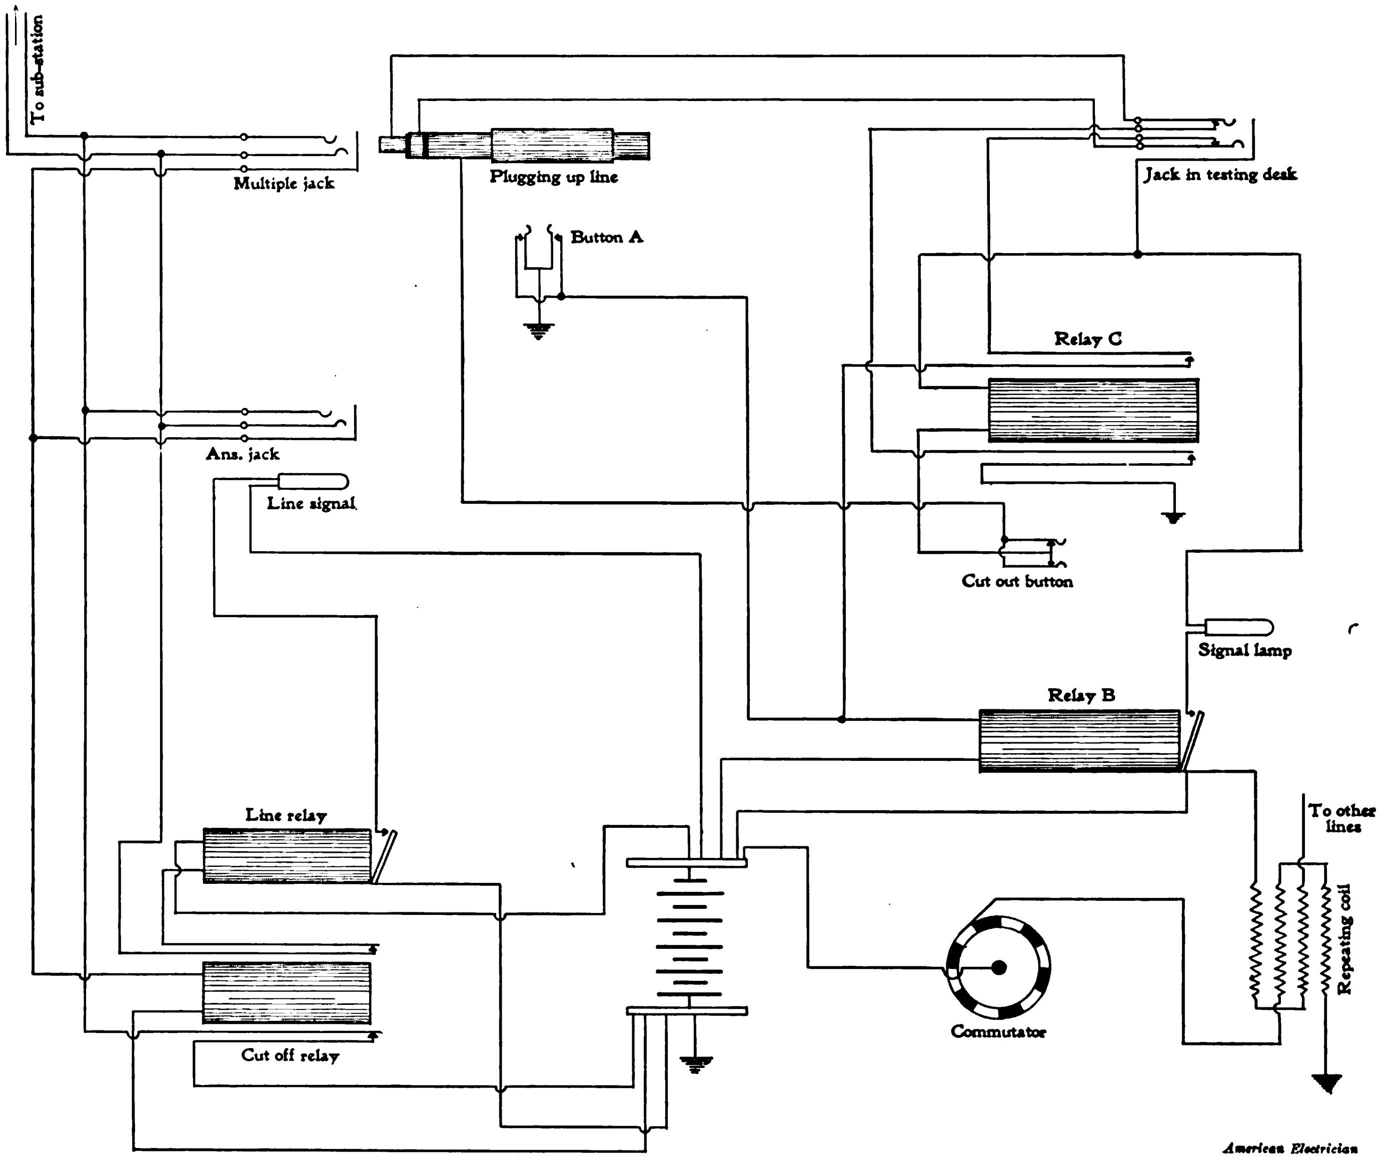


FIG. 2.—ARRANGEMENT OF PLUGGING-UP LINE AND ITS CONNECTIONS TO A SUBSCRIBER'S LINE.

It will be apparent from the foregoing description that the advantage of a test circuit of this nature lies in the fact that the line is cleared and ready for use the instant that the source of trouble is removed, and that it is not necessary for the lineman, or trouble hunter, to report to the wire chief in order to have the plugging-up line taken down and the cut-off relay restored. Promptness and despatch in clearing trouble on subscribers' lines is unquestionably of the highest importance in the operation of a telephone central office, and the necessity of a trouble "position," properly equipped with efficient plugging-up lines, has come to be thoroughly recognized.

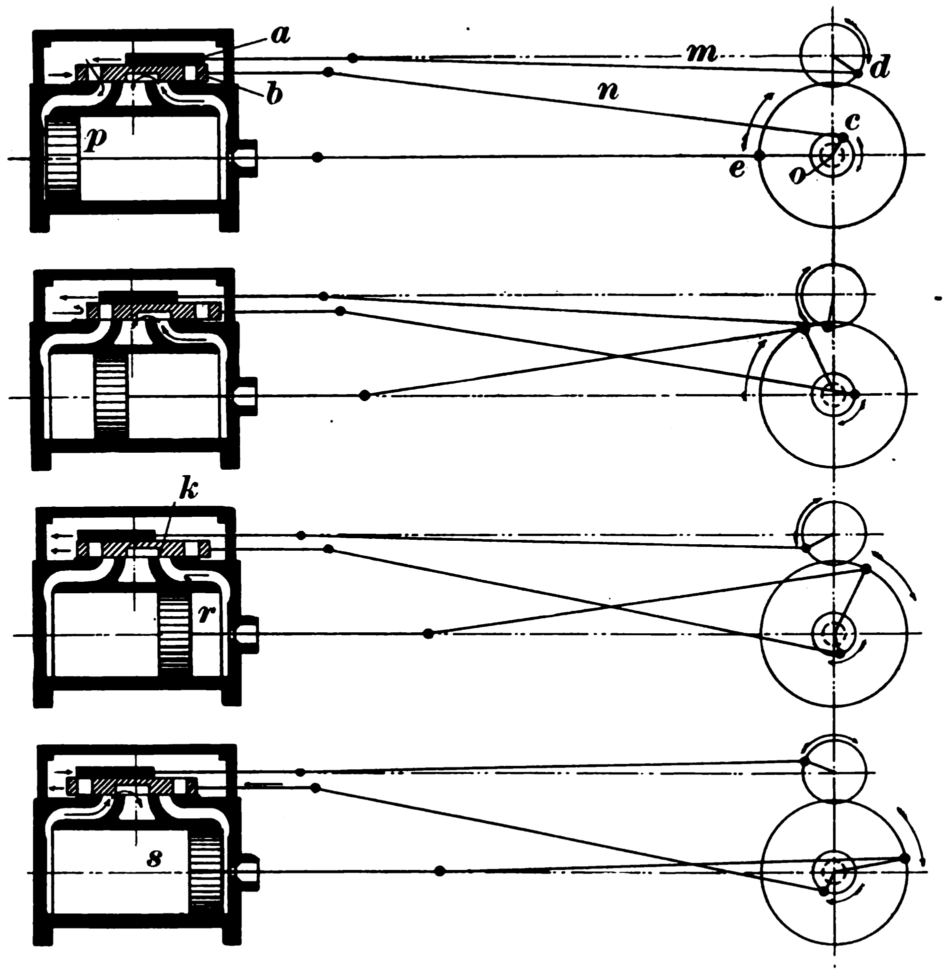
ENGINE VALVES AND VALVE GEARS.

BY C. C. MAJOR.

The Riding Cut-Off.

The single slide-valve is simple in construction and cheap and is used principally on comparatively small engines where an early cut-off is not desired. This form of valve will not give good steam distribution when cut-off is to occur at half stroke or earlier. To secure an early cut-off, the amount of lap must be increased, which decreases the angle through which the eccentric must move to reach its center, thus limiting the movement of the valve when opening the port for the admission of steam. This increase in the angle of advance of the eccentric also interferes with the exhaust functions of the valve, so that some modification of the slide-valve or separate valves controlling the exhaust are used when a high degree of expansion is desired.

One method of securing several expansions is to use two slide-valves which may work in the same or in separate valve chests. The auxiliary valve in this arrangement is known as the "riding cut-off." The main valve is ported and slides upon the valve-seat in a manner similar to the single slide-valve. It is driven by a separate fixed eccentric having a small angular advance, as the steam port is to be closed late in the stroke by this valve. The functions of the main valve are to admit steam to the cylinder, to open the exhaust port, and to produce compression. The duty of the upper valve is to cut off the admission of steam to the ports of the main valve; hence, it is called the "cut-off" or "expansion valve." This valve is operated by an eccentric, the angular advance of which is changed by a governor to control the point of cut-off.



FIGS. 17, 18, 19 AND 20.

Figs. 17, 18, 19 and 20 show the relative positions of the valves, piston, crank and eccentrics of an engine having a riding cut-off valve; *a* is the cut-off or expansion valve, seated on the top of the main valve *b*. The center of the shaft is at *o;* the circle *c* is the path of the center of the eccentric controlling the movement of the main valve *b*, and the circle *d* is the path of the expansion valve eccentric. This latter circle is drawn in the position shown in order that the movement of the expansion valve and the relative position of its eccentric may not be confused with that of the main-valve eccentric.

Fig. 17 shows the crank on the dead center nearest the cylinder and the piston at the head end of the cylinder about to commence its forward stroke. The main-valve has moved far enough to uncover the port to the amount of lead required and the corresponding position of the eccentric is shown by the dot at *c*. As this valve is to close the port late in the stroke, it has only a small amount of lap, consequently, the angular advance of the eccentric is not very great. The expansion-valve eccentric has passed the dead center and the valve is moving to the left, while the main valve is moving to the right as indicated by the arrows.

In Fig. 18, the piston has traveled through one-third its stroke and the main-valve eccentric has reached its dead center, giving the port full opening; but at this point the expansion valve has moved sufficiently to the left to cover the port in the main valve and cut off the steam. The piston will complete its stroke driven by the expansive force in the steam and the energy stored in the flywheel.

Both valves will now move to the left and the next event of the stroke is shown in Fig. 19. The piston has traveled two-thirds of its forward stroke and the exhaust edge *k* of the main valve has closed the port, thus preventing any further escape of the exhaust steam from the space *r* between the piston and the end of the cylinder. The relative positions of the valves and eccentrics are also shown.

In Fig. 20 the piston has nearly reached the end of its stroke, the expansion valve has reached the end of its travel and is returning to the right; while the main valve is just opening the head-end port to exhaust the steam from the space *s* behind the piston.

The advantage of this arrangement of valves over the single slide-valve can be readily seen. Cut-off can be made to occur at any desired point without interfering with the points of compression and release. These two events are changed by giving the main valve a greater or less amount of steam and exhaust lap. As lead is due to the angular advance of the main valve eccentric and this eccentric is fixed to the shaft, the lead is constant. This is also true of the simple slide-valve with its eccentric fixed to the shaft and the engine governed by throttling the steam supply.

Since cut-off occurs when the valves are traveling in opposite directions, the cut-off is quite sharp, thus preventing wire-drawing.

To set the valves of an engine equipped with a riding cut-off, follow the method described in the previous article for the simple slide-valve, setting the main valve first. The crank is placed on dead center, as shown in Fig. 17. The main eccentric is moved around the shaft in the direction in which the engine is to run; or, if there are rocker-arms, move the eccentric to the proper position on the shaft to give the desired lead, and in such a position that the steam port will be opened when the engine turns in the right direction.

After getting the lead, the crank is placed on the opposite center to see if the lead is the same. It should be approximately the same if the connecting-rod has been adjusted to the right length; if it is not the same, the lead must be equalized as previously explained. After the main valve is adjusted, turn the crank over until the piston is in the position desired for cut-off to take place. Turn the expansion valve eccentric on the shaft to cause the valve to move in an opposite direction to that of the main valve until the outside edge of the expansion valve just closes the port of the main valve, as shown in Fig. 19.

The valves of an engine are necessarily set when all the parts are comparatively cool, and, however carefully the work may be done, the steam distribution may be far from perfect when under working conditions, as the metal surrounding the ports, the valves and valve-stems and to a lesser degree the eccentric-rods, are all affected by the heat. The expansion of these various parts may make considerable difference in the adjustment of the valves, and the only true guide is the indicator, which should be used as an aid in making the final adjustment.

A USEFUL DEVICE FOR BAKING ARMATURE COILS.

BY F. B. O'HANLON.

The writer was formerly connected with a station containing a number of Brush open-coil arc light dynamos. From time to time we had armature coils burn out, and found it cheaper and more convenient to rewind these ourselves than to send them back to the makers. Each armature coil contained some 27 pounds of cotton-covered wire, so that it required careful baking out before the machine could be safely put to work at any considerable voltage. As we did not get a large amount of winding to do we could not, of course, afford to install a regular baking oven, and for a considerable time had been in the habit of baking the coils by running the machines slowly on short-circuit through an ammeter, and allowing them to generate a current of about twelve amperes. In order to thoroughly expel all moisture from the coils, it was necessary to continue this baking for at least 50 hours, and as in our case the dynamos were driven in pairs from separate engines, it will readily be seen that this process was a very expensive and inconvenient one. The writer got out an arrangement which overcame these objections and reduced the cost of baking to a nominal one.

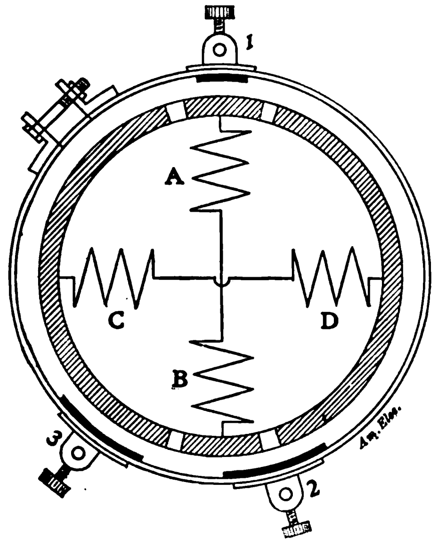


FIG. 1.

A clamp carrying a set of contacts and terminals was fixed to the commutator and a current sent through the coil or coils requiring to be baked. This clamp was made from a piece of ordinary 1-inch leather belting, and the necessary clamping lugs, contacts, and terminals were riveted on as shown in the sketch, which shows the interprojecting segments of a commutator encircled by the clamp. It also shows the arrangement of armature coils which for convenience have been drawn inside the commutator segments; for simplicity only four coils are shown. Diametrically opposite coils are connected in and to diametrically opposite commutator segments; hence by placing the narrow contact, 1, on the narrow interprojecting portion of a segment it is possible by connecting the source of current to terminals 1 and 2, to put coils *A* and *B* in series. Or by connecting from terminal 2 to terminals 1 and 3, the coils are placed in two series of two in parallel.

It will of course be understood that the clamp is made to fit tightly on the commutator instead of as shown in the sketch. It was found that a current of about six amperes was quite enough to bake out a coil when this device was used, although it took about twice as much if the machine was run on short-circuit. This was of course due to the intermittent and varying current density in the latter case, and to the fanning action.

With suitable modifications the device can just as readily be applied to other armatures.

Lessons in Practical Electricity

CAPACITY—THE CONDENSER.

If two sheets of conducting material be arranged parallel to each other a very small distance apart, and then connected to a dynamo or other source of direct current, as indicated by Fig. 1, the plate connected to the positive terminal (+) will receive a positive "charge" of "static" electricity, and a "charge" of opposite polarity will be received by the plate connected to the negative terminal. If now the dynamo be suddenly stopped from supplying its e.m.f., the plates will discharge back through the dynamo and restore the original conditions which existed before they were charged. If, instead of stopping the dynamo from generating, one or both of the connections between it and the plates be broken, and the plates be connected by a piece of wire or other conducting material, as shown in Fig. 2, the plates will "discharge" through the wire. The similarity between this action and the results produced by connecting and disconnecting a magnet to and from a source of current will be evident; in the latter case the applied current sets up magnetic lines of force which induce a momentary e.m.f. when they are allowed to die away by the removal of the exciting current; in the present case, the applied current sets up an electrostatic stress between the two plates which, when released, manifests its existence by a discharge. The property to which this action is due is called "capacity" and sometimes "condensance"; the latter term is derived from the technical name given to the plates, which is "condenser." The unit of capacity is the "farad," so named in honor of Michael Faraday, the great physicist who discovered the phenomenon of electromagnetic induction in 1831. The symbol for capacity is *C*.

The value of the unit of capacity is derived from the relations between the charging current and the e.m.f. produced by it at the terminals of the condenser. If a current averaging one ampere "charges" a condenser to a potential of one volt in one second, that condenser will have a capacity of one farad. Condensers, therefore, have a "time element"; consequently it is not the strength of current alone that determines the charge, but the current strength multiplied by the duration of the charge in seconds. When a steady e.m.f. is first applied to a condenser, the current flow is heavy, but as the potential of the condenser rises the current becomes smaller and smaller, until the potential of the condenser is equal to the applied e.m.f.; then there is no further flow of current, and the condenser is said to be "charged." If the e.m.f. is absolutely steady, the current will decrease at an even rate, and the average current will be one-half of the maximum; if the first rush, for example, were 4 amperes, the average current would be 2 amperes, and if the condenser required 0.1 second to acquire its full charge the quantity of electricity delivered to it would be 0.1 × 2 = 0.2 coulomb. The relations between the applied potential, *E*, the capacity, *C*, of a condenser, and the quantity, *Q*, of electricity delivered to the condenser are as follows:

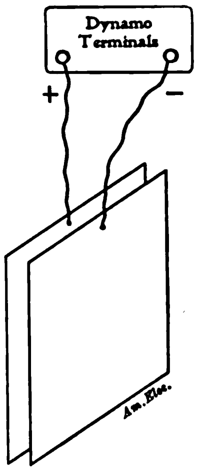

FIG. 1.

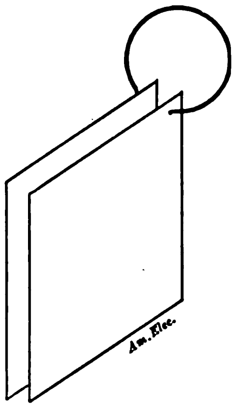

FIG. 2.

$$EC = Q; \qquad \frac{Q}{E} = C; \qquad \frac{Q}{C} = E.$$

The quantity, *Q*, is the product of time and *average* current, as stated previously; the period of charging, however, is extremely short when the charging current is supplied by a dynamo or other source capable of delivering large currents.

If a condenser be connected to a source of alternating current, it will be charged to a potential equal to the ***maximum*** applied e.m.f. during the first quarter of a cycle, discharged during the second quarter, charged again, but in the opposite direction, during the third quarter of the cycle, and discharged during the fourth quarter; this will continue as long as the condenser remains in circuit and the source of alternating current continues to operate. Under these conditions current will flow in the circuit wires just as though the plates of the condenser were all connected together, owing to the rapidly recurring charges and discharges. The relations between applied e.m.f., current, frequency and capacity may be analyzed as follows:

Assuming that the alternating e.m.f. and the current vary according to the sine law (which is always assumed in making computations), the maximum e.m.f. applied to the condenser will be 1.414 times the effective e.m.f. (the value commonly considered, and represented by E). The *average* current strength will be $2/\pi$ times the maximum current strength, and the maximum strength is 1.414 times the effective current strength; consequently, the average current is equal to $2.828/\pi$ times the effective current, I. If the frequency in cycles per second be indicated by f, the time required to charge the condenser to the *maximum* e.m.f. will be $\frac{1}{4} \times 1/f$ second, the charge being imparted in ¼ of a cycle. The quantity, Q, of electricity delivered to the condenser at each charge is equal to the product of the average current, $2.828\ I \div \pi$, and the time, $1 \div 4f$, or

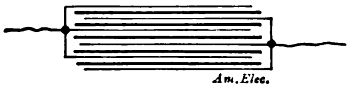

FIG. 3.

$$Q = \frac{2.828\,I}{4\pi f} = \frac{0.707\,I}{\pi f}.$$

Since the maximum e.m.f. $= 1.414\ E$, and also equals $Q \div C$, it follows that

$$1.414\ E = \frac{0.707\,I}{\pi f C},\ \text{so that}\ E = \frac{I}{2\pi f C};$$

therefore,

$$2\pi f C \times E = I,\ \text{and}\ 2\pi f C = \frac{I}{E}.$$

From the last three equations, which are the fundamentals of capacity calculations in alternating-current work, it is evident that capacity is a property in many respects the opposite of inductance. The greater the capacity of a condenser, the more current will pass through it with a given applied e.m.f.; whereas the current that can be passed through an inductive device by a given e.m.f. is *inversely* proportional to the inductance of the device. Moreover, the current passing through a condenser is caused to shift its phase relation with the applied e.m.f. so that it actually *leads* the latter instead of lagging behind it, as in the case of the current in an inductance; the condenser "boosts" the current phase ahead of the e.m.f. while the inductance retards it. If it were possible to pass current through a condenser without encountering any resistance, the current would lead its e.m.f. by exactly one-quarter of a cycle. This will be discussed more fully in the next Lesson.

The capacity of a condenser depends on the area of the facing surfaces of its plates and the specific inductive capacity of the insulating medium which separates the plates, and also upon the proximity of the plates. The specific inductive capacity of the insulating medium is compared with that of air, which is taken at unity. The insulating material between the plates is termed the "dielectric," the reason for which will be obvious upon consideration of the meaning of the word. As the condenser plates are always in intimate contact with the dielectric material between them, the thickness of that material may be taken as the distance between the plates. Representing this by t, the specific inductive capacity of the dielectric by k, and the area of the facing surface of one plate in square inches by A, the capacity of a condenser is given by the formula

$$C = 0.000000000000225\ \frac{A\,k}{t},$$

from which it is evident that with a dielectric only 1/100 inch thick, and a specific inductive capacity as high as 8, a condenser having a capacity of only one farad would have to have a surface of 5,555,555,555 square inches, or 462,929,293 square feet! The unit of one farad is, therefore, too large for practical use, and it is customary to use one-millionth of a farad as the practical unit; this is called the microfarad. The symbol commonly used is the same as that used to denote farads, but it is much better practice to use C for farads and c for microfarads, and this is done by many writers.

In order to obtain an appreciable amount of capacity within a small space, it is customary to make each half of a condenser of several sheets connected together, the sheets of one half intermeshing with those of the other half, with dielectric sheets between, as indicated in Fig. 3, where the thin lines indicate sheets of conducting material and the heavy lines sheets of dielectric material. The sketch shows only the edges of the sheets. Because of this common construction, condensers are always represented in diagrams by the arrangement of lines shown in Fig. 4; this merely represents the conductor plates of the condenser without the dielectric plates. For condensers of the construction indicated by Fig. 3, the capacity formula becomes

$$c = 0.000000225\ \frac{A\,k\,n}{t},$$

n being the number of dielectric sheets; A, the area of one side of each dielectric sheet, in square inches; t, its thickness in inch measure, and k, the specific inductive capacity of the dielectric material. The accompanying table gives the specific inductive capacities of the materials that have been used for dielectrics in condenser construction, the inductivity of air being taken at 1.

Dielectric.	k.
Glass, hard and new	3.11
Glass, hard and old	6.96

Petroleum, refined	2.1

A condenser does not necessarily consist of a number of parallel plates, although that is always the commercial form. Any two parallel conductors constitute a condenser if they are insulated from each other, but the capacity of two ordinary wires situated parallel to each other is very small unless their length is enormous. If a piece of tinfoil be wrapped about an incandescent lamp bulb, the lamp will become a condenser, the foil being one electrode and the filament the other. Similarly, electrical conductors made up into the form of an insulated cable, with an outer sheath of lead, form a condenser, the central conductors being one electrode and the lead sheath the other.

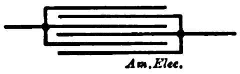

FIG. 4.

[Note.—In the Lessons department last month the equation on page 161, giving equivalents of alternating-current conductance G, included the expression $Z \cos \phi$; this was a typographical error and should have read $K \cot \phi$. $Z \cos \phi$ is equal to the resistance, not the conductance, of the circuit.]

Letters on Practical Subjects

The Underwriters' Rules and Inspection.

To the Editor, American Electrician:—

In a communication printed in your January number, Mr. Roy C. Jackson takes the Underwriters to task because they have failed to provide rules governing the erection and maintenance of buildings in more respects than the manner in which electric wiring shall be installed and used. Mr. Jackson finds all his ground for complaint in the carelessness with which the other parts of a building are constructed, and in the fact that the electrical inspector usually camps closely on the trail of the electrician So far as my experience goes, I have yet to see a branch of the building trades that produces more careless mechanics than are found among electrical workers. By a system of instruction and examination the Brotherhood of Electrical Workers is attempting to rid the fraternity of the "jerry" wireman, but the efforts in this direction are scarcely begun, and it will probably be necessary for several years yet for the ubiquitous inspector to "camp upon our trail."

Referring to other things about buildings in which there seems to be almost criminal carelessness, I think that upon investigation Mr. Jackson will find that nearly every town of any size attempts to regulate the construction of public buildings, although it must be admitted that the intentions of the people in such matters are more often disregarded than faithfully carried out. This is, however, the fault of the officials appointed to do the work. Probably in most cases, municipal inspectors are appointed through political influence and discharge their functions according to political lights rather than conscientious motives; it is beyond question that the depth of American worthlessness is reached in the breed of petty politicians peculiar to this country. Mr. Jackson will find that we have about all the rules and regulations required if we only had officials appointed on merit and imbued with a determination to see justice done to all concerned. Let us, the electrical workers, strive always to work conscientiously and keep in mind perpetually the moral obligation to safeguard human life and property; then the inspector may camp upon our trail to his heart's content.

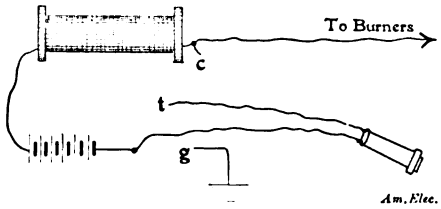
Houghton, Mich. GEO. S. CRABBE.

A Simple Method of Testing Gas Lighting and Electric Bell Circuits.

To the Editor, American Electrician:

Thinking that some of your readers might be interested to know of a simple but good method of testing gas lighting, electric bell and similar circuits for leakage, I submit the accompanying diagram and the following explanation. The diagram here shown is intended to apply to gas lighting circuits. One terminal of a sensitive telephone receiver is connected to the terminal of the battery which is usually grounded, the ground connection being temporarily broken. The other terminal, *t*, of the receiver is then applied to the burner circuit where it leaves the spark coil at *c*, being put in contact with and removed from the wire several times in order to note clearly the strength of the click caused in the receiver. Then the free terminal *t* is touched repeatedly to the ground connection or a gas pipe. If there is any leakage a click will be heard, and a comparison of the sounds obtained in the last test with those obtained when the telephone is connected to the spark coil terminal will give a good indication of the extent of the leakage. If no click is heard when the receiver is connected to the ground and the battery, the circuit is clear, assuming, of course, that the wires from the spark coil to the burners are all sound.

It is well known that a small leakage will weaken the batteries in a short time, even though the leaking current may not be sufficiently strong to be detected in the ordinary way without the use of expensive instruments.



CONNECTIONS FOR TESTING GAS LIGHTING AND CALL BELL CIRCUITS.

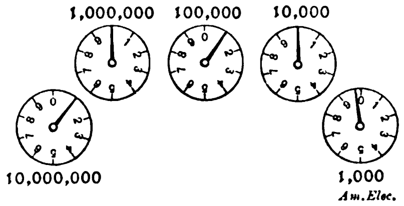
The same method may be applied to electric bell circuits; in this case there is no spark coil, of course, so that the terminal *t* is touched to the circuit terminal of the batteries in the first part of the test and to the ground or common-return wire in the second. The receiver can also be used to tell whether or not a bell rings when a button is pushed by connecting the receiver terminals to the contacts of the push-button and pressing the button two or three times; if a buzzing noise is heard in the receiver after the connection between the push-button contact is broken, the bell rings. If the bell fails to ring, the receiver will merely give a single click, and if the circuit is broken between the button and the bell no noise will be heard in the receiver.

Brookline, Mass. E. S. LINCOLN.

Mr. Ryder's Meter Reading.

To the Editor, American Electrician:

Referring to Mr. Ralph Ryder's tricky meter reading published in the March number, I should say that the meter reads 1,009,900, and submit the following explanation of this result: It is plain that the first dial reads between 900 and 1000, since the hand has not quite reached zero; the reading here, therefore, would be taken as 900. The second dial, though apparently indicating zero, must be taken to read 9 until the hand on the first dial has completed its revolution; so that these two dials indicate 9900. The third dial is a little misleading, the pointer being exactly over the 1, but this dial cannot read 1 until the second dial indicates zero, and the first dial proves that this is not the case. Since the third dial is well started on its revolution, the fourth dial will read zero as it indicates, in which case the fifth dial must read 1. If the pointer of the first dial had been actually at zero, then the reading of all the other dials would have been exactly as they appear to indicate.



A TRICKY METER READING.

New York. LEWIS C. REYNOLDS.

[NOTE.—The same result and reasoning have been sent in by C. J. Abbey, Skowhegan, Me.; A. B. Case, Chicago, Ill.; H. Lee Clark, Canton, Pa.; C. C. Daugherty, Princeton, Ind., and Charles M. Green, Conneaut, Ohio.

The same result, without the detailed explanation of its derivation, was sent in by J. R. Adams, River Fall, Wis.; Walter Beck, Doylestown, Pa.; Ralph L. Britain, Richmond, Vt.; Ervin J. Casper, Vallejo, Cal.; Frederick L. Crass, Hartford, Conn.; Linwood Cushman, Bar Harbor, Me.; E. E. Devendorf, Amsterdam, N. Y.; S. C. Ensor, Mt. Washington, Md.; Thomas M. Gibbes, Atlanta, Ga.; Geo. A. Gould, Phillipsdale, R. I.; William G. Hurtzig, Morristown, N. J.; E. R. Horseley, Goldfield, Colo.; Henry D. Jackson, Boston, Mass.; Percy M. Jones, Paterson, N. J.; V. H. Julian, Ridgefarm, Ill.; E. Keenan, Auburn, N. Y.; Burton E. Lucas, Ovid, Mich.; F. J. Meyer, Oklahoma, O. T.; C. C. Michael, Bristol, Conn.; Robert Montgomery, Jeffersonville, Ind.; H. Notthoff, Santa Monica, Cal.; Nutting & Goodwin, Litchfield, Conn.; D. S. Overdorff, Johnstown, Pa.; Allan W. Pattee, Monmouth, Ill.; John G. Peebles, Nashville, Ill.; E. S. Rockafeller, Monticello, N. Y.; W. S. Stratton, New York; J. C. Sweeney, Lima, Ohio; F. H. Tice, Baltimore, Md.; George Veidt, St. Louis, Mo.; J. A. Ward, Sturgis, So. Dak.; A. S. Weibel, Allentown, Pa.; J. G. Whittemore, Benson, Minn.; Samuel Wilkinson, Northville, Mich.; Herbert Williams, Charlotte, Mich.; L. F. Woodhead, Union City, Tenn.; F. H. Woodhull, Coatesville, Pa., and C. F. Zachau, Arlington, N. J. —EDITOR.]

To the Editor, American Electrician:

The meter dials shown by Mr. Ryder in the March issue are somewhat of a puzzle until it is remembered that the position of each pointer on its dial is determined not alone by an inspection of the pointer itself but by knowing the position of the pointer preceding it. The extreme right-hand dial reads 975; the next dial appears to be at zero, but as the pointer on the first dial has not completed its revolution that on the second dial cannot have reached zero, so that the latter still indicates 9. The third dial is still in the zero space because it cannot have reached 1 until the pointer of the second dial has completed its revolution. The pointer of the fourth dial has passed its zero for the reason that the pointer of the third dial has completed a revolution and is on its way to the 1 mark. The pointter on the last dial obviously indicates 1, as the pointer on the dial preceding it has passed zero. The total reading, therefore, is 1,009,975.

Jordan, Minn. S. L. SLY.

[NOTE.—Similar solutions to that of Mr. Sly have been furnished by Joel Gomborow, Lynn, Mass., and J. G. Hackley, New York, the only difference being that these two readers estimate the position of the right-hand pointer to be at 980 instead of 975. The difference is, of course, negligible, and the correct reading may be taken as 1,009,975, 1,009,980 or 1,009,900. In some stations it is the practice to read the position of the right-hand pointer down to a half division, but not closer. Under this rule the reading would be 1,009,950, as the right-hand pointer has passed the half-way point between 9 and 0.

The second and fourth dials in the diagram should be numbered in the counter clockwise direction instead of clockwise; the error in numbering was due to our engraver, who evidently supposed all of the dials should be numbered in the same direction. The error, however, does not affect the result, as the pointers of both of these dials are in line with the zero mark.—EDITOR.]

Voltage Disturbance in Parallel Operation.

To the Editor, American Electrician:—

I have in my care four 110-volt generators operating in multiple; their capacities are as follows: Two of 75-kw. each, driven by one engine, one of 100-kw. driven by another engine, one of 200-kw. driven by a third engine; the engines are in no way connected together.

While running the generators all take their proper load when regulated by their different rheostats, but the trouble is that throwing one in or out of circuit with the other changes the voltage of the circuit and therefore the speed of the motors. This change of speed is only for about 15 seconds, but in that time the speed of the motors changes and in turn the machinery is effected, and the material manufactured by it is injured by the change.

If we only use lights instead of power it would make no difference for that short time, but as it is the machinery must run at a steady speed at all times. Kindly ask some of your readers to suggest a remedy for the trouble. Is there any voltage regulator or anything that will keep the voltage absolutely constant at all times?

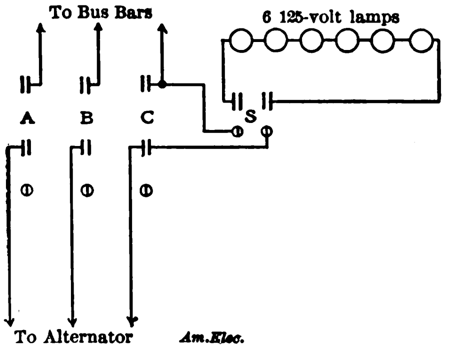
Union Hill, N. J. ERNEST F. HARTWELL.

◆◆◆

Mr. Bailey's Synchronizing Voltage.

To the Editor, American Electrician:

In answer to Mr. E. W. Bailey's question in the March issue regarding the voltage across his synchronizing lamps, I should like to point out that when the machines are in synchronism the voltage across the lamps is, of course, zero, the two voltages being equal and opposed when the lamps are dark. When the machines are out of step, however, the voltage depends upon the amount of variation; and when the phases are exactly opposed, or 180 deg. apart, the voltage across the synchronizing lamps is equal to the sum of the voltages of the two machines. The reason that the voltmeter never indicates this value is because the period during which this condition exists is so short that the instrument does not have a chance to indicate it. If Mr. Bailey will try to get his machines in step with the lamps bright and then read the voltage, he will notice that this is true.



CONNECTIONS FOR SYNCHRONIZING.

Boston, Mass. HENRY D. JACKSON.

[NOTE.—The same explanation has been submitted by A. B. Case, Chicago, Ill., and Henry Mulford, Patchogue, L. I., except as to the reason why the voltmeter never indicates more than 720.—EDITOR.]

◆◆◆

Adjusting the Compounding of a Dynamo.

To the Editor, American Electrician:—

In your February number "D. R. P." asked for "two ways to adjust the compoundinng of a direct current dynamo." When a machine is over compounded is it not well to increase the flow of current in the shunt coils and reduce the speed of the machine (provided, of course, the wire will permit) so as to diminish the flow in the series? Or if under compounded, diminish the flow in the shunt by introducing more resistance and increasing the speed? For instance, I have a ten-pole machine very much over-compounded. I separate the shunt field magnet winding into two groups of five coils each and connected the two halves of the shunt field in parallel. I could then reduce the speed about 15 revolutions per minute and the machine balanced perfectly. The reduction in speed was desirable in this as the machine worked most of the time on about one-half load. The coils did not heat perceptibly but the rheostat showed some distress, but not more than I have seen some others connected in the ordinary way.

From the way the question was asked, I have no doubt "D. R. P." had something of this kind in his mind. A case of under compounding came "up to me" some years ago aboard ship. I had two small by-polar machines which were rated at 360 r.p.m., but with the resistance of the rheostat all cut out the voltage would go down at full load. I began increasing the speed and cutting in resistance until I reached 390 r.p.m. and had all the field resistance cut in, under which conditions the voltage would come up with just the pilot lamps on, and remain the same to full load. I never found it necessary to change the position of the rheostat as long as I remained in charge. I might add that previous to my time, the shunt field coils got very hot, in fact, they burned out on both machines. Of course, we know these are the results of miscalcultaions in building, but what is the engineer to do is often what we have to determine.

Washington, D. C. LEWIS JONES.

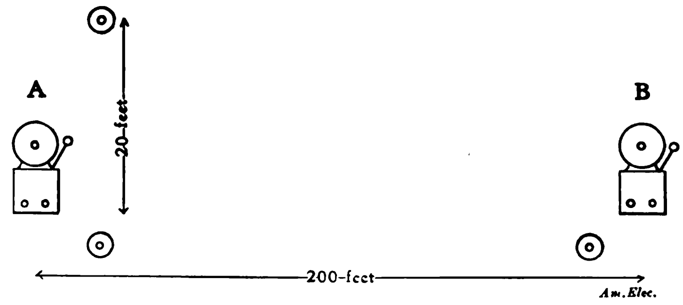
Another Problem in Bell Connections.

To the Editor, American Electrician:

The accompanying diagram indicates two ordinary electric vibrating bells and three push-buttons, two of the push-buttons and one bell being located at Station *A* and the other push-button and bell at the other station, *B*. The distances between the two bells and the bell and upper push-button at Station *A* are marked on the diagram. Each of the two push-buttons at Station *A* must be connected so that the bell at Station *B* may be rung by depressing either of them. The push-button at Station *B*, of course, is connected to ring the bell at Station *A*. The problem is to make the connections with the most economical use of wire. I should like very much to have this little problem submitted to readers of the AMERICAN ELECTRICIAN.



PROBLEM IN BELL CONNECTIONS.

St. Louis, Mo. FRED D. MAHAFFEY.

[NOTE.—Solutions of the above problem, in order to be published in the May number of the paper, must reach this office not later than April 16. Readers who would like to submit solutions but prefer not to have them published may do so with the assurance that their communications will receive the same attention as those intended for publication. —EDITOR.]

The New Double-Commutator Motor.

To the Editor, American Electrician:—

In your March issue, containing a description of the new variable speed motor, of the Commercial Electric Company, I beg to call your attention to an error in your description of the method of winding the armatures and the method of control used in these machines. It is stated in your description that the motors "have two armature windings exactly alike, connected to commutators at both ends of the armature" and that the control is effected by connecting these two armature windings in series, or in parallel, according to the speed required. As a matter of fact, the windings connected to the two commutators are *not alike*, but are of the same size wire having different numbers of turns, which are usually in the ratio of three turns on one end to two turns on the other end, and in this feature lies the distinct difference between the "Commercial" motor and the ordinary two-commutator motor which has been in use for some time, the change enabling us to secure three, or even four, fundamental speeds with a given field strength, by properly combining these armature windings,, instead of two which are all that can be obtained when the simple series-parallel system of control is used.

To obtain the various speeds, these windings are connected to a supply circuit of constant voltage singly, or in series cumulatively, or in series differentially; as the windings are of the same ampere capacity, the maximum current input to the motor is the same whatever combination is used; and as the efficiency is practically constant a constant brake horse-power is developed at all speeds, instead of a horse-power varying with the speed, as is obtained by the series parallel system. This system of connection also has the result that the maximum ampere-turns of the armature are inversely proportional to the speed, so that the torque exerted by the armature is the greatest at the slowest speed, and lightest at the highest speed, which is exactly the condition required to secure the maximum output from any machine tool, such as a lathe, or boring mill, in which the maximum depth of cut and maximum feed are desired at a constant cutting speed, whatever the diameters may be.

M. O. SOUTHWORTH,
Engineer, Commercial Electric Company.
Indianapolis, Ind.

Queries and Answers

IMPORTANT.—No attention will be given to any inquiry which does not give the full name and address of the inquirer.

Where can castings be obtained for the gas engine described in the January number of the AMERICAN ELECTRICIAN? L. I. L.

From Parsell & Weed, 129 West 31st Street, New York City.

In the December number of the AMERICAN ELECTRICIAN, the description of an ammeter on page 601 calls for a phosphor-bronze spring No. 30x40 (in the second column, the second line, beneath Fig. 7). What do the figures 30x40 mean? C. A. B.

B. & S. gauge numbers. Mr. Brocksmith writes, however, that the spring may perferably be made 0.005 × 0.2 inch.

If the charge in a gas engine cylinder were exploded with the moving parts all blocked, and the cylinder remained air-tight and undamaged, would the pressure due to the explosion remain at the same point as at the instant of explosion? E. C. B.

No. The pressure would fall slowly as the temperature of the gases within the cylinder became lower due to the conduction of heat through the cylinder walls to surrounding air.

What size of wire should be used to wind a medical coil having a core 7/16 inch in diameter and 3¼ inches long? (2) Will double cotton insulation be suitable? (3) Why are the contact screws on induction coil vibrators tipped with platinum? U. D.

No. 24 B. & S. gauge, making the coil three inches long parallel with the core and ½ inch deep. (2) No; double silk-covered wire should be used. (3) In order to prevent sparking from damaging the contact points.

Why are split spools used for magnet coils? (2) Under which conditions will dry batteries last longer, when supplying 1½ amperes for a quarter of a second at five-minute intervals, or when supplying 3 amperes for a quarter of a second at ten-minute intervals? N. J.

In order to prevent the metal spool from acting as a closed secondary with relation to the winding of the magnet; they are usually unnecessary except for alternating-current magnets. (2) The batteries would last longer giving 1½ amperes every five minutes.

What is the best method of installing 110-volt direct-current incandescent lighting circuits in a very steamy place? (2) How can I make a direct-current ceiling fan motor run 25 per cent faster than it now does? A. R. T.

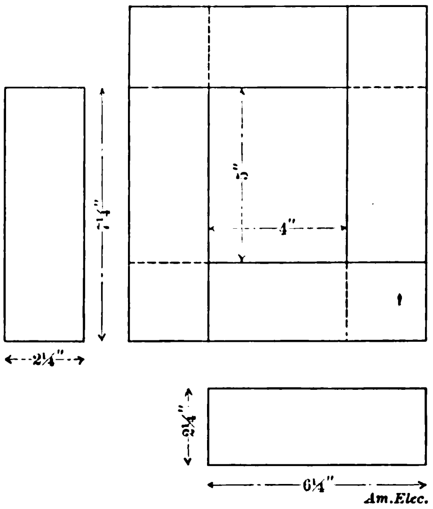
Run the wires in insulated iron conduit and do not use any pendants. Use weather-proof sockets attached to galvanized iron pipe and cover the joints between the sockets and the pipes with rubber tape. (2) You may be able to obtain this result by connecting a resistance coil in parallel with the field-magnet winding. You will have to determine by experiment the amount of resistance necessary.

When two compound-wound dynamos are operated on a three-wire system, would there be any advantage in exciting the shunt field windings of both machines from one of them? (2) Should the series fields be connected by an equalizer as in the case of parallel operation? G. A. V.

No; this would be rather a disadvantage than otherwise, since both machines would be useless if the one to which the shunt winding were connected should become disabled. (2) Certainly not; the machines are practically in series and connecting them by a low-resistance conductor would have the effect of short-circuiting one-half of the three-wire system, and one of the dynamos.

Can you give me the necessary data for the construction of a transformer having a 110-volt primary and a 5-volt secondary, the secondary current to be 200 amperes and the frequency of the supply current 60 cycles? W. A. T.

Make the core of annealed sheet steel strips 2¼ inches wide and 25 mils thick, putting 75 strips in each leg and each cross-bar of the core. The lengths of the strips must be such that the core when built up will have the dimensions shown in the accompanying sketch. Use No. 9 double cotton-covered magnet wire for the primary winding, putting 5 layers on each leg of the core and 35 turns in each layer, so as to obtain 350 turns total. Make the secondary winding of strip copper 3-16 inch thick by 2⅛ inches wide. Put 8 turns on each leg of the core and divide the winding on each leg into two sections, side by side, of four turns each, and connect the two inner ends of these sections in order to avoid leading a terminal out from the inside. The two sections must, of course, be wound in opposite directions from the joint between their inner terminals. Apply a strip of shellacked linen to the inner surface of the copper strip before winding it in place.



What is the formula for the flow of gas through a pipe of given diameter and length with a given drop in pressure? C. W. K.

Representing the quantity of gas in cubic feet per hour by Q, the diameter of the pipe in inches by d, the drop in pressure in pounds by p, the specific gravity of the gas by s, and the length of the pipe in feet by L, the formula is

$$Q = \sqrt{\frac{d^5\, 830p}{s\,L}}$$

The value of s is the ratio of the weight of gas per cubic foot to the weight of air per cubic foot at a given temperature.

How can permanent magnets be made of cast iron? (2) What size of wire and how much will be required to make a set of resistance coils from 0.01 to 1 ohm in steps of 0.01 ohm and from 1 to 10 ohms in steps of 1 ohm? (3) How many volts are required to jump across one inch of dry air when a static machine or large induction coil is used? H. H. T.

Permanent magnets cannot be made of cast iron; the very best grade of either tungsten or chrome steel is required. (2) The size of wire depends upon the strength of current your resistances are expected to stand. Either German silver or platinoid wire should be used, and the quantity cannot be calculated without knowing the exact quality of the wire. (3) About 20,000 volts.

A bipolar shunt-wound motor built for 500 volts was changed to run at 110 volts by connecting the armature coils in groups of four in parallel, each group of four being considered a single coil. The correct speed was obtained, but the motor took an abnormal current at no load and heated badly. It tested clear of grounds and short-circuits and held its speed under load. What was the probable cause of the excessive no-load current and overheating? (2) Can a two-path armature wound to operate at 500 volts in a four-pole field-magnet be changed to run on 110 volts by putting two coils in parallel, connecting the winding lap fashion, and putting on four sets of brushes? G. E. M.

Some of the armature coils were probably connected up wrong so as to form closed circuits in the winding. If all the coils in each group of four were not precisely alike, this would account for part of the trouble mentioned. (2) Yes, provided one coil be omitted and dead-ended so as to leave an even number of coils. Two of the commutator segments would have to be bridged together into one.

If one has a formula such as $m = \frac{a\ b\ c}{x\ y}$, what is the rule for finding the value of one of the other letters when m is known? (2) Is the end of a compass needle which points north actually the north pole of the needle? (3) Does excessive pressure of a brush on the commutator of a dynamo or motor produce green or red sparks at the brush tips? G. A. J.

Your equation can be transposed to read $m\ x\ y = a\ b\ c$, and this can be further transposed by putting any two factors in one member of the equation underneath the three factors of the other member, according to which one of the six factors is unknown. For example $x = \frac{a\ b\ c}{m\ y}$; $a = \frac{m\ x\ y}{b\ c}$; $c = \frac{m\ x\ y}{a\ b}$. You will find in any good school algebra a full exposition of all kinds of equations. (2) The end which points north is the north pole according to the accepted magnetic nomenclature and corresponds to that pole of a dynamo field-magnet which is ordinarily termed the north pole. As a matter of fact, however, these poles are of the same magnetic sign as the south pole of the earth. (3) Not unless the sparks previously existed beneath the brush, or unless the pressure is so great as to grind off small particles of copper from the brushes and commutator segments.

POWER PLANT OF THE NEW ENGLAND CONFECTIONERY COMPANY, BOSTON, MASS.

One of the greatest difficulties that confronts the engineer when designing a power plant to serve a factory, located within the limits of a large city where land is expensive, is the placing of the apparatus in the smallest possible space without overcrowding it. This problem has been masterfully handled in the New England Confectionery Company's works, in Boston, Mass., as reference to the illustrations will show. The buildings are located on the South Boston side of Fort Point Channel, and cover a ground area of about 40,000 square feet. The demand of this plant for power is not a small one. For general power purposes about 40 Crocker-Wheeler motors aggregating 365 horse-power are used, mostly for group driving by belt and shafting. In addition there are five elevators direct-driven by Holtzer-Cabot motors and five Sturtevant fans for ventilating, driven by direct-connected motors of the same make, the ten outfits representing a combined total of 110 horse-power. Two ¼-h.p. motors for a pneumatic tube system and some fifteen desk fans complete the list of the power consumers. For lighting, the building is provided with about 1300 16-c.p. incandescent lamps and three arc lamps. It is quite remarkable that all of the apparatus, including the boiler equipment, engine-generator equipment, refrigerating outfit and pumps for boiler feeding, condensing, house service, returns from heating system, etc., are contained in a section of the basement 6038 square feet in area, or but 15 per cent of the total ground area occupied.

The boiler-room contains 3530 square feet; this includes a storage space for about 200 tons of coal and allows for the future installation of double the present equipment of boilers. The three now in place are of the return tubular pattern built by Edward Kendall & Sons, Cambridgeport, Mass., and generate steam at a pressure of 145 pounds. Each is 78 inches in diameter by 18 feet long, and has a total heating surface of 2376 square feet, and a grate surface of 49 square feet. A 10-inch gauge, a 5-inch safety valve and a Reliance water column is provided for each boiler. The smoke outlets connect to a breeching 4 x 6½ feet in cross section, which contains a Mason damper regulator and leads to the base of a stack 6 feet in internal diameter and 125 feet high. The steam outlets, each 6 inches in diameter, connect through Wainwright corrugated expansion joints to a 12-inch header at the rear of the boilers, in which provision has been left for the connection of the three additional boilers, as it becomes necessary to erect them.

The live-steam main for the engines is taken off near one end of the 12-inch header and contains a Locke emergency automatic safety shut-off valve and an 8-inch Cochrane steam separator. From the other end of the header through another Locke shut-off valve a 10-inch connection is made to a short auxiliary header in the engine-room which supplies the various pumps, and through a 6-inch Watts regulating valve, reducing to 90 pounds, connects to a riser which conveys about the building the steam used at this intermediate pressure for manufacturing purposes. Through another Watts reducing valve from the auxiliary header a 15-pound pressure is obtained for manufacturing use and the heating system, when the exhaust from the various pumps and the small non-condensing engine is not sufficient. On the low pressure side each

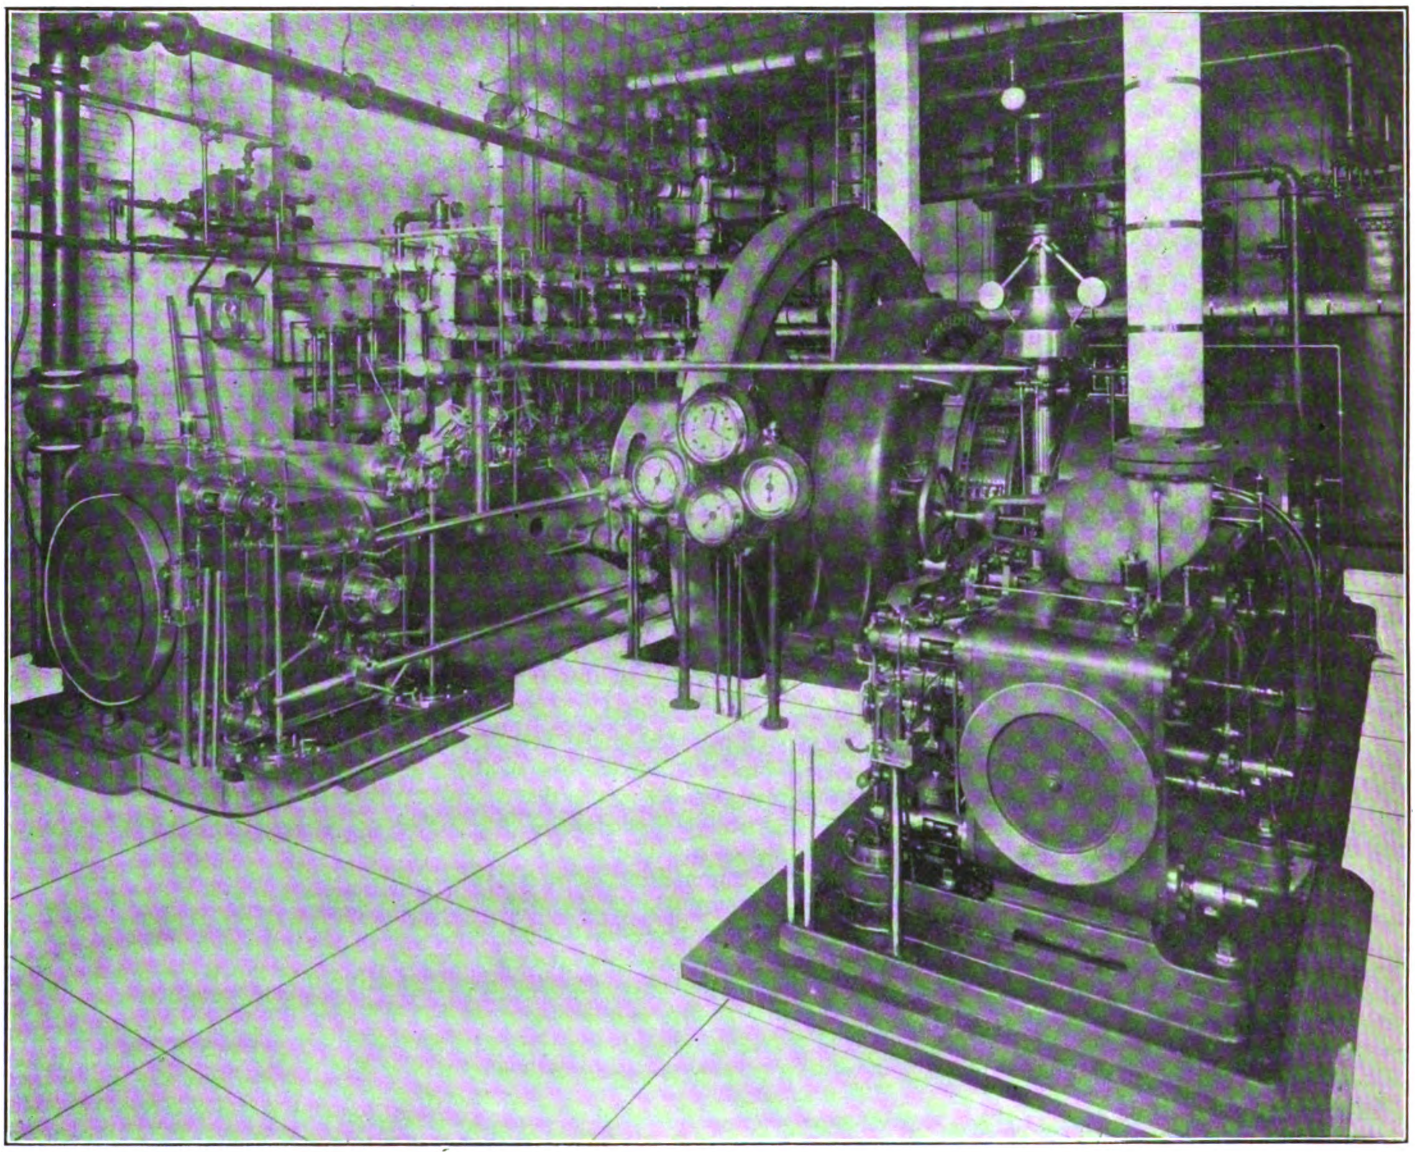


FIG. I.—VIEW OF ENGINE ROOM SHOWING MAIN GENERATING UNIT.

reducing valve has a Crosby inspector safety valve, the first set to blow off at 100 and the other at 25 pounds. Steam piping is of wrought steel with Van Stone flange joints for 5-inch and above, and the sizes below are wrought iron with flanges screwed on.

The engine-generator equipment includes two direct-connected sets, delivering direct-current at 230 volts. The larger one, used during working hours, consists of a 12-pole Crocker-Wheeler generator of 370 kilowatts capacity, driven at 120 revolutions per minute, by a 16 and 32 x 36-inch Corliss-type compound engine, built by the Filer & Stowell Company, of Milwaukee, Wis. During the lunch hour this set is stopped and a smaller set, having a capacity of 50 kilowatts, often used for night loads also, is run instead. The dynamo is a 6-pole Crocker-Wheeler machine and is driven at 275 revolutions per minute by an 11 x 12-inch simple horizontal Ames Iron Works engine. This set is run noncondensing and exhausts into the low-pressure system through a 5-inch Lowden oil extractor. The compound engine exhausts to a Knowles 9 x 18 x 12-inch vertical twin air pump and jet condenser, which maintains a vacuum of about 26 inches. Between the high and low pressure cylinders there is a gauge board containing a clock, a gauge for the initial steam pressure, one for the pressure at which the steam is exhausted from the first to the second cylinder, and one for the vacuum in the condenser. In addition to the ordinary oil cups which are used only in case of emergency, all bearings and rubbing parts are lubricated through a gravity oiling system from an elevated reservoir, having a capacity of 60 gallons. After being used the oil is passed through two 2-gallon White Star filters made by the Pittsburg Gauge and Supply Company, and is returned to the storage tank by a 2½ x 1¼ x 3-inch Warren pump.

From the generators to the switchboard the feeders are taken in conduits under the floor. The switchboard is an exceedingly simple one and handily located near both generators and away from the wall so that all parts are accessible. It is 78 inches wide by 84 inches high, and was built by the Albert and J. M. Anderson Manufacturing Company, of Boston, Mass. The equipment is clearly shown in Fig. 3 and is as follows (reading from left to right and from top to bottom): a voltmeter with a 250-volt scale; a 2000-ampere ammeter for the large generator; a 300-ampere ammeter for the small generator; a double-pole single-throw switch for the engine and boiler-room lights; four similar switches for the

FIG. 2.—PLAN VIEW OF THE NEW ENGLAND CONFECTIONERY COMPANY'S POWER PLANT.

lighting in the first, second, third and fourth buildings; a plug switch for connecting the voltmeter with either generator; a ground-detector lamp for each machine; a field rheostat for the large machine; three double-pole, single-throw switches for power in the first, second and third buildings; a rheostat for the small machine; a double-pole single-throw switch controlling the feeders to the elevators; a double-pole double-throw switch for connecting the bus bars to either generator, and a double-pole single-throw switch for the power in the fourth building.

The pumps for the most part are placed vertically along or close to the walls, and it is in this way that the great saving of floor space in the engine-room is effected. Inasmuch as the plant is located on the shore of the Fort Point Channel, an inlet from Boston harbor, salt water is available in large quantities and at no expense. It was endeavored to take advantage of this condition of affairs by utilizing salt water for condensing purposes and for use in toilet fixtures, the city supply of fresh water being drawn upon only for the boiler feed, manufacturing service and drinking water. The salt-water supply is taken through two 8-inch pipes leading from the harbor, each having a removable Blake copper wire strainer. These combine into a 14-inch pipe which passes along a trench into the engine-room, where it enlarges to 16 inches and connects to the suction ends of two Warren steam pumps, the compound-engine condenser and the ammonia condensers. The discharge from the condensers passes into a waste elbow through the wall between the engine and boiler-rooms to the east end of the latter and returns to the channel. All the salt-water piping is of cast iron, extra strong, coated inside and out with tar and made up with flanges. The salt water pumps which supply the circulating water for the refrigerating system and that used for sanitary purposes have cylinders 14 x 9 x 12 inches, and are cross-connected so that they may be used interchangeably.

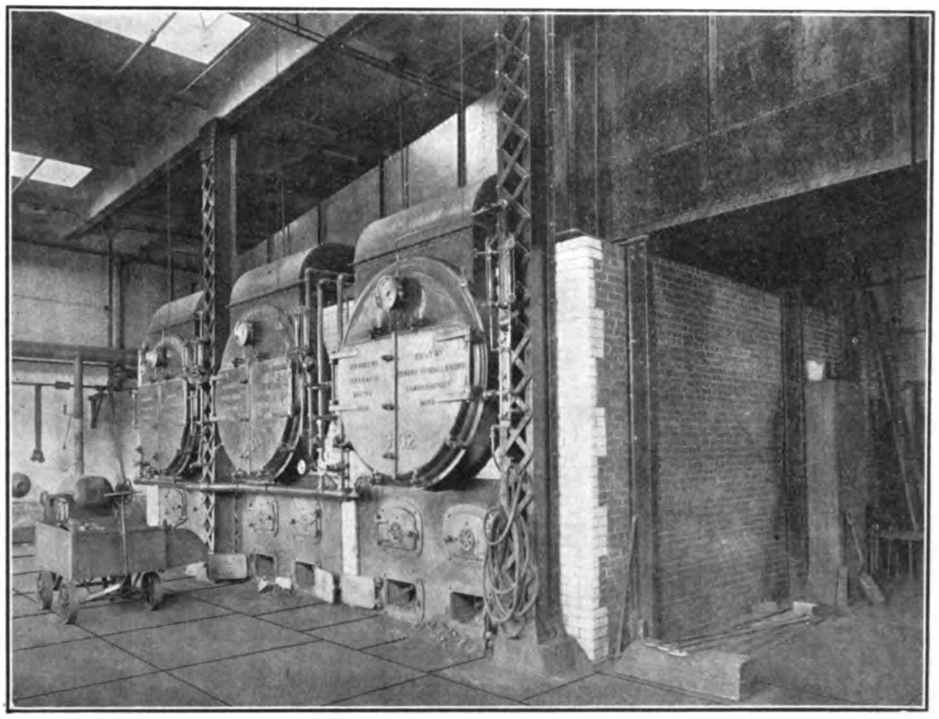

FIG. 4.—BOILER ROOM.

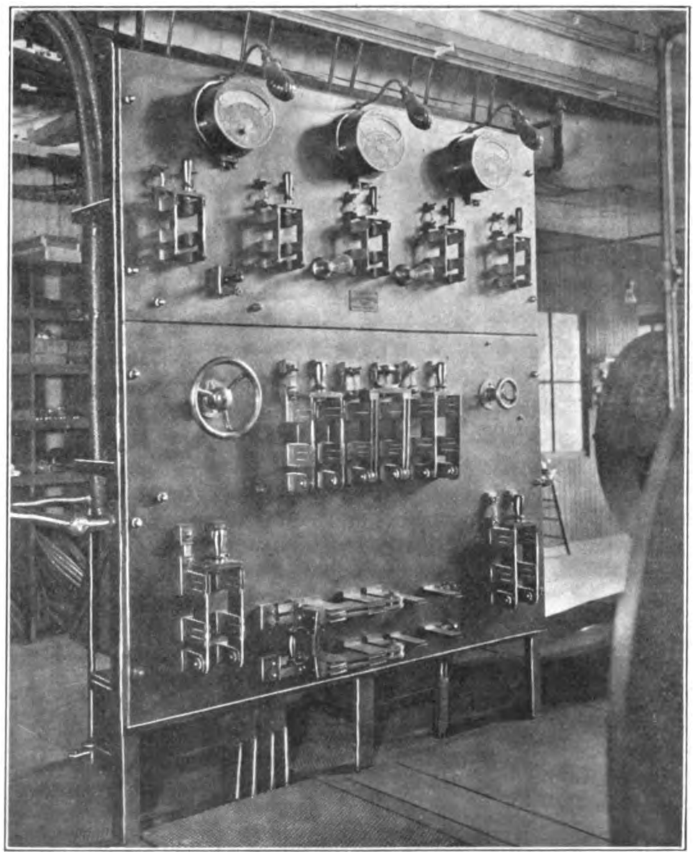

FIG. 3.—SWITCHBOARD.

The fresh-water supply is taken from the main through a 3-inch connection which immediately enlarges to 6 inches and finally to 8 inches near the pumps. For boiler feeding there are two vertical cross-connected 8 x 5 x 12-inch Warren pumps. Another vertical pump of the same make with cylinders 7½ x 4 x 10 inches is for house-service, and discharges through air chambers which provide the pressure necessary to distribute it to all parts of the building. The pressure on the air chambers is provided by an air compressor, manufactured by the New York Air Brake Company.

The hot-water house-service is obtained from a heater, the steam supply to which is controlled by a Curtis thermostat made by the Julian D'Este Company of Boston. On their steam supplies all the pumps are provided with Locke governors, making them automatic in their operation, and the feed, salt-water and house-service pumps have American Steam Gauge Company's water-relief valves, connecting the discharge and suction ends. The one on the feed pump opens at 200 pounds and the others at 100.

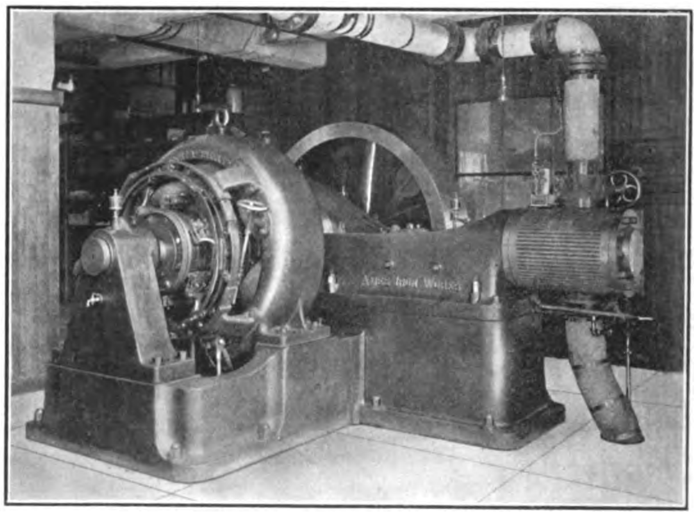

FIG. 5.—AUXILIARY GENERATING UNIT.

The exhaust steam from the pumps combining with that from the Ames engine goes into the low-pressure system for heating and manufacturing purposes. Condensation from this system and the drip from all clean steam pipes is withdrawn through V. D. Anderson steam traps and brought back to a receiver, 3 feet in diameter by 4 feet long, connecting with a Deane 8 x 5 x 12-inch horizontal return pump, which discharges direct to the boilers. Greasy drips such as those from the oil extractors or from parts of the exhaust piping containing unclean steam are discharged into the salt-water waste pipe. All traps are by-passed.

The feed-water heater is of the National closed type and receives steam from the low-pressure system, the excess being passed out through an 8-inch spiral-riveted galvanized-iron exhaust pipe, containing a Schutte back-pressure valve and leading to the roof, where it is surmounted with an exhaust head. This same riser has a connection to the large engine exhaust pipe, which contains an 8-inch Blake automatic exhaust relief valve.

In case of any trouble with the condenser this valve will open automatically and allow the engine to exhaust direct to the atmosphere. The feed pumps discharge through the heater, but they are also arranged to deliver cold water directly from the city mains to the boilers. The feed piping between the pumps and heater is of wrought iron and that between the heater and boilers is of brass, iron-size and thickness, as is also the discharge pipe from the return pump.

The refrigerating equipment operates on the ammonia absorption system, has a capacity of 100 tons of refrigeration per twenty-four hours, and was installed by the Carbondale Machine Company. It includes a Hendrick brine cooler, a generator, an absorber, two condensers, two ammonia pumps and two brine pumps. The connections and locations of the parts are clearly indicated in the accompanying plan. The ammonia pumps are cross-connected and of the same size and make, *i. e.*, Deane, 14 x 5½ x 12-inch pumps. The brine circulating pumps are also cross-connected and of Deane make, one having 14 x 8½ x 12-inch cylinders, and the other 7½ x 8½ x 10-inch. For the circulating of the drinking water a 3 x 2 x 3-inch duplex Warren pump is used, drawing from a supply tank, which is cooled by brine coils and kept filled by a float valve controlling a connection from the city service. All pumps are duplex with the exception of the ammonia pumps, and all are placed vertically except the ammonia pumps, brine pumps, drinking water pump and hot water return pump.

To Messrs. Dean and Main, of 53 State Street, Boston, engineers and mill architects, are due the structural features and general layout of the apparatus in the power plant, as well as the refrigerating system. Mr. E. F. Brigham, who remains in the employ of the company, was the engineer for the electrical work, and the present chief engineer in charge of the plant is Mr. F. C. Kennedy. The steam piping and heating system were installed by the Walworth Construction and Supply Company, of Boston.

INTERESTING CONDUIT WORK IN BROOKLYN.

The Brooklyn Heights Railroad Company had just had installed for it an interesting piece of conduit work running from its new power house on Gowanus Canal and First Street to Fifth Avenue and First Street, where the feeders emerge and are fastened to the elevated railway structure, supplying both elevated and surface railway demands. The feeders after leaving the direct-current switchboard pass downward along the wall of the power house to the floor of a compartment in the basement immediately beneath the switchboard. Here the feeders enter the conduit, spread out on the floor as shown in Fig. 1, and pass out of the building to a manhole at the northeast corner of the power station. From this manhole emanates a 72-duct line, arranged 9 high and 8 wide. The basement of the power house being on a level with the outside ground, the conduit runs along the ground, being encased in concrete as shown by Fig. 2, which is a view outside the new power house, the old power house being shown in the background. The street level is considerably higher than the ground upon which the power house is built, so that the conduit runs underground, as soon as it reaches the street, to a double manhole outside the station on First Street near Third Avenue. Before reaching the manhole, however, it is fanned out so that a 36-duct line enters one manhole and two 18-duct lines enter the other. These latter are arranged 9 high and 2 wide, while the former is arranged 9 high and 4 wide.

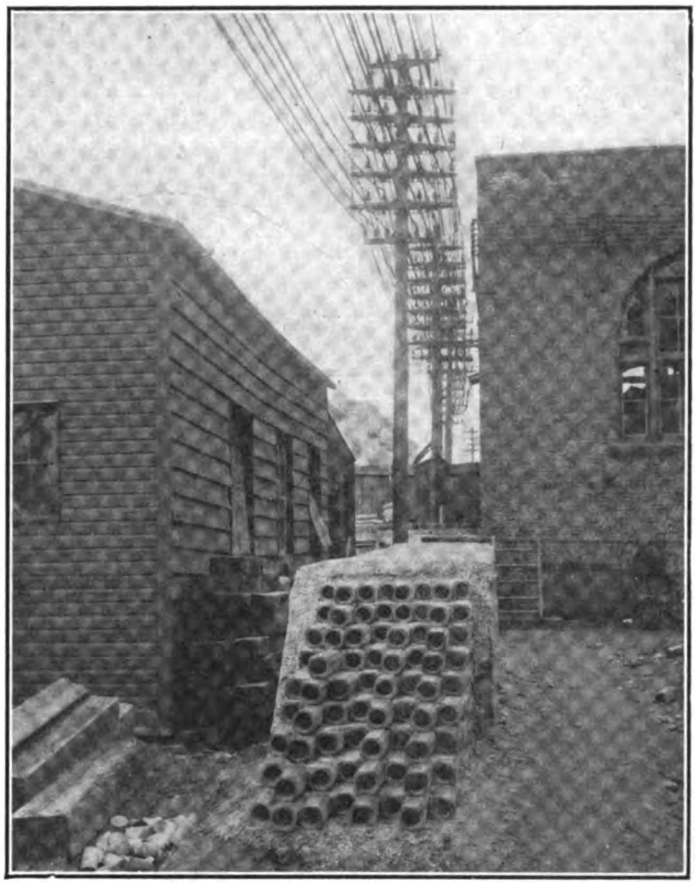

FIG. 2.—CONDUIT IN THE STATION GROUNDS.

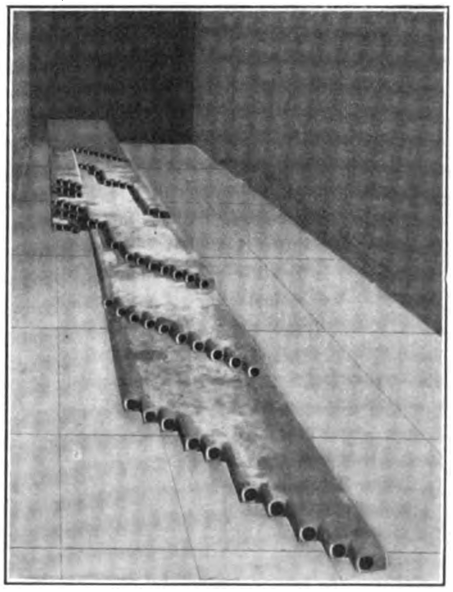

FIG. 1.—LAYOUT OF CONDUIT IN POWER HOUSE BASEMENT.

Serious difficulties were encountered at Third Avenue in the shape of water mains, gas mains and already existing conduit lines, the surmounting of which necessitated no little labor. The Third Avenue manhole is a vault 3 ft. 10 ins. wide, 6 ft. 4 ins. deep and 24 ft. long, having two covers. From

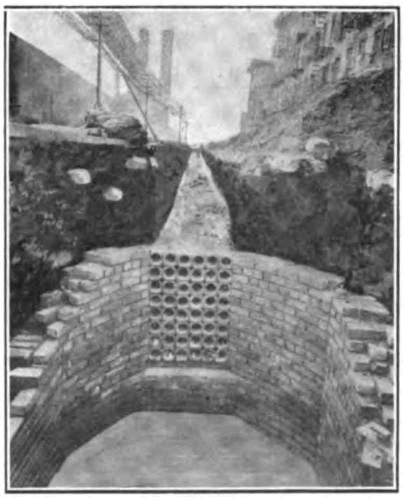

FIG. 3.—CONDUIT LINE ON FIRST STREET.

the 36-duct manhole, 33 ducts, 3 high and 11 wide, emanate in two conduit lines and enter the Third Avenue vault, one line containing 9 ducts and the other 24 ducts. From the manhole in which two 18-duct lines enter, 2 wide and 9 high, a 16-duct line 2 wide and 8 high runs to the far end of the Third Avenue vault and another 16-duct line, 4 wide and 4 high, enters the vault near the center well up toward the top. A 6-duct line runs parallel with Third Avenue from one end of the vault and a 16-duct line runs along Third Avenue from the other end. From the side of the vault, two 24-duct lines, 3 high and 8 wide, run to a manhole in the middle of First Street above Third Avenue, where they unite in a 48-duct line and run up First Street to a manhole at Fifth Avenue. Fig. 3 is a view of the conduit line on First Street. At Fifth Avenue, three 16-duct lines run to three manholes situated on the northwest, southeast and southwest corners, from which the feeders ascend along the pillars of the elevated railway structure. Fig. 4 is a diagrammatic view of the manholes and conduit layout at Third Avenue and shows how the conduit lines are arranged in order to pass the obstructions mentioned. The obstructions of course are not shown.

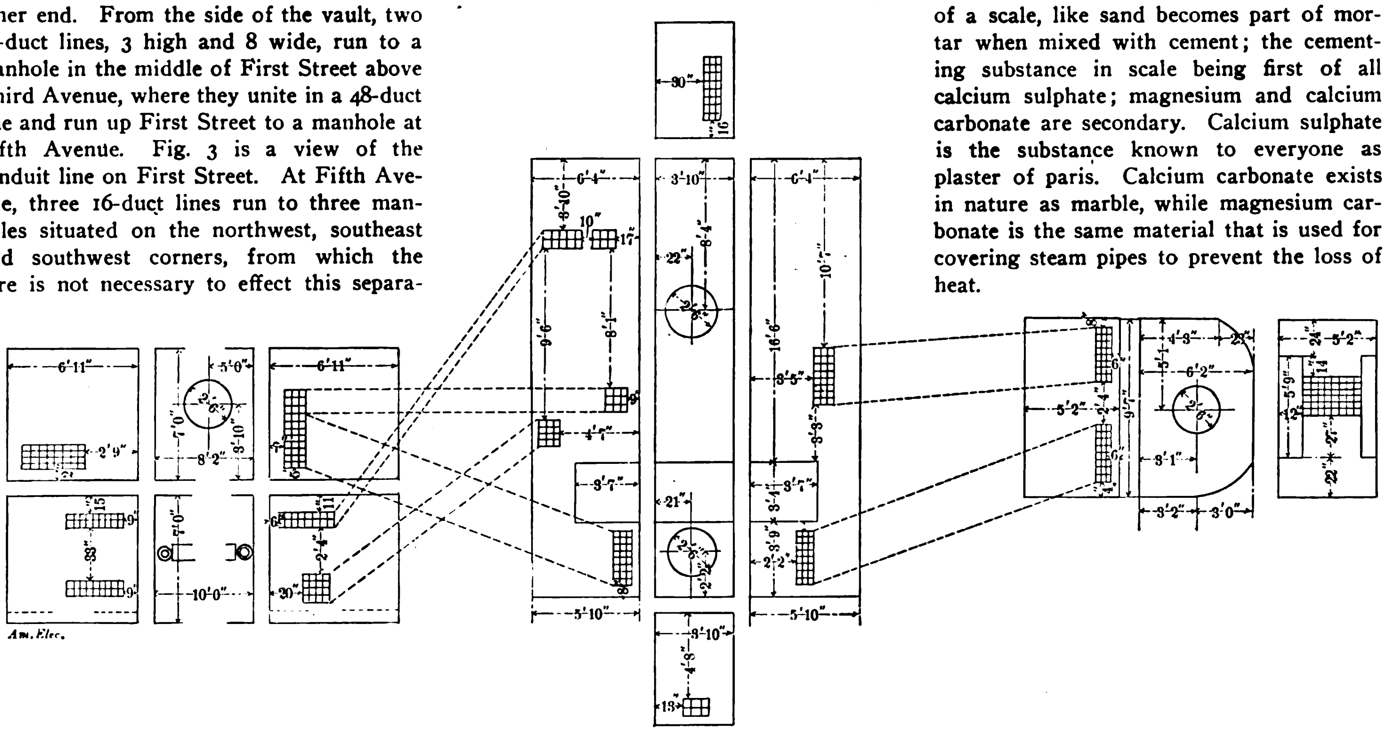

FIG. 4.—DIAGRAMMATIC VIEW OF CONDUIT LAYOUT AT THIRD AVENUE.

The contractor for the conduit work was Mr. G. M. Gest, of New York and Cincinnati.

BOILER SCALE.

BY GEO. W. LORD.

That nearly every water used in manufacturing plants for the production of steam contains solids which, upon evaporation of the water, form boiler scale, is well known to engineers generally, but it does not appear to be so well known in what manner that scale is formed, or what chemical reactions take place to cause the formation. In order to divide these solids they may be classed separately as sulphates and carbonates. The carbonates are calcium carbonate and magnesium carbonate, both of which are held in solution by reason of their excess of carbonic acid. From a temperature of about 180° Fahr. to the boiling point and above this excess of carbonic acid is driven off, and the carbonate of lime, or magnesia, robbed of its solvent deposits. An exceptionally high temperature is not necessary to effect this separation, and it is for this reason that carbonates deposit in feed-water heaters and economizers, as well as at the point in the boiler where the feed-water enters. The carbonates, when existing in a water without any calcium sulphate being present, form a porous accumulation, varying from a crystalline to amorphous formation, and even occurring as a fine powder. The latter is more often the case when the feed-water contains in solution a considerable quantity of sodium chloride (common salt).

Calcium sulphate, which is held in solution by nearly every natural feed-water, and especially in England, is not precipitated at the comparatively low temperature mentioned. In an experiment made in our own laboratory a water heavily saturated with calcium sulphate was heated to a temperature producing ten pounds of pressure, but no precipitation of the calcium sulphate was caused. Some authorities claim that the separation, or the change of the calcium sulphate from solution to suspension, takes place on the surface of the water in the boiler. If this were a fact the calcium sulphate scale would accumulate in those parts of a boiler nearest the water surface. The contrary, however, is the case, as scale of this nature invariably forms at the parts of the boiler which are exposed to the highest temperature. It is for this reason that we claim that the actual separation from a certain quantity of water takes place the minute that quantity of water is changed into steam, and we claim that this change takes place at the point where the heat is transmitted through the iron of the boiler to the water.

When an atom of water reaches a sufficiently high temperature to become steam it forms a minute globule, rises through the water to the surface, where the slight coating of water covering the globule breaks. At the point where this globule is formed, that is, at the heating surface, there being nothing to hold the calcium sulphate either in suspension or solution, it must separate, and forms a very small crystal. If the ebullition of the water permits it to do so it will adhere to the iron at the point where it had its origin, or it may be carried by the circulation until it reaches something to which it can adhere. The scale which is formed of calcium sulphate alone is very hard, but a formation of this kind is rare, the great majority of scales consisting of the three substances mentioned, as well as other mineral and vegetable substances.

These latter substances, which are held in suspension by water instead of in solution, become part of a body of scale only mechanically. That is, they become part of a scale, like sand becomes part of mortar when mixed with cement; the cementing substance in scale being first of all calcium sulphate; magnesium and calcium carbonate are secondary. Calcium sulphate is the substance known to everyone as plaster of paris. Calcium carbonate exists in nature as marble, while magnesium carbonate is the same material that is used for covering steam pipes to prevent the loss of heat.

From the very nature of scale-forming substances their accumulation is a source of trouble to the engineer and expense to owners of plants. There are, no doubt, many cases where additional expense does not worry the engineer, but there are probably more cases where the additional trouble to the engineer does not worry the owner of the plant. There is no question, however, but that both would be benefited if the accumulation of the scale could be prevented and taken care of.

The problem is a rather difficult one, as not only does each source of water vary greatly in the scale-forming solids, but each individual source varies from time to time. One can readily see, therefore, that the analysis of a single gallon of water does not give a great deal of information, but the analysis of a sample of scale does give complete information, as each sample of scale represents the residue left after the evaporation of large quantities of water. We, therefore, contend that if a sample of scale is divided and separated into its various ingredients, chemical treatment can be undertaken successfully. Without such determination, however, it is impossible to provide reagents which on the average can be assured to give satisfactory results.

If it were possible to compute the loss in fuel alone from this cause, the results would reach an enormous total, and would call the attention of the owners and engineers of plants to the great importance of the subject.

New Apparatus and Appliances

HIGH-TENSION INSULATOR TESTS.

The accompanying illustrations show the results of some interesting tests made by The R. Thomas & Sons Company, of East Liverpool, Ohio, on their No. 14 C-T insulators. These are of brown glazed porcelain made from English china clay and are glaze-filled; the individual parts being dried separately in an oven by a process known as "biscuit firing," dipped in glazing material, fitted in each other, put in a sagger petticoat uppermost and placed in a kiln. The petticoats are thus welded together by seams of glass-like glaze, which, it is claimed, are stronger than any of the other parts of the insulator. For the purpose of determining the potentials that arc over them, the insulators were mounted on tin-covered wooden pins. Current was supplied by a 150-kw. testing set, the requisite potential being obtained by means of a step-up transformer. No dry test was made, as this is of little value, since the potential at which the arc jumps from the head to the pin can be predetermined by measuring the shortest distance between them and referring to a curve of arcing distances in air. In the wet arcing test a stream of water from a sprinkling nozzle was played on the insulator, the quantity of water thus striking the insulator amounting to ¾ inch per minute. The insulator shows by Fig. 1 was subjected to a potential of 57,000 volts before the current "jumped." In Fig. 2 the current arced to the pin when the potential was 87,000 volts. In Figs. 3 and 4 the insulators withstood a potential of 98,000 and 107,000 volts, respectively before the current flashed over to the pin. This type of insulator measures 13⅝ inches high, 14¼ inches in diameter and weighs 24 pounds. It is intended for 70,000-volt service.

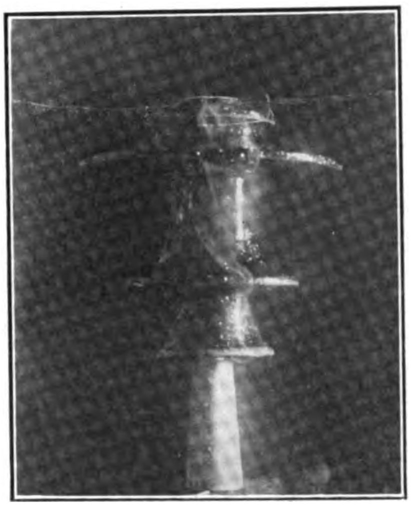

FIG. 4.

SIGNALING APPARATUS FOR CENTRAL STATIONS.

Charles Cory & Sons, of New York City, have brought out a modified form of ship telegraph apparatus for signaling between the engine room floor and elevated switchboard galleries. While this is rather unique in this class of work, it possesses obviously decided merit in generating stations of considerable size, especially if the switchboard attendant be more or less isolated from the engineer's natural post of duty, and where the use of some positive means of cummunication is an item of value in facilitating the rapid and accurate execution of orders. In marine practice for which this system was originally designed, there is used for each propelling engine one set of this apparatus, the set consisting of duplicate dial stands, one in the engine room and the other in the pilot house. A lever at each stand mechanically operates the indicating pointer on the other dial, a gong sounding also. Receipt of the order is acknowledged by placing the engine-room lever at the same position, the indicator on the pilot's dial showing that the order has been understood and is being obeyed. When the order has been executed the engineer may advise the pilot of the fact by moving his lever away from the ordered setting and immediately returning it thereto, this operation sounding the gong and calling attention to the accomplishment of the desired change. In adapting this signal system to power plant work, duplex sets of the apparatus are installed, two stands being used at each end as shown by Fig. 5. One indicates the unit and the other shows the order to be executed. This latter stand has its dial arranged to indicate the various details of manipulation which may require to be communicated either way between the engine-room floor and the switchboard galleries. Connections between the stations are mechanical, being made by means of rods and chains.

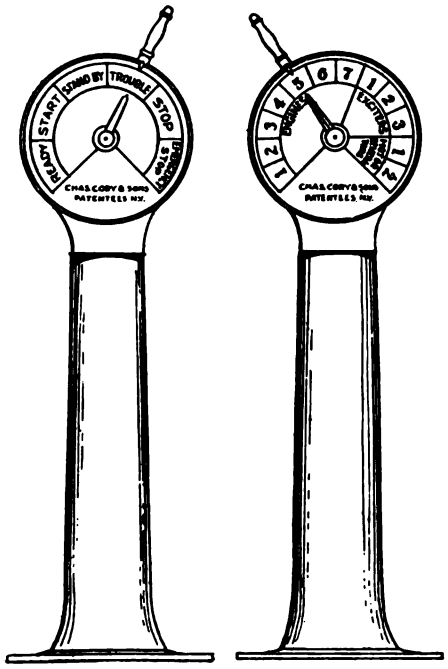

FIG. 5.—SIGNALING APPARATUS.

A NEW LINE OF DYNAMOS AND MOTORS.

The C. & C. Electric Company, New York, has brought out a new line of direct-current dynamos and motors in which special means for securing ventilation have been embodied, with the result that the maximum temperature rise, after running 24 hours under full load, is 30° C. (54° Fah.). The company's engineers have been at work nearly two years on this line of machines, perfecting their design and construction in the minutest details; they now have eight sizes of frame ready for the market, these eight sizes giving a range of outputs from 1 horse-power to 40 horse-power in slow and moderate speeds with corresponding dynamo ratings.

In brief the construction of the machine is as follows:—the magnetic frame, supporting brackets and magnet poles are of soft homogeneous cast steel; pole-shoes are bolted to the ends of the poles by bolts passing through from the outside. The field magnet coils are wound on insulated sheet iron spools. The self-oiling and self-aligning bearings and the brush rigging are carried by cast-iron brackets which are cast solid with the frame finishing rings. The armature is of the slotted hollow drum type wound with formed coils; the commutator is unusually large in diameter, composed of hard-drawn copper bars insulated with mica, and is attached to the shaft and the armature body by means of bolts, keys and set-screws; the brush holders are of the well-known "C & C" reaction type, carrying carbon brushes.

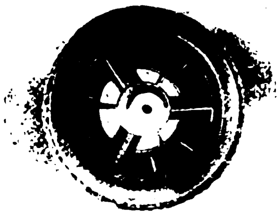

FIG. 6.—END VIEW OF ARMATURE.

The very low temperature rise is obtained by means of forced air circulation. The armature discs, are punched out of very soft sheet steel (which is subsequently oxidized for insulating purposes); adjacent to the center shaft-hole in the disc are three horse-shoe shaped holes, so punched that when the armature body is assembled on the shaft there are three axial tunnels next to the shaft. In the center of the armature body a spider, or spacing plate, is placed which has arms radiating from the ring by which this spider is attached to the shaft. The back and front end plates which clamp the armature body together, and which support the free ends of the armature coils, are also of the spider construction, their spokes also acting as fan vanes. The commutator shell also has arms projecting radially from its hub, forming additional fan vanes. The assembled armature therefore has three air passages running through from one end to the other, connecting with lateral passages in the middle of the body. When the armature is in operation the air is drawn in through the commutator shell at the front end and forced through the armature, part of it being discharged through the lateral passages in the middle of the armature body, and part going through the back end, thus creating a forced draft through the center of the armature and fanning the fields with cool air. An idea can be secured of the ventilation of this armature by a glance at Fig. 6 which shows a back end view of it.

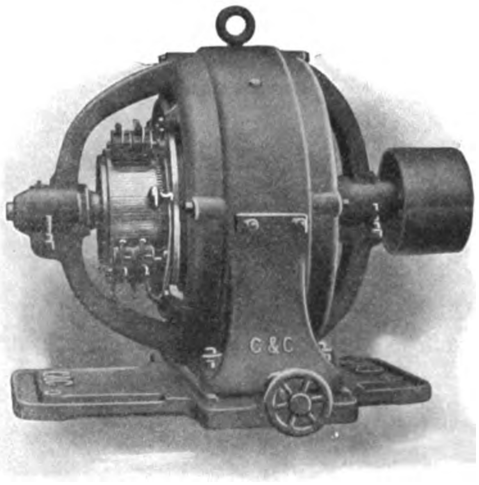

FIG. 7.—TYPE "S" C. & C. MOTOR.

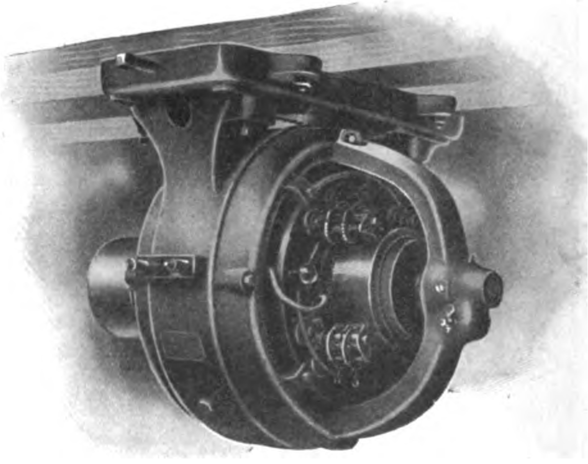

FIG. 8.—TYPE "S" C. & C. CEILING MOTOR.

The "Type S" machines are well adapted for mounting on machine tools for direct driving. Fig. 7 shows the standard form of the machine and Fig. 8 the ceiling type. The machines are also made in the entirely enclosed type, the semi-enclosed type and the vertical open and enclosed types.

CAPITAL AIR-COOLED GASOLINE MOTORS.

The Capital Gas Engine Company, Indianapolis, Ind., has brought out a line of very compact gasoline motors intended primarily for automobile purposes but adaptable to launch service also. Fig. 9 herewith shows a complete 2-cylinder engine, and Fig. 10 shows the same engine with one cylinder and the valves removed. the piston of the removed cylinder being shown supported on the end of its connecting-rod, which protrudes from the crank case. These little motors are of the four-stroke-cycle class and designed to run at 1100 to 1300 r.p.m., according to the load. Both the admission and exhaust valves are mechanically opened by means of cams, rollers and rocker-arms, so that a full charge is taken in each cylinder at each suction stroke. The valves are all provided with closing springs and each valve is mounted in a detachable cage or chamber,

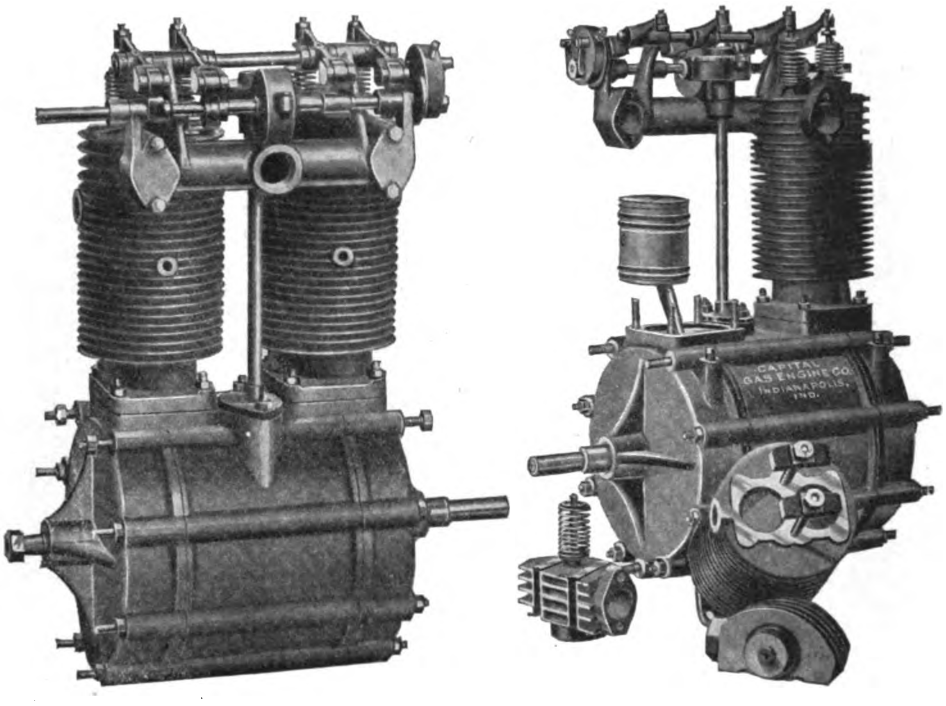

FIG. 9.—CAPITAL AIR-COOLED GASOLINE MOTOR.—FIG. 10.

as indicated in Fig. 10, where one of the valves and its chamber are shown near the end of the crank case. The valve chambers have deep flanges with ground joints which require no packing. The cams and rollers are of tool steel. The secondary shaft is mounted horizontally, as shown in Fig. 9, and driven through spiral gears by a vertical shaft which is shown rising from a stuffing box in the crank case, this shaft, of course, being driven from the main shaft by spiral gears. The igniter commutator is mounted on one end of the cam shaft; in Fig. 9 it is shown at the right-hand end and in Fig. 10 at the left-hand end, the two views being from opposite sides. Each cylinder is cast in a single piece with its head, so that no packing is required, as is the case with removable heads, of course. The spark plugs are located immediately within the path of the incoming charge, and it is stated that they do not foul. The crank-shaft is of forged steel in the smaller sizes and built up with heavy balance discs and tool-steel journals in the larger sizes. The crank-shaft journals are supported in three long phosphor-bronze sleeves in the four-cylinder engines and two sleeves in the two-cylinder and three-cylinder machines. Lubrication is automatic, all of the bearings being lubricated by oil contained in the crank case. A single mixing valve is used, which automatically mixes the gasoline and air in the proper proportion. Speed regulation is obtained by means of a throttle valve in the mixing chamber, which regulates the quantity of explosive mixture admitted to the cylinders. The two-cylinder engine is rated at 5 horse-power, the three-cylinder at 7½, and the four-cylinder machine at 10 horse-power. The height over all is 24 inches, the width transversely to the shaft 10 inches, and the length parallel with the shaft is 19 inches for the two-cylinder size. The three-cylinder and four-cylinder sizes are, of course, larger parallel with the shaft, but the other dimensions are unchanged.

U. S AUTOMATIC INJECTOR.

Fig. 11 herewith shows the U. S. automatic injector made by the American Injector Company of Detroit, Mich., who claims for it many points of vantage. Each injector is provided with a drip cock, which constitutes a distinctive feature. By this means the injector is drained when not in use, and may be started even with the check valve closed. The injector, it is also claimed, will start with lower steam. Moreover by leaving the drip-cock open when not in use, it prevents the suction pipe from getting hot, or jet from liming up when steam or check valve leaks. Another feature of the injector to which the manufacturer draws attention is the construction of the disc valve on the delivery tube, which being cup-shaped, is forced to rise to its seat by the jets of water thrown against it from beneath. This causes it to operate, it is said, even where there is a formation of limey deposit on the tube. Fig. 12 is a cross-section showing the internal arrangement of the injector, and Fig. 13 shows the various parts. Here *A* is a steam jet; *B* the suction jet; *C* the delivery tube; *D* the tail pipe; *E* the tail pipe nut; *F* the delivery cap; *G* the overflow cap; and *H* the overflow valve. The steam, water, overflow and boiler connections are clearly indicated in Fig. 11, so that the construction of the injector and its operation are easily followed from the engravings.

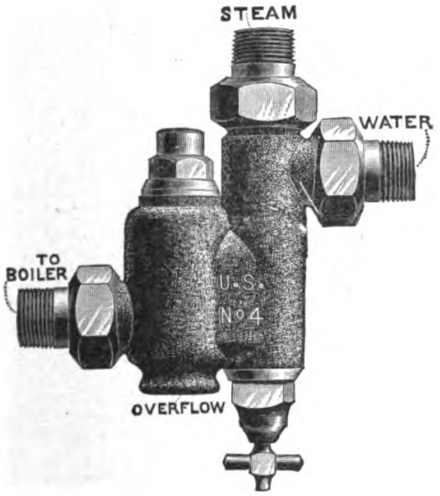

FIG. 11.—U. S. AUTOMATIC INJECTOR.

FORCE FEED LUBRICATOR.

Fig. 14 herewith shows one of the latest inventions in the line of force feed lubricators brought out by the Penberthy Injector Company, of Detroit, Mich. One of its main features is found in the use of two ratchets, one of which drives the plunger while the other acts on the plunger itself. The ratchets are interchangeable, so that when the "dog" will no longer hold on the outer ratchet, which is most subjected to wear, this can be replaced by the ratchet acting on the plunger and vice versa. The valves are placed in the center of the oil reservoir where they cannot be affected by changes of temperature. By closing the jaws of the lubricator with the nut *B* the feed is increased, whereas the opposite is true if the jaws are opened. When the proper amount of oil is being fed, the lock nut *D* is screwed down so as to hold the nut *B* in place. Extra oil can be secured by screwing down the nut *B* and operating the plunger by hand. A hole is provided in the bottom of the cup so that the latter may be readily cleaned.

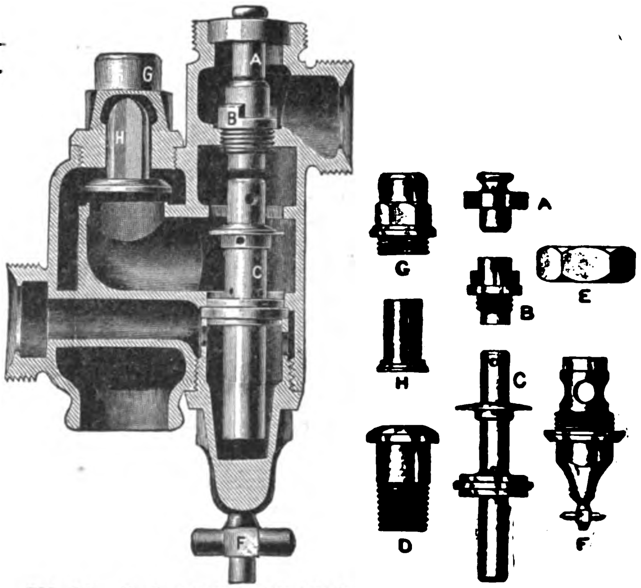

FIG. 12.—U. S. AUTOMATIC INJECTOR AND PARTS.—FIG. 13.

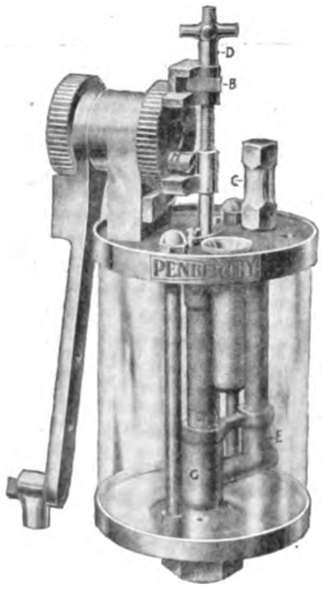

FIG. 14.—FORCE FEED LUBRICATOR.

OIL CAR CIRCUIT BREAKERS.

The use of circuit breakers as a means of protecting the car equipment from dangerous overloads has become quite general and has led to the development of several different types of breakers designed especially for this class of service. The oil car circuit breaker herewith shown, manufactured by the Hartman Circuit Breaker Company, of Mansfield, Ohio, is designed to take the place of the fuse-block and hood-switch of the car. It automatically opens the circuit in case of overload on short circuit and can be operated by hand as readily as the usual hood-switch. The switch and current-carrying parts are immersed in oil within a tight cast-iron case. The feature of oil insulation permits of very compact and simple construction. The distinctive feature of the circuit breaker, however, is the use of a series break, consisting of five double-break plug contacts connected in such manner as to give ten breaks in series. The circuit is said to be broken simultaneously at ten distinct points, and the break taking place in oil,

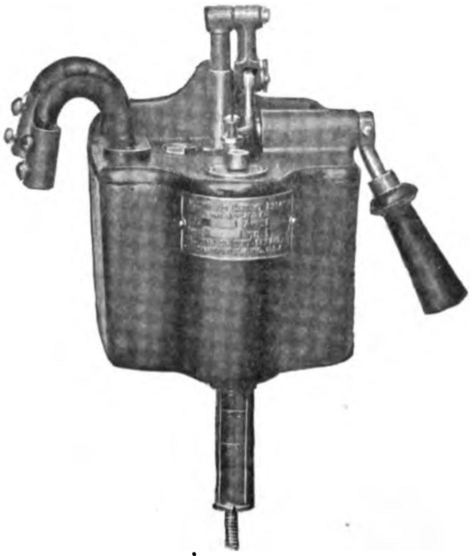

FIG. 15.—HARTMAN CIRCUIT-BREAKER.

there is no destructive arcing. The operating mechanism consists of a vertical rod, to the lower end of which are attached the movable bridging contacts. The rod operates in a brass bearing and is controlled by a toggle. A slight turn of the handle will cause the toggle to straighten out, thus raising the contact rod and effecting the closing and locking of the switch. The tripping coil is immersed in oil within the case, and, when an overload occurs, the plunger or core operating within the brass tube of the solenoid, delivers a strong hammer blow against an extension of the lower joint of the toggle, throwing the toggle out of center and effecting the opening of the switch. Ample space is provided between the live parts of the switch and the cast-iron case, and, as an additional precaution against grounding, the case is lined with insulating cement. Connection to the outside circuit is made within the case by means of insulated cable.

THE REEVES VERTICAL CROSS-COMPOUND ENGINE.

Any refinements on improvements that add to economy, efficiency and convenient handling of a steam engine, when of a nature that lessens personal attention and assures constant operation, are always appreciated by engineers, and this article, which briefly describes some of the features employed in the Reeves engine built by the Reeves Engine Company, of Trenton, N. J., will, we believe, be of interest. Fig. 17 shows a cross-compound engine built by this company, the design of which permits of the development of great power within very small floor space, and provides for easy access and adjustment of all of the parts. Chief interest will probably be centered in the steam distribution and valves of the engine, a section through the cylinders and valves of which is given in Fig. 19. This shows the high-pressure piston about to start on its downward stroke, the low pressure on its upward. The admission valve is moving upward, admitting steam on the top of the high pressure piston and across through the connecting port *B*, and around the head of the main valve. At the same time the main, or centre, valve is moving upward, admitting steam under the low pressure piston. This is the exhaust steam from the previous stroke of the high pressure piston, and it passes through the port *B* around the neck of the main valve and through port *C* into the bottom of the low pressure cylinder. When the pistons have moved about three-eighths of their stroke the admission port has been opened and admission valve returned to point of cut-off. The main, or centre, valve is now moving upward and finally closes port *C*. At this point compression commences in the high pressure cylinder and continues until the main valve opens port *C* again; meanwhile the main valve closed the upper port and compression took place in the low pressure cylinder. The steam distribution gives practically an equal division of work in the high and low pressure cylinders and there being no receiver employed, losses from free expansion and condensation are obviated. The engines are so designed that either cylinder can be used, independently of the other, should necessity require. The chamber *A*, around the sleeve in which the admission works, acts as a separator and is drained, as can be seen, at the extreme lower end. The sleeve receives the direct impact of the steam instead of the valve, and the valve is absolutely balanced, as all its exposed surfaces are under constant uniform pressure. Each of the three openings in the sleeve are larger than the steam pipe, therefore, the steam is not wire drawn in passing to the cavity inside the sleeve. The cubical capacity of chamber *A* together with space inside of the sleeve is greater than the amount of steam the high pressure cylinder can take, up to ¾ cut-off, and, as a result, the cards show remarkable steam lines, the actual difference between the initial cylinder pressure and pipe line pressure being extremely small. The space formed by the separator acts as a storage from which the engine draws its supply of steam.

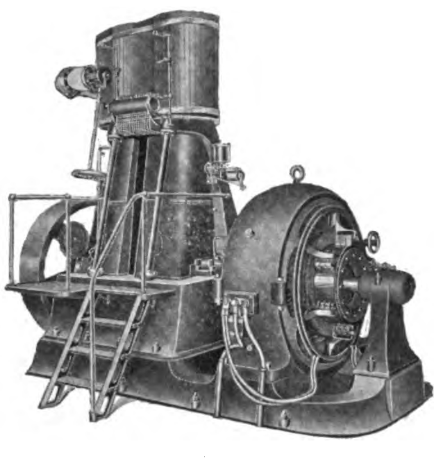

FIG. 17.—REEVES CROSS-COMPOUND ENGINE

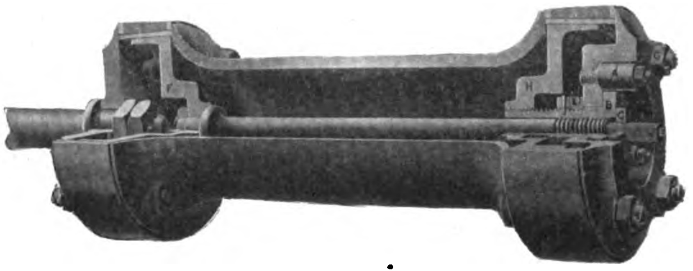

FIG. 18.—PISTON VALVE OF REEVES ENGINE.

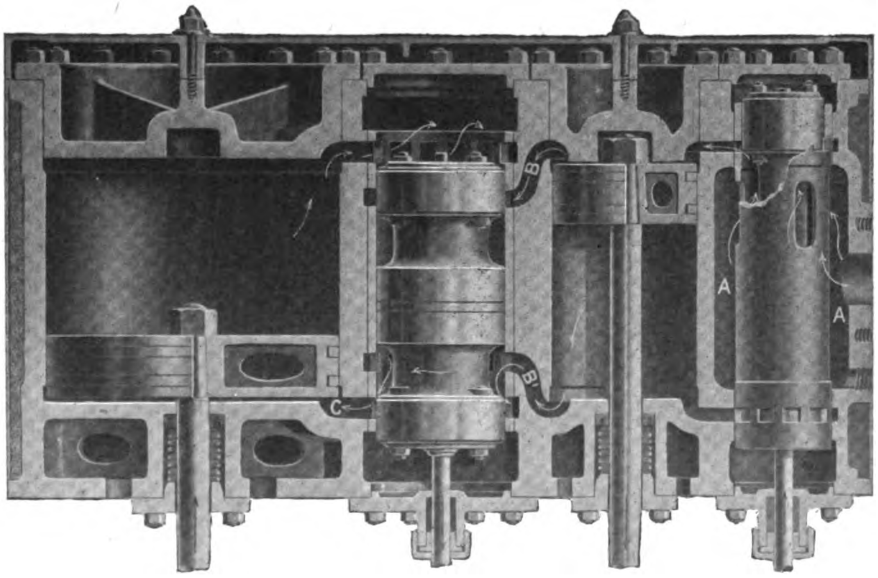

FIG. 19.—CROSS-SECTION THROUGH CYLINDERS AND VALVES OF REEVES ENGINE.

The separator being so close to the high pressure cylinder acts also to a degree as a superheater, so that instead of being a source of loss it is here a direct gain because it is evident that any heat it may lose must be taken up by the cylinder. This cut also illustrates very forcibly that there is no repassing of steam over same surfaces, which is, in itself, a guarantee of economy. The low cylinder heads are cast integral with the cylinders which reduces the number of joints to keep tight. The piston valves are readily adjustable at each end independently and without removal from the valve cylinder. This result is obtained by means of the construction shown in Fig. 18. Regulation of these engines is guaranteed to be within three-quarters of one per cent., this remarkable result being secured by having the intermediate valve driven by a fixed eccentric which thus gives a compression in the high-pressure cylinder that varies with the load. The high-pressure valve is worked from an eccentric controlled by a Rites governor of very simple construction. This governor embodies a unique feature in that the suspension pin is turned slightly by a ratchet each time the engine starts or stops, preventing uneven wear.

NEW BOOKS.

The Indicator Handbook. Part I. Second Edition. By Charles N. Pickworth. New York: D. Van Nostrand Comapny. Buckram; 130 pages, 5 ins. x 7½ ins.; 81 illustrations. Price, $1.50.

The present edition of this handy little book is like the first edition in all particulars which do not change with time. The chapter describing the different makes of indicator has been revised in accordance with the changes in construction which

American Electrician.

Vol. XVI. New York, May, 1904. No. 5.

INDEPENDENT TELEPHONE DEVELOPMENT IN THE NORTHEAST.

AUTOMATIC TELEPHONE EXCHANGE OF THE NORTHEASTERN TELEPHONE COMPANY, AT PORTLAND, MAINE.

In 1882 the Dirigo Telephone Company of Maine was organized in the city of Portland, with an authorized capitalization of $500,000. It, therefore, claims to be the oldest independent telephone company in the United States, continuously in service. It received a special and extremely liberal charter from the state in 1883, giving it general and unlimited rights to construct its lines along and upon all highways, over railways, canals and bridges; in conjunction with the right to build underground and submarine construction, additional to the right of eminent domain. This charter preceded any legislation governing telephone line construction, hence its broad and unlimited character.

In 1895 the company began to extend its lines in the rural communities from Farmington in Northwestern Maine, toward Portland, the chief commercial city of the state. In 1900 the management of the company was acquired by Mr. Lewis A. Goudy, who had been interested in the development of other competitive public service facilities in the city of Portland, as a member of the city council. From the beginning of Mr. Goudy's connection with the company, to the present, the battle for expansion of the independent telephone business in the Northeast, has been continuous and most aggressive.

In 1902 the company's name was changed to the Northeastern Telephone Company, giving it a broader application. Mr.

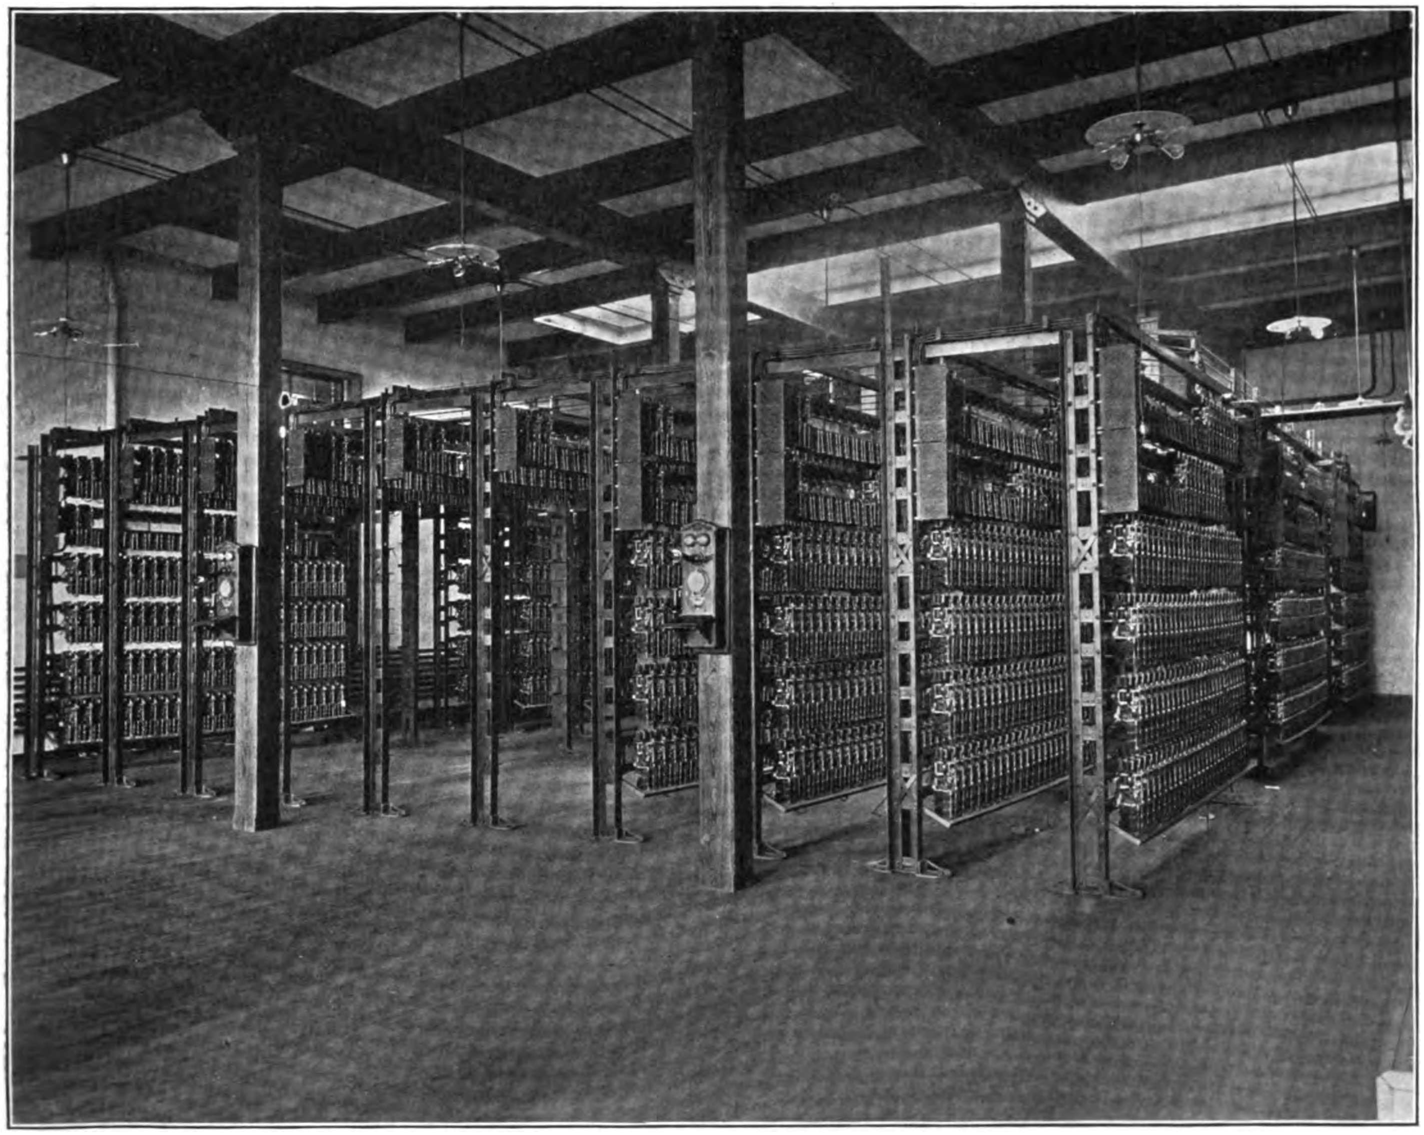

FIG. 1.—GROUP OF AUTOMATIC SWITCHBOARDS IN THE NORTHEASTERN TELEPHONE COMPANY'S EXCHANGE.

Thomas R. Brooks, of Scranton, Pa., was elected president; Edwin W. Gearhart, of Scranton, Pa., treasurer, and L. A. Goudy, vice-president and general manager. At the time the company's name was changed it had completed its trunk line from northwestern Maine through to Portland (the principal city of the state), and was the only company which owned its complete long-distance trunk or toll lines, in conjunction with its rural village and city installation and connections.

During 1903 the company constructed a new exchange building for the general headquarters of the company in Portland, costing nearly $40,000. Installation of its underground system, and aerial lines has cost several hundred thousand dollars, being sufficient to accommodate 5000 subscribers on outside construction, with an ultimate exchange capacity for 10,000. Two thousand five hundred automatic switches are already installed in the exchange, with which nearly 1500 instruments have been connected within the past three months, with some 700 contracts for subsequent installation, which the company expects will reach the full capacity limit during 1904, for the switches already installed.

The building in which the automatic exchange of the Northeastern Telephone Company is housed is constructed of brick and stone. It has a ground area of 3500 feet. Its floor space above basement amounts to 10,000 feet. It is three stories in height. The interior construction consists of iron girders, hard pine with wire lathing and no air spaces. The large basement contains steam heating apparatus enclosed in a fire-proof room, fuel compartment, large fire-proof vault for office supplies, maps and papers, fire-proof tunnel for underground cables from the company's conduit system; the remainder of the basement being used as a general stock room. The first floor consists of business offices, a fire-proof vault, director's, manager's, engineer's, superintendent's, manager of contracting and assistant engineer's departments with public reception room, long-distance booths, etc. The second floor is used for battery rooms (a view of the batteries being shown by Fig. 3 herewith), distributing rack, and testing station. On the third floor are to be found the switchboards with 2500 switches installed for immediate connection and with extra racks sufficient to accommodate 500 additional switches. There is enough surplus room for 2000 switches, giving an ultimate capacity for 5000 subscribers on this floor. This room is lighted by double glass skylights. The building is fire-proof throughout.

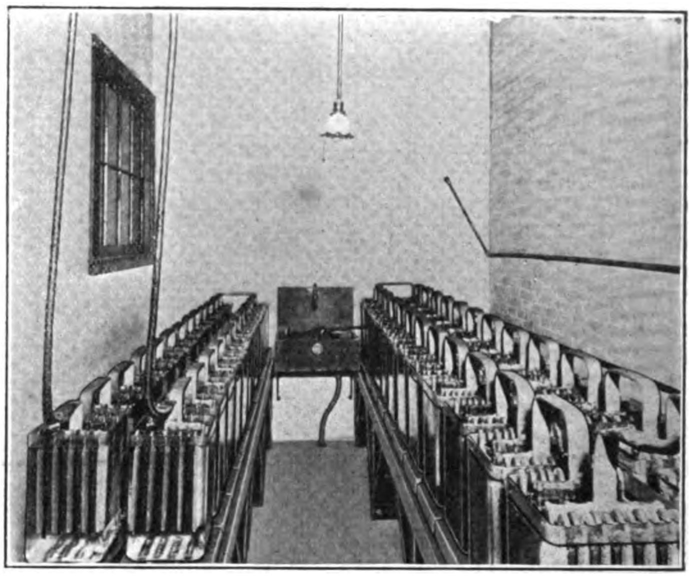

FIG. 3.—STORAGE BATTERY EQUIPMENT.

Fig. 1 shows the group of switchboards arranged in three tiers of 10 boards each; each tier representing 1000 subscribers. The open space at the center of the first tier will be used for increasing the exchange from 2500 to 3000 subscribers. This increase will be made by placing additional shelves with 25 switches on each shelf in frames already established. The cables connecting the different groups and shelves can be seen leading from the terminal heads on the end of each board along the top of the iron frame, which joins the boards together.

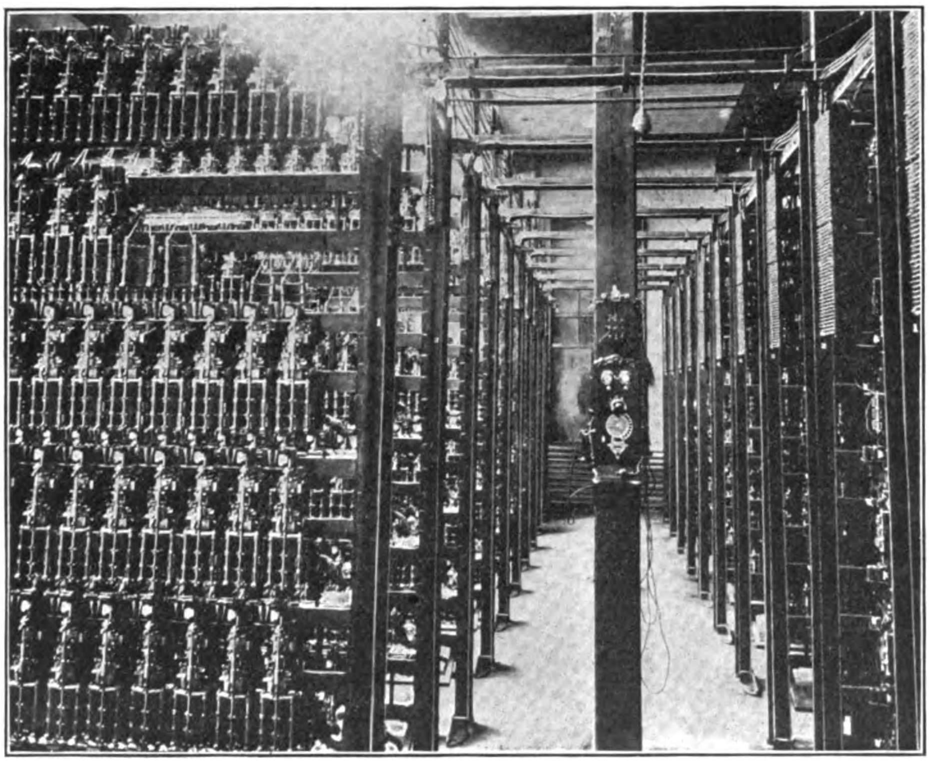

FIG. 2.—AISLE LEADING BETWEEN THE 1000 AND 2000 GROUPS OF SWITCHES.

Fig. 2 shows an isle leading between the 1000 and 2000 groups of switches. The entire power equipment of this exchange is in duplicate. The batteries are arranged in two series of 26 cells each; one of 200 ampere hours capacity and the other of 300 ampere hours. The terminals of the cells are burned together in the customary manner, the cells being supported on a substantial stand in such a way that the wooden block on which each cell rests is insulated by porcelain knobs from the remainder of the rack.

The charging machines, ringing machines and interrupter machines with power board are shown in Fig. 4. Each charging machine consists of a General Electric Company's two-phase, 60-cycle motor directly connected to a 75-volt generator. The ringing machines are of Holtzer-Cabot make; one consists of a two-phase, 60-cycle motor directly connected to a ringing generator. This machine is operated from a commercial power circuit. The other ringing machine is a dynamotor which is operated by the storage battery current, and is used at night or in case of a breakdown of the larger machines during the day. The two interrupter machines shown in the glass case are used to furnish the interrupter current for automatic switches, and they also carry busy back and holler wheels. These are operated from a storage battery. All of the power machines rest on a substantial foundation built of brick and covered with white tile. The power board consists of three marble slabs equipped with necessary knife switches, enclosed fuses, Weston ammeter, overload and underload circuit breakers for the charging circuit and with the necessary field regulators for the charging generator. Just beyond the power board stands a lamp board or tell tale board on which are the signal lamps which connect the section of the switchboard on which a fuse or heat coil may have blown. These lamps are mounted on a slate slab supported by iron frame work.

The operation of the automatic telephone is already familiar to most telephone people throughout the country. The telephone itself consists of the usual telephone box equipped with ringer, transmitter, receiver and induction coil, but with the addition of a calling device inside the box connected to the center of a revolving dial on the outside. Around the edge of this dial are ten finger holes numbered from 0 to 10 consecutively. To call a number, say 2345, the finger is first placed in hole No. 2 and the dial turned until the finger reaches the stop just below the dial. The dial is then released and is carried back to normal position by a spring. The finger is then placed successively in Nos. 3, 4 and 5, and the dial turned in the same manner. The button is then pressed which rings the bell of telephone 2345. The switch action at the central station when such a call is made will be as follows: When the first turn with the finger in No. 2 is made, a first selector switch is energized which selects a trunk line leading into the group 2000. With the next movement in hole No. 3, a second selector switch is energized and a trunk line selected leading into group 300 of the group 2000 already selected. The next two movements operate a connector switch which gives the tens and units of the call, and connects the calling subscriber with the line of subscriber 2345.

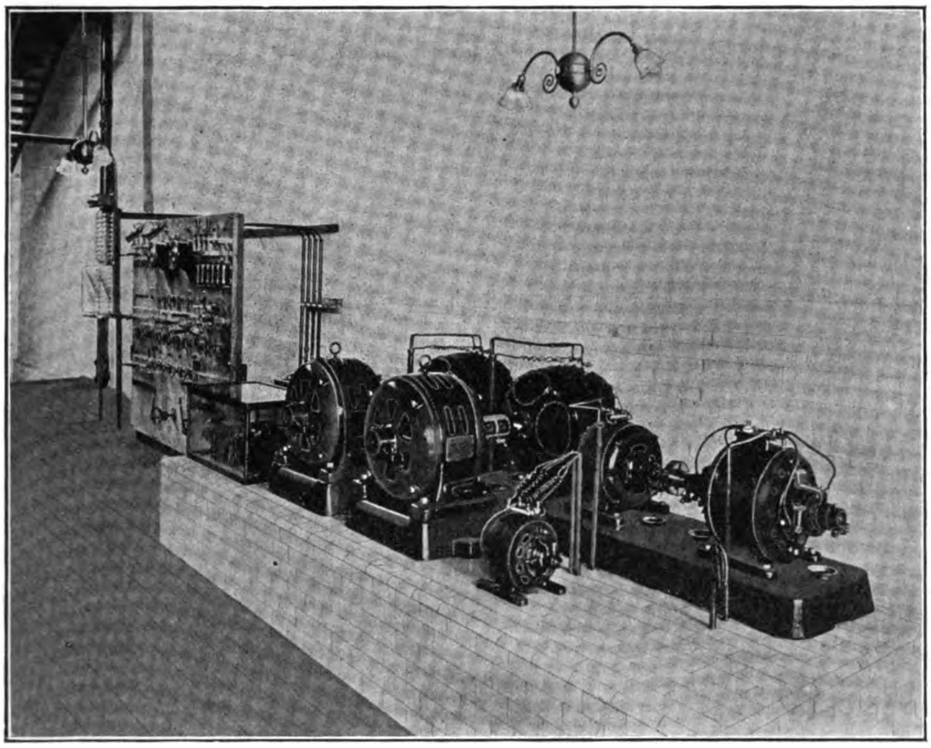

FIG. 4.—CHARGING, RINGING AND INTERRUPTER MACHINES, WITH SWITCHBOARD.

The Northeastern Company now has some 250 miles of rural pole line construction, with about 175 miles of trunk line, connecting between 60 and 70 towns, villages and cities in northwestern Maine, with 12 exchanges and 75 to 80 pay stations outside of Portland. It connects with several rural and farmer line independent companies covering territory adjacent to the company's main lines. It is also, under its licensee company's management, the Lewiston-Auburn Telephone Company, preparing to build an exchange for those two cities, connecting by trunk line with the company's main exchange in Portland, 35 miles away.

THE STEAM TURBINE SITUATION.

BY A. M. EARL.

During the past four or five years, the electrical and mechanical engineering fraternity has been treated to a great many stimulating doses of theory and prophecy by the advocates of the steam turbine. So stimulating have these doses proved that it is a serious question whether some of us have not been thrown a little off our balance, and it may be pertinent to inquire if it is not time to sober down—or up—tie a wet towel around our heads, and try to do a little straight thinking.

To begin with:—"Where are we at?"

The development of the steam engine covers, virtually, a period of 125 years. The steam turbine, as a commercial machine, is about twenty years old. It does not follow, as some have argued, that the turbine is, relatively to its ultimate development, where the engine was at a corresponding age. The development of the engine was slow because during the life of Watt and his coworkers, and for many years thereafter, metallurgy was practically an unknown science; the laws of physics and chemistry were little understood; there were no iron foundries or forge shops to speak of; there was comparatively little demand for steam power; the public was sceptical; capital was timid, and, perhaps most important of all, there were no trained engineers and no precedents to guide. The development of the turbine has been as rapid as that of the engine was slow because it has had every possible advantage:—splendidly equipped shops, a large demand, enthusiastic public support, unlimited capital, brains and experience by no means exhaust the list.

It can hardly be denied that today, with respect to development, the Parsons turbine is on the same plane as the engine, and there is no evident reason why the engine, from now on, should not improve just as fast as this type of turbine.

The Curtis turbine is, commercially, still in the experimental stage and it may be several years before the predictions which have been made for it can be verified or disproved from actual experience; the most that can be said today is that the somewhat meagre reports of machines in actual service indicate limitations which render it very doubtful if the hopes of the designers will be fully realized.

In the smaller sizes there is a moderate demand for the De Laval turbine, but its manufacturers long ago abandoned the idea, if they ever held it, that it was to revolutionize the engine industry.

I have been assured that the talent engaged in the development of the turbine is of such an eminent and able character that the difficulties now besetting its path will all be overcome. Such an argument is not only inconclusive, it is illogical and even absurb. Several hundred just as able designers of steam engines have been for years, and are now, wearing their gray matter into shreds and tatters trying to overcome certain limitations in their product. Sometimes they have had partial success; in other instances they have found it necessary to retreat. By one consideration or another, physical, chemical, mechanical, or commercial, the boundaries are defined beyond which they cannot go. There is a limiting steam pressure, superheat, vacuum, rotative speed, piston speed, bearing speed, size of low pressure cylinder, degree of regulation, pressure on bearing surfaces, cylinder clearance — and so on down the long list.

A few years ago, we were assured that the coming thing in electric power plants was the quadruple expansion engine working under an initial pressure of 250 lbs. or more; it was tried, and so were triple expansion engines; today, the quadruples that are in actual service can be counted on the fingers of one hand with fingers to spare, and you will have accounted for the triples before reaching the last of your toes.

Then came the craze for high degrees of superheat. Well—there seems to be a perceptible drift in opinion back to the position of the conservative old fogies who thought that at a superheat of 125° Fahr. the central station manager had secured about all the benefit that could be profitably extracted, all things considered.

Now comes the turbine; but its creators should not forget that they are human, of the same humanity as engine builders, and their product, if not subject to the same, will be subject to similar limitations. For example, the steam consumption of the turbine has been a disappointment; there is an increasing preponderance of evidence that the turbine, under similar conditions, does not compare favorably with the better types of reciprocating engines, and this fact will go far toward offsetting any difference in the first cost of the station as a whole.

Recent tests indicate a probable limit to superheat that may prove to be not far above the economical limit for engines. High temperature means large expansion and large clearances with a correspondingly decreased economy. Furthermore, high temperature can only be secured by increased coal consumption and after a certain point is reached the saving in the turbine is largely offset by the loss in the superheater.

It is doubtful if the high vacuums talked about can be maintained, at least, with a resulting gain commensurate with the cost. A vacuum of 29 inches is not hard to obtain when the apparatus is new, the engineer interested, and experts keep everything tuned to concert pitch. Will it remain 29 inches when the packing gets worn, the tubes begin to deteriorate, the engineer is busy, and the experts have gone home? Furthermore, blades wear and strip; governors get out of order; bearings heat and cut; lack of perfect mechanical balance creates disturbances; and so on down the list—just as long, just as serious, just as difficult of solution as the engine problem list.

Few people realize the remarkable adaptability of the steam engine. In this respect, the turbine compares most unfavorably with it. The steam engine can operate under high, medium or low steam pressures, with superheated, dry or wet steam; at high, medium or low speeds; can be built simple, compound, triple or quadruple expansion; horizontal or vertical; to run forward or backward; condensing or non-condensing; direct-coupled, belted or geared. This is certainly an impressive list of practical qualifications. Furthermore, the engine is not as sensitive to changes in operating conditions as the turbine. The same engine will give very fair results if supplied with wet instead of superheated steam, if thrown from the condenser to the atmosphere, and under varying steam pressures.

I trust the reader will not misunderstand my position. I do not say that the turbine is a failure; on the contrary, I believe it has a field which it will fill with a reasonable degree of satisfaction (and so also has the gas engine); but I wish to point out that the reciprocating steam engine has secured its present prominence by force of sheer merit, that as an all around mechanical athlete it is unsurpassed by any other form of motive power, and that the turbine will have to show a very considerable advance over its present record both as to economy, reliability and adaptability before it can hope to drive the steam engine into obscurity.

It is more probable that the outcome will be a gradual specialization brought about by the test of experience, and resulting in the selection of the prime mover best suited to the conditions attaching to each particular problem. This prime mover may be a steam engine, a gas engine, an oil engine, a steam turbine, a water turbine, or what not; but the greatest of these is the steam engine.

◆◆◆

STEAM ENGINE SPEED REGULATION.

BY J. J. M'GUIRE.

The governor, as applied to any type of engine, has a double purpose. First, it must prevent racing, and must not allow the speed to exceed a certain defined limit. Second, it must regulate the heat energy supplied to the engine, so as to maintain the proper ratio between that energy and the load under which the engine is working. In the water-wheel, for example, it opens or closes the gate more or less, thus supplying more or less water, as the conditions require, and in the steam engine it varies either the pressure or the amount of steam used. It is driven by the motor it regulates and is usually so constructed that any variation in the speed of the motor will cause the governor to check that variation in speed automatically. The operation of most governors depends upon counteracting the centrifugal force generated in a rapidly revolving body, by some other force, such as gravity or the tension of a spring.

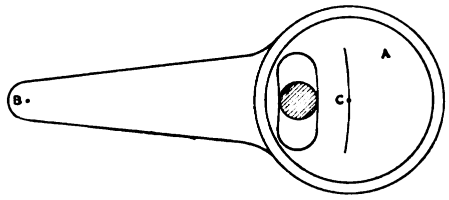

FIG. 1.

One of the oldest and most common forms of governors is the pendulum or so-called "fly-ball" governor, but on account of the number of parts it is difficult to construct and its variation in height for a given variation in speed is very small so that it is hard to regulate for high speeds. By the "height" of a pendulum governor is meant the distance from that point where two lines intersect that are drawn through the centers of the balls and their links, to the plane in which the balls revolve. It might also be added that the height of a revolving pendulum is independent of the weight of the balls or the length of the links and depends solely upon the number of revolutions.

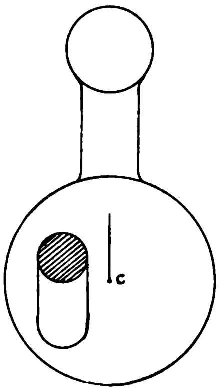

FIG. 2.

The variation in the opening of the throttle valve can only be caused by a variation in the height of the governor, which variation, in height, is in turn due to a change in speed. Hence the governor cannot control the speed except within certain limits. A well-designed engine will not vary more than 2 per cent above or below a specified speed. Therefore, to move the valve through its full range of action, the governor must be so constructed that it will have sufficient variation in height due to these two extremes of speed. When an engine is running at 100 revolutions per minute, with an ordinary pendulum governor, the height of the governor is 3.529 inches, and the allowable variation for this speed is only .14 inch, which, as will be readily seen, is a very small amount to control the working of a cut-off mechanism, or throttle valve, throughout its whole range of action.

With the introduction of modern high-speed engines it became very evident that a governor with fewer parts, and one that would give close regulation at high speeds was necessary. This end the shaft governor is specially designed to attain. The shaft governor derives its name from the fact that it is mounted on the main shaft of the engine. It consists of revolving weights the centrifugal force of which is balanced by means of springs. There are different types of shaft governors, but they are all based on the principle of changing the position of the eccentric center with reference to the shaft, and thereby changing the point of cut-off.

A simple form of shaft governor consists of the arrangement shown in Fig. 1, where *A* is the eccentric from which the slide valve is worked. In this arrangement there is a slot cut in the eccentric, as shown, which permits the center *C* to move in an arc of a circle the center of which is at the point *B*, at which the eccentric arm is pivoted. This movement of the eccentric, which is produced by the centrifugal force generated by the revolving weights of the governor when the speed of the fly-wheel changes, causes a change in the relative positions of the center of the eccentric and the center of the shaft.

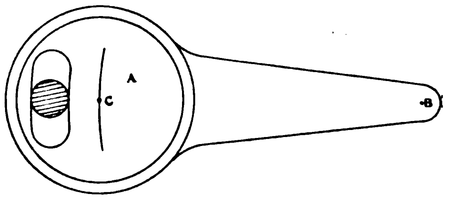

FIG. 3.

The movement of the eccentric center, due to a change in speed of the engine, may be arranged to take place along any one of three different paths, namely, (1) along a line curved toward the center of the shaft, as in Fig. 1; (2) along a straight line, as shown in Fig. 2, and (3) along a line curving away from the center of the shaft, as shown in Fig. 3. In the first case, when the eccentric is made to change its position, the lead will be increased, the path of the eccentric center being an arc curving toward the center of the shaft; in the second case, the path of the eccentric is a straight line running through the center of the eccentric and the center of the shaft, and the lead will be constant for all positions of the eccentric; when the path of the eccentric center is an arc which curves away from the center of the shaft, the lead decreases.

The character of the curve, toward or away from the center of the shaft, along which the center of the eccentric moves depends on the position of the point of suspension, *B*, of the eccentric arm. This will be readily seen by referring to Fig. 1 and Fig. 3. This refers to the more common methods of suspending the eccentric. The point of suspension, however, may be so located that it will cause the movement of the eccentric center to take place along paths varying greatly from those shown in Figs. 1, 2 and 3. For example, the suspension may be so arranged as to give equal leads for the maximum and minimum throw of the eccentric. Where the lead changes with the throw of the eccentric the nature of the change, whether it increases or decreases the lead, depends not only upon the direction in which the path of the eccentric center curves, but also upon the position of the point of suspension *B* of the eccentric arm.

A governor is required only where the load is variable, and is not necessary where the resistance is constant, such as in marine and hoisting engines. But when an engine is used to drive machinery which must be operated at as nearly constant speed as possible, such as spinning and electrical machines, the engine must be fitted with a governor, and one that will give close regulation. In this case the fly-wheel plays an important part, for while it is the duty of the governor to adjust the effort of the engine to any large or permanent variation of the load, such as would be caused by throwing the machinery in or out of gear, it is the duty of the fly-wheel, on the other hand, to adjust the effort of the engine to sudden fluctuations of load resistance that may occur during a single stroke of the engine.

As is well known, after the point of cut-off is reached the shaft type of governor has no control over the engine during the remainder of the stroke, so that if the load were suddenly increased between the point of cut-off and the end of the stroke, the engine speed would be greatly affected if there were no fly-wheel. In such a case the inertia of the fly-wheel would keep the engine running until the governor could act on the return stroke and cause the cut-off to occur later, thereby admitting more steam. If, on the other hand, the load were decreased after the point of cut-off, the fly-wheel would keep the engine running steadily, because by the time the inertia of the fly-wheel is overcome the governor will have had time to act, making the cut-off occur earlier in the stroke and thereby decreasing the amount of steam admitted to the cylinder.

It is also the duty of the fly-wheel to equalize the varying tangential effort on the crank-pin by storing energy while the piston is in the middle of the stroke, where the crank effort is greater than the resistance, and returning it when the crank is at the dead point, where the tangential effort is zero.

When regulation under load is considered, the high-speed engine has an advantage over a low-speed engine, for the reason that in a given time it makes many more revolutions, and, therefore, the change will be more gradual since the difference between each succeeding revolution is not so great as in a low-speed engine. For example, suppose the time required to affect a regulation is one second, then if one engine runs at the rate of 200 revolutions per minute, it makes 3⅓ revolutions per second. Now if the other engine makes 80 revolutions per minute, it will make 1⅓ revolutions per second. Therefore, the change per revolution in the high speed engine is much less than in the low speed engine, and the regulation is smoother.

Governors may be divided into two principal classes, namely, those that throttle the steam, and those that vary the point of cut-off. Each has its own advantages and disadvantages, some of which may be enumerated.

In the throttling governor, when the steam is forced through a small opening, it has the effect of superheating the steam and thereby reduces the loss by cylinder condensation. An engine using a throttling governor has no complicated valve gear and is, therefore, easier to build and cheaper to buy. The steam is admitted throughout a great portion of the stroke, which will cause the initial and final effort on the piston to be more equal. Some of the disadvantages of the engines using a throttling governor are: There is a greater loss of heat in the exhaust, due to the fact that the final pressure is comparatively high and consequently the exhaust steam will have a higher temperature; the governor is not as sensitive, so that it does not regulate as closely as the variable cut-off governor.

On the other hand, the variable cut-off governor has the advantage of being more sensitive; just enough steam is admitted to the cylinder to do the work required in each stroke; there is increased expansion of steam and less loss of heat in the exhaust on account of the final pressure being lower. It is at a disadvantage because the complicated valve gear increases the first cost and makes it more liable to get out of order; the greater range between the initial and final pressures causes unequal strains and necessitates a larger fly-wheel.

In an engine in which the point of cut-off is regulated by the governing mechanism, the point at which the valve will cut off may be changed by changing the number of revolutions, or by changing the boiler pressure, as will be evident from the following:

When the cut-off is too early, if the boiler pressure be lowered the mean effective pressure will be lowered, and in order to maintain a constant horse-power, the point of cut-off will have to be made later in order to bring the mean effective pressure up to its original value. This change in the point of cut-off is accomplished automatically by the governing mechanism. Similarly, when the cut-off is too late, if the boiler pressure be increased, then the mean effective pressure will have to be decreased to maintain a constant horse-power, and this means making the point of cut-off somewhat earlier, which is accomplished by the governing mechanism. If the number of revolutions is decreased to remedy a too early cut-off, the horse-power is correspondingly decreased, and, in order that the engine may deliver its usual power, the governor shifts the point of cut-off to a later point in the stroke, thereby increasing the mean effective pressure and bringing the power of the engine up to its proper amount. In like manner, when the cut-off is too late and the number of revolutions is increased, the horse-power is increased, and, in order to maintain a constant output, the governing mechanism shifts the point of cut-off to a somewhat earlier point in the stroke, which decreases the mean effective pressure sufficiently to give the proper horse-power.

TELEPHONE ENGINEERING.

Protective Devices.

BY F. J. DOMMERQUE.

The protective devices used on telephone circuits are of three kinds: lightning arresters; strong current protectors, or fuses, and sneak current arresters, or heat coils. Lightning arresters are to protect against atmospheric electricity and high-tension currents; strong current protectors or fuses against currents from electric light, power and all circuits of moderate potential; heat coil against sneak currents, which are caused by leakage or poor and defective insulation and are very weak, but still strong enough to damage the very fine wire in the coils used in telephone apparatus; these currents are often referred to as stray currents.

When speaking of "lightning" in connection with lightning arresters, it is not the direct stroke of lightning that is meant, as there is hardly any chance left for a telephone line struck in that way to survive, even with the best protection; fortunately the direct striking of a pole line by a flash of lightning is a rare occurrence. It is electrostatic induction that interferes most with telephone lines. A heavily charged cloud forms with the earth a huge condenser, the intervening sheet of air forming the dielectric. The telephone line or system, insulated from the earth but near to it, will be charged inductively, and when finally the cloud becomes discharged abruptly by a flash of lightning the charge upon the telephone line is set free and tends to pass to earth suddenly. The discharge will follow the shortest path to ground, but it will not hesitate to jump across air-gaps in its flight. For instance, instead of following the convolutions of fine wire around a coil it would cut across from layer to layer. To prevent harm being done to cables, coils and other telephonic apparatus, a short path to ground is provided at such places where the discharge may enter the cable or the switchboard.

Present practice recognizes only one style of lightning arresters as safe, namely, two carbon blocks separated by a thin sheet of mica or silk, one of the blocks being connected to the line and the other one to ground. Carbon is the most suitable material because it does not melt, does not oxidize and is cheap. A metallic line requires two sets of carbon blocks, one set for each conductor. The mica sheet between the two carbons separates them about 0.0055 inch and will allow the passage of a discharge at a difference of potential of 350 volts between the plates. When the discharge comes to the carbon arrester it will follow the short path across the separator to ground rather than follow the long path offered by the wires in the cable to the exchange. Fig. 1 shows the carbon blocks and the mica separator. This separator is cut out to a U shape and inserted with the open side downward so as to let any carbon dust that may come off drop out. The figure also indicates how the blocks are put together. As shown the upper block is provided with a groove with which the spring engages that holds the arrester in place.

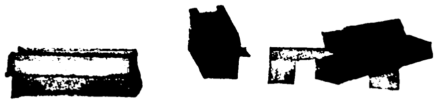

FIG. 1.—LIGHTNING ARRESTER PARTS.

The mounting of lightning arresters for terminals consists either of one spring holding the blocks against a ground bar or of two springs holding the blocks between them, in which case each block is grooved. The method of mounting lightning arresters upon the distributing frame at the exchange is a little more complicated, due to the use of a heat coil in conjunction with the lightning arrester, while at the terminal box a line fuse is combined with the lightning arrester instead of a heat coil. Metallic lightning arresters have been employed, but are not so reliable and, therefore, not recommended. Under this class comes the serrated plate arrester frequently found on telephone instruments. The function of the carbon lightning arrester in the first instance was to divert a lightning discharge from the line to the ground, but as the distance between the carbon blocks is adjusted by means of the mica separator for a difference of potential of 350 volts, high-tension circuits may also be taken care of. A street railway current of 500 volts, for instance, might also find a path to ground through the lightning arrester, but there is no certainty that it would. In any case, it is not safe to rely solely upon the carbon blocks.

A trolley current or an electric light current of moderate voltage would force a greater amount of current over the telephone line than it could stand, and the heating effects of such a current would be detrimental first of all to the lead cable, because the line wire enclosed as it is in the envelope of paper would quickly become hot enough to burn its insulation and the cable would soon be destroyed. In order to protect the cable in such a case, a fuse is inserted in each conductor that will open the line whenever a current of more than the carrying capacity of the fuse enters the cable. The size of the fuse depends on the size of the wire to be protected. With fine gauge wire such as is used in cables, a 2½-ampere fuse is recommended; with heavier wire, a 5-ampere fuse may be allowed. The fuse wire should be enclosed so as to prevent the arc from spreading to adjacent objects and also to prevent the fuse wire from scattering and setting fire to any inflammable material near it. The higher the tension of the current against which the fuse is to protect, the longer the fuse should be. A line fuse that meets present conditions fairly well consists of a piece of fine copper wire or a thin strip of lead enclosed in a fibre or wooden tube, the fuse wire being 4½ ins. long.

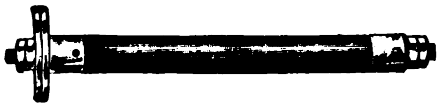

FIG. 2.—EARLY FORM OF FUSE.

In the earlier forms the ends of the fuse tube were provided with nuts, two at each end, to take the terminal springs between them, as shown by Fig. 2. In a latter form, shown by Fig. 3, a button terminal is provided at each end that engages the forked end of the terminal spring. The forms of tubular fuses shown by Figs. 2 and 4 have been used in some cases on lines that did not require lightning arresters. These kinds of fuses are inserted in the line either at the point where the drop wires enter the subscriber's house, or at the insulator upon the distributing pole. The clamp at the one end is attached to the line wire where it ends dead, while the bridle wire is held between the nuts at the other end. The fuse shown in Fig. 2 hangs vertically, while the one in Fig. 4 hangs horizontally in close proximity to the wire so as to be less liable to be caught by the lineman working upon the pole. Fig. 5 illustrates the two methods of attaching the fuses to the line wire.

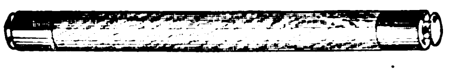

FIG. 3.—LATER FORM OF FUSE.

At the subscriber's station and at the telephone exchange, part of the apparatus contains such fine wire that a current that would pass the line fuse without blowing it would still be heavy enough to burn out that kind of apparatus. Therefore, at these two places a protector is required that takes care of the weak currents that may pass by the line fuses. At the exchange, heat coils are always provided with the lightning arresters, while at the subscriber's station a heat coil when required is mounted best upon one base with the lightning arrester and line fuse. If the line extends from the exchange in a cable to a distributing pole and then drops from this distributing pole in an insulated pair of wires direct to the subscriber's telephone, or contains only a short piece of open wire, the following arrangement is necessary and should be put in in this order, starting at the switchboard: Heat coil, lightning arrester, lead cable, cable terminal box without protection, drop wire to wall of house, line fuses where drop wires enter the house, interior wires to binding posts of instrument. When long open-line wires enter into the line between the cable and the subscriber's station, the following is the order of arrangement from the switchboard out: Heat coil and lightning arrester, lead cable, cable terminal box with lightning arrester and line fuse, open wire, drop wire, interior wire, lightning arrester, fuse and heat coil to the binding posts of the instrument.

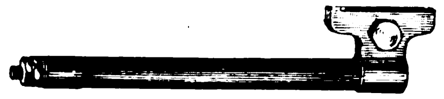

FIG. 4.—TELEPHONE LINE FUSE.

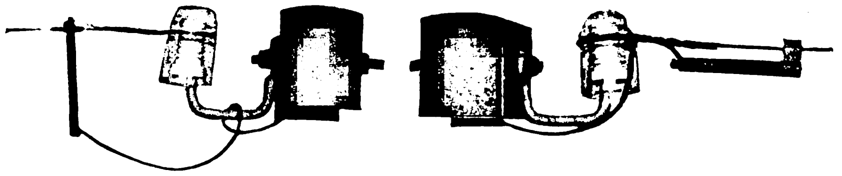

FIG. 5.—TWO METHODS OF ATTACHING FUSES TO LINE WIRES.

The best heat coil consits of a coil of German silver wire on a conducting shell surrounding a metallic pin to which it is soldered with an alloy of a low-temperature melting point, the whole being mounted in a hard rubber or fibre case and held upon a fork between a strong German silver spring and a ground plate at one end and supported by another spring at the other end. The outer spring is arranged so that when the coil becomes heated and the fusible metal melts, it pushes the entire coil down and forces the pin through the enveloping shell upon the ground bar. A heat coil of this kind and its mounting upon the main distributing board frame is shown in Fig. 6, the heat coil being also shown on an enlarged scale at the right. In another form of heat coil, when the fusible metal melts, the two springs spreads apart and pull the pin out of its enveloping shell or sleeve, the one spring making ground connection by means of a projecting pin, as shown in Fig. 7. As will be noticed from these illustrations, the lightning arrester and heat coils with their springs are mounted upon an iron bar which forms the ground bar of the main distributing board. In some cases an alarm devise is added which closes a battery circuit through an alarm bell whenever a heat coil goes, as a signal for the trouble man to replace the coil and re-close the circuit. There are so-called self-soldering heat coils on the market, but they should be carefully investigated as to their construction before buying, as it is not easy to construct a coil that will restore every time.

The specifications for heat coils vary according to whether they are to be used for common battery or for local battery systems. The specification for the heat coil in Fig. 6 for local battery is: Resistance 41.5 ohms of No. 37 B. & S. double silk-covered German silver wire, 36 inches long; the inner end soldered to the copper tube, the other end to the German silver washer; the coil to operate in less than 45 seconds with 0.16 ampere. For common battery: Resistance 5.25 ohms of No. 30 B. & S. double silk-covered German silver wire 23 inches long; the inner end soldered to the copper tube, the other end to the German silver washer; the coil to operate in less than 60 seconds with 0.4 ampere. Some specifications call for a larger fusing current, but reduce the time of operation.

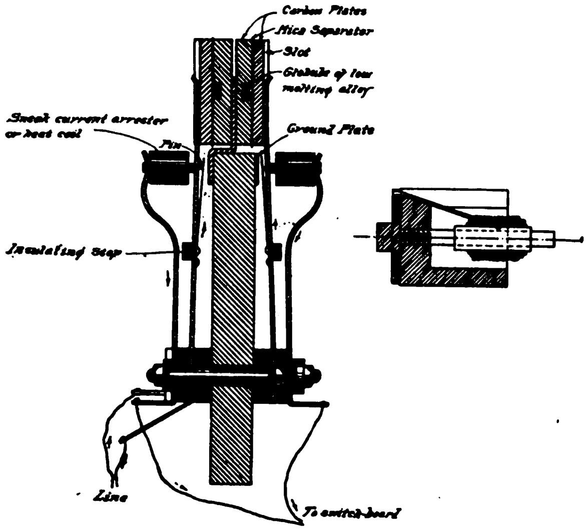

FIG. 6.—HEAT COIL PROTECTOR.

A well-designed combination of lightning arrester, line fuse and heat coil for subscribers' stations is illustrated in Fig. 8. The carbon blocks and heat coils are covered by a glass case. Though it is not a decorative addition to a room to have such a large protective device mounted above the telephone, this arrangement is more convenient than having a corrponding device mounted outside on the wall where the wires enter the house, because the protector is more accessible inside the building for cleaning and a blown-out fuse or coil can be more easily detected than when the apparatus is out of sight. On the other hand, a ground connection must be provided for the lightning arrester, and this may be easier to obtain on the outside of the building, though a water pipe is usually to be found handy on the inside. As mentioned before, however, in cities lightning arresters at subscribers' stations are nowadays exceptions rather than the rule, because cable has taken the place of aerial lines.

In late years rural telephone service has been developed to a great extent. The so-called farmers' lines are, of course, very long open wires greatly exposed to atmospheric discharges and therefore should be provided with lightning arresters. Simultaneous with the development of rural telephone service, the interurban electric railways have erected net-works of wires over the country and not only are 500-volt trolley circuits encountered but in many instances feeders at very high tensions are strung along the right of way. It is not always possible to keep the telephone lines away from these railway lines and often it is necessary even to cross trolley wires and high-tension feeders. In such cases the telephone wires should be insulated and in addition, insulated guard wires should be spanned under the telephone wires so as to prevent the telephone wires, should they ever break, from coming in contact with the trolley or high-tension wires. Wherever telephones are connected to open lines that cross such railways, the instruments should be protected by lightning arresters, line fuses and heat coils. The fuses to be used should be as long as possible; the fuses of to-day are in reality too short for such conditions and with further expansion of interurban electric railways a longer fuse is sure to come.

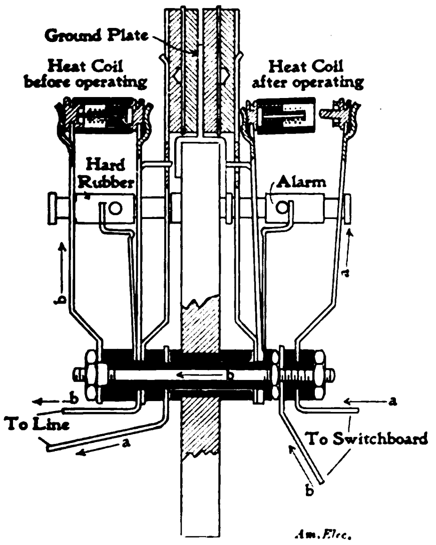

FIG. 7.—HEAT COIL PROTECTOR.

On farmers' lines that never come in close proximity to electric lines, a fuse and heat coil are very often omitted and a less expensive lightning arrester used which consists of carbon discs separated by mica, as illustrated in Fig. 9. However, such practice is not to be recommended. If it costs too much to put in proper protection in the shape of a carbon arrester, fuse and heat coil, a switch should be inserted between the line and the telephone, and this switch kept open during a thunderstorm.

The proper protection of toll lines is a very difficult problem. Some telephone men contend that it is not economical to have protectors at all at toll stations, but to risk the burning out of a coil (which they claim does not happen so often anyway) rather than to look after the arresters and keep them in working order. It seems practicable, however, to train the toll station agent and also the farmer sufficiently to enable them to take care of the arresters, fuses and heat coils, giving them sufficient reserve stocks of fuses and heat coils to draw from. A combination lightning arrester, line fuse and heat coil such as that illustrated by Fig. 8 costs from 75 cents to one dollar and is a good investment on exposed open-wire lines.

The protectors shown by Figs. 6 and 7 are used upon distributing boards in exchanges. This method of mounting the arresters upon an iron ground bar is always used in connection with multiple switchboards where the cables from the outside terminate in pot-heads. To terminate the outside cables in cable-heads and mount the protective devices upon these cable-heads, which are fastened to a separate frame and connected to the main distributing board by switchboard cables, does not conform to modern practice. In consideration of the fact that a distributing board with lightning arresters and heat coils of the design shown in Figs. 6 and 7 is rather expensive for small non-multiple switchboards, it has become the custom to construct a cheap distributing frame, consisting of a board to which the lightning arresters and ¼-ampere open fuses are screwed by means of wood screws and washers. In this respect, it may be said once for all that saving on protective devices is false economy; the best on the market is none too good even for the smallest installation.

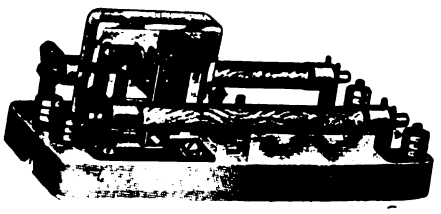

FIG. 8.—COMBINED LIGHTING ARRESTER, FUSE AND HEAT COIL.

As stated before, city lines are not much exposed to the influences of lightning, being surrounded by high buildings and other objects that form mediums for carrying the lightning discharges to earth, while toll and cross-country lines are practically without exception exposed over their entire length. Such lines are liable to be struck by direct lightning discharges from clouds, but the attempts that have been made to protect such lines have been successful to a great extent whenever the protection has been applied at the proper place. In open flat countries every tenth pole has been provided with a simple guard wire of iron; this wire being stapled to the side of the pole from top to bottom before setting, leaving a few inches of the wire extending above the top of the pole and bending the other end of the wire under the butt or coiling it around the butt, so as to provide a good ground connection. Preferable to this is the provision of ground-wire branches attached just below the cross-arm,

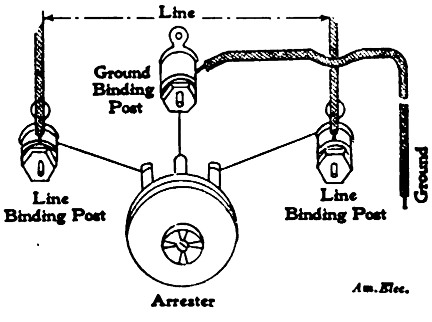

FIG. 9.—LIGHTNING ARRESTER.

or below the top cross-arm if there are more than one, these branch wires leading along the cross-arm and each terminating with a short rectangular bend under each of the line wires, leaving an air-gap of about half an inch. All these wire points will combine in drawing the discharge off to ground.

In hilly districts this kind of protection when applied at regular intervals may leave the most exposed poles unprotected; therefore, under such conditions the protection should be placed upon all the exposed poles, even if they are close together, while the sheltered poles may be left without. The method just described is the simplest one. Construction men have varied the method to suit their fancies, but the principle remains the same.

PIPE THAWING BY ELECTRICITY.

BY CHARLES H. PETERS.

The recent appearance in electrical journals of one or two articles on this subject has undoubtedly awakened many central station managers to the advantage of being equipped for this class of work when cold weather sets in. After a winter of active service, the writer takes pleasure in describing an equipment used by The Durango Light and Power Company, Durango, Colo., which has given excellent satisfaction.

Owing to an unusually light snow fall, the ground was frozen in places to a depth of four feet, and as digging is almost impossible under such conditions owing to large granite boulders underlying the surface, the "ambulance" was constantly in demand for nearly a month. The accompanying engraving gives a fair idea of its construction. There is no water rheostat; everything is ready at a moment's notice for action. The advantage of being able to do away with water when hurrying from one point to another is apparent. In the wagon box are placed four Westinghouse transformers with 55-volt secondaries, such as were used here several years ago, but have been replaced with the oil type of higher secondary voltage; by using these, old stock was made to earn good money. It will be noticed that the wagon box has a removable top several inches deep; this carries the rest of the equipment.

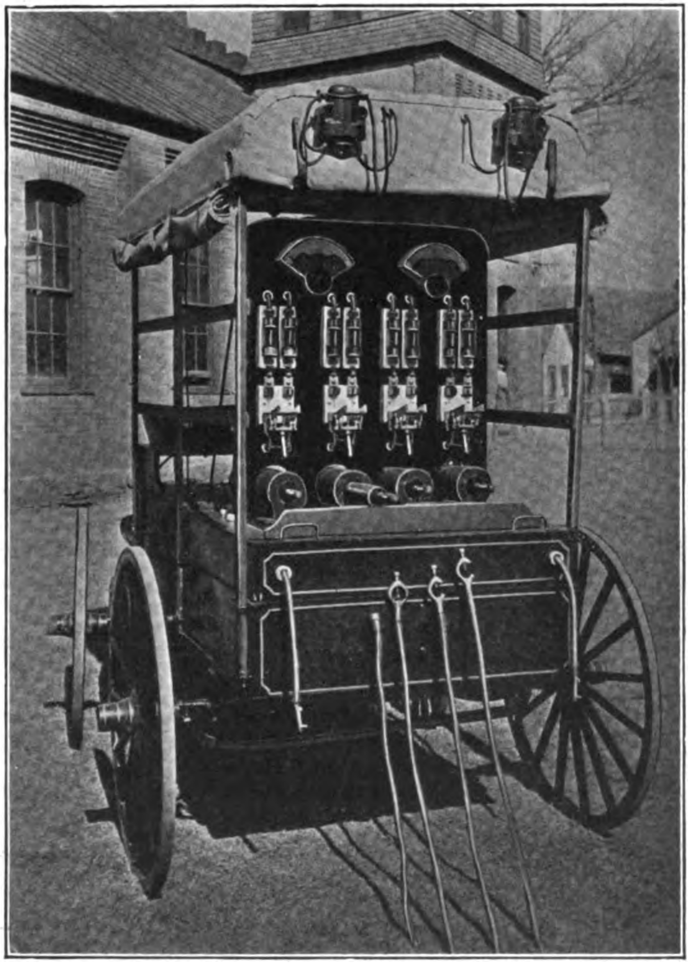

FIG. I.—PIPE THAWING EQUIPMENT.

At the bottom of the switchboard are four reactive coils, used to regulate the secondary voltage of each transformer. These are each 18 inches long, and the tube into which the core slides is 2½ inches inside diameter. The ends are brass castings, and a slot was cut lengthwise through the tube and ends to prevent the formation of a closed secondary circuit. After being well insulated, each tube was mounted on a wooden mandrel exactly fitting the bore, to prevent the edges at the slot from being squeezed together, and wound with two layers of No. 4 d. c. c. magnet wire (four layers were tried first, but two layers were found to be better). This winding was coated with insulating varnish, and after drying, covered with extra heavy insulating paper to prevent abrasion. The cores are each 18 inches long and composed of 500 No. 14 annealed iron wires, carefully straightened and assembled around a central soft-iron rod which is threaded at each end and carries two fibre heads turned to fit the tube easily. Before these heads were put on, the iron wires and rod were forced into a short piece of 2-inch iron pipe to hold them firmly together. One fibre head was then slipped on and tape wrapped over it and the iron wires as they were withdrawn from the pipe. The other fibre head was then slipped on, taped over, and the two heads clamped against the ends of the wires by a handle screwed on to one end of the rod and a nut on the other. Next, a layer of cotton tape was applied and coated with baking varnish.

Above the choking coils, on the switchboard, are four 75-ampere double-pole knife switches, eight 100-ampere single-pole D. & W. cartridge fuses, one 350-ampere ammeter, one 150-volt voltmeter, and four small lamps, the sockets of which are shown over the top edge of the board in the picture; each of these lamps shows when the corresponding transformer is active. On the back of the wagon covering are two G. E. transformer type 30-ampere primary cut-outs, and back of these, just inside, is a 30-ampere double-pole 500-volt quick-break knife switch, to open the primary circuit, which it does successfully; the primary e.m.f. is 1100 volts. Entering through porcelain tubes in the tailboard of the wagon will be seen the No. 00 cable leads with connectors attached, and between these stand the No. 0 cable connections for rapid attachment. The one on the left of the group is for connecting to the ordinary street washer box; the next one is for the valve screw of fire hydrants; the third and fourth are for connecting to common water faucets and ¾-inch pipe. On the other end of each of these is a straight connector for taking No. 0 wire; the cables to the primary cut-outs are also furnished with straight connectors, to take No. 8 wire.

For quick work, three men form the crew of this pipe-thawing machine. Arriving upon the scene, one man climbs the nearest pole and attaches the primary wires, which he has previously connected to the cut-outs. The other men take each a coil of No. 1 wire and roll it out to the faucets, or points where connections are to be made for thawing; they then connect the other ends to the leads on the wagon. The primary and secondary switches are then closed, and the cores are pulled out of the choking coils until the desired amount of current is obtained for the service under treatment. All service pipes here are iron, and generally speaking, extend from 75 to 100 feet from the main. For this length of ¾-inch pipe, we use 135 amperes, and water usually flows in from five to ten minutes. The chief reason for not using more current is to avoid any possibility of damaging the lead connection which is often used where the service pipe comes from the main; another reason is that it avoids too sudden a rise in the temperature of the pipe joints. If water does not flow in from eight to ten minutes, the current is increased slightly, but it is seldom over 15 amperes for this class of work.

On one occasion, this apparatus thawed out over 700 feet of 1-inch pipe, on which were five houses; it was frozen solid. One wire was attached to the farthest house and the other to a fire hydrant near where the pipe was tapped to the main. In this case, 175 amperes were applied, and water was running at all the houses in twenty minutes. A second case was the thawing of nearly 1500 feet of 4-inch cast-iron pipe. This was thawed in sections, starting at the main. On account of the working connections being made to service pipes, the current was limited to 250 amperes; the entire length was clear in three hours.

For thawing an ordinary service pipe, the charge is five dollars, and we often thaw two at once, so it can readily be seen that this field, as a source of revenue, is worth developing. Our observations are that a buried pipe rarely bursts until it has been frozen for over twelve hours, and less than 10 per cent of them burst at all; therefore, if people notify us promptly, the pipes are usually thawed before the ice has expanded sufficiently to cause any damage. As the cost of digging up an ordinary service pipe here in winter is about fifty dollars, the benefits derived from electric pipe thawing are mutual.

The writer wishes to acknowledge valuable aid given him in the construction of the thawing outfit by his assistant, Matt Harrington, and the company's first engineer, S. B. Richey.

◆

THE ZEUNER VALVE DIAGRAM.

BY C. C. MAJOR.

In a previous article, the relative positions of the valve, piston, crank and eccentric were shown by drawing these parts in their proper positions, under assumed conditions for the different events of the stroke. A clear understanding of these relations is necessary before the subject of valve setting can be thoroughly understood; but there are other questions which come up in connection with the subject of valve gears, and these can best be studied by means of the "valve diagram."

When an engine is to be designed, the steam distribution is assumed and the dimensions and movements of the valve determined to give the desired results; while on the other hand, the operator or engineer wishes to know the steam distribution after the dimensions and movements of the valve are fixed. The indicator card, when we learn to interpret it correctly, tells us many things about the operation of the valve and when the different events occur, but for a complete analysis of the subject, the valve diagram is indispensable.

There are many valve diagrams used for solving problems relating to valve gears, and no doubt each has its special advantages. The Zeuner diagram is simple and yet is comprehensive enough to analyze the movements of practically all ordinary valves such as the slide valve, Meyer valve, link motion, etc. By means of this diagram, the angles which the crank makes with the horizontal and the corresponding piston positions may be readily shown for all the events of the stroke; also, the travel of the valve from its mid position and the amount of steam and exhaust port opening for any piston and crank position.

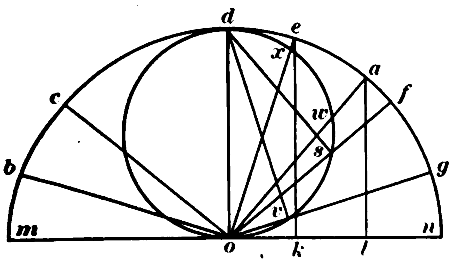

FIG. I.

If the valve is without lap, as illustrated in a previous article, the crank and eccentric will be at right angles to each other. In Fig. 1, let *o—m* represent the crank on the dead center and *o—d* the corresponding position of the eccentric. The length *o—d* should be made equal to the eccentricity *r*, Fig. 2, which is the distance between the center of the shaft and the center of the eccentric. As the crank moves to the positions *o—b* and *o—c*, Fig. 1, the eccentric will occupy the corresponding positions *o—c* and *o—a*. If from the points *e* and *a*, the perpendiculars *e—k* and *a—l* are let fall upon the diameter *m—n*, the distances *o—k* and *o—l* will represent the travel of the valve from its mid position for the positions *o—e* and *o—a* of the eccentric.

The travel of the valve for any crank position may also be shown by drawing perpendiculars from *d* to imaginary crank positions on one side of the center corresponding to the actual positions on the other side. Then the travel of the valve is the distance from *o* to the foot of the perpendicular on the assumed crank position. For the crank positions *o—b* and *o—c*, draw the lines *o—g* and *o—f*, and let fall the perpendiculars *d—v* and *d—s* to these lines; then the movement of the valve for the crank positions *o—b* and *o—c* will be respectively *o—v* and *o—s*. It was shown that the valve travel for the above positions of the crank is respectively *o—k* and *o—l*, but it can be proved by geometry that *o—v* is equal to *o—k*, and *o—s* to *o—l*.

When a circle is drawn on the hypothenuse of a right angle triangle as a base, the apex of the triangle will lie in the circumference of the circle, consequently, the locus of all the points obtained by dropping perpendiculars from *d* to the different crank position will be a circle drawn on *o—d* as a diameter. Then the valve travel for any position of the crank is the chord of the arc intercepted by the crank. When the crank occupies the positions *o—g*, *o—f*, *o—a* and *o—e*, the corresponding valve travels are *o—v*, *o—s*, *o—w* and *o—x*.

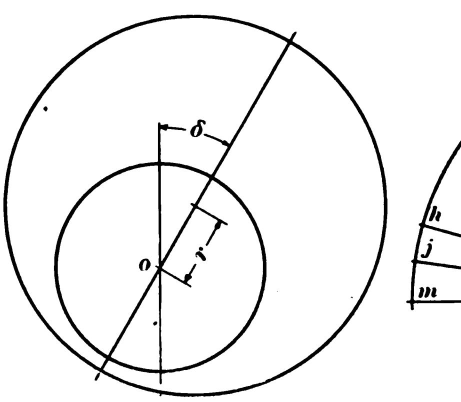

FIG. 2.

When on the dead centers *o—n*, the crank does not cut the circle, consequently, the valve is in its mid position and the ports are covered. When the crank-pin moves from the position *o—n*, it will cut the circle and the valve will have traveled a distance corresponding to the angular movement of the crank, and will evidently remain open until the crank reaches the opposite dead center *o—m*. Steam will enter the cylinder during the entire stroke and its expansive force will not be utilized.

To draw the diagram when the valve has steam and exhaust lap:—In Fig. 3, *s* is the steam lap; *i*, the exhaust lap; *p*, the width of the steam ports; *b*, the width of the bridge, and *e* that of the exhaust port. In Fig. 2, *r* is the eccentricity of the eccentric and δ the angular advance. Let *o—m* and *o—n*, Fig. 4, represent the dead centers of the crank, and *o—p* the center line of the eccentric when the valve is in its mid position. Make the angle δ equal to the angular advance of the eccentric. Take *o—c* equal to the eccentricity, *r*, of the eccentric, and on *o—c* as a diameter, draw the valve circle *o—d—c—b*. About the center, *o*, with the radius *o—w* equal to the steam lap *s*, Fig. 3, draw the lap arc *d—w—e* cutting the valve circle at *d* and *e*; and with the radius *o—v* equal to the exhaust lap *i*, Fig. 3, draw the exhaust lap arc *l—v—k*, cutting the valve circle at *l* and *k*.

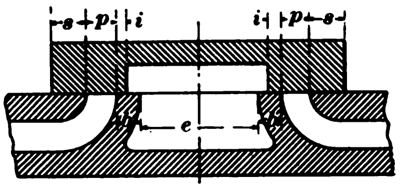

FIG. 3.

The distance *o—c* represents the extreme movement of the valve from its mid position in either direction. Since *o—w* is the distance the valve extends beyond the port, the valve must move this distance to bring its edge in line with the port; so that *w—c* is the maximum amount of port opening, providing the valve does not travel beyond the inside edge of the port.

When the crank is in the position *o—s*, the valve has moved from its mid position the distance *o—e*, and is about to open the port to the admission of steam; consequently, *s* is the point of admission. When the crank has reached the dead center *o—n*, which is here assumed to be nearest the cylinder, the valve has moved to *b* and the steam port is open the distance *a—b*, the amount of lead. At the same time the exhaust port in the crank end is open the distance *i—b*, the amount of exhaust lead. As the crank turns in the direction indicated by the arrow, the port

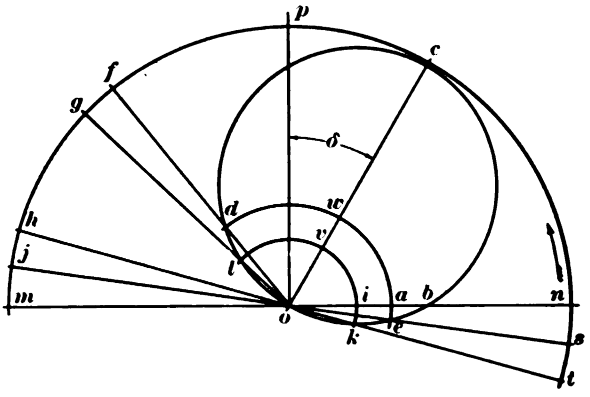

FIG. 4.

opening increases until the position *o—c* is reached, giving the maximum steam and exhaust port opening. Beyond *o—c* the port opening decreases and when the crank is at *f* the valve is just closing the port; hence, *f* is the point of cut-off.

As the crank reaches *o—g*, the exhaust port in the crank end closes and *g* is the point of compression for the crank end. At *o—h* (or *o—k* prolonged backward) the exhaust opens in the head end and *h* is the point of release. When the crank reaches *o—j*, or *o—e* prolonged backward, admission occurs in the crank end.

It will be noticed that the line representing the center of the eccentric is drawn in the first quarter of the circle when the crank is at the dead center *o—n*. This is not the true position of the eccentric, but it is the usual position in drawing the Zeuner diagram.

Separate diagrams, as shown in Fig. 5, may be drawn for each end of the cylinder. The circle *m—p—n* represents the path of the crank, *o—m* and *o—n* being the dead centers; *o—c* is the eccentricity *r* of the valve and δ the angle of advance, *d—w—e* is the steam lap arc and *l—v—k* the exhaust lap arc. The valve circles *d—c—e* and *l—u—k* are drawn on *o—c* and *o—u* as diameters, each being equal to *r*.

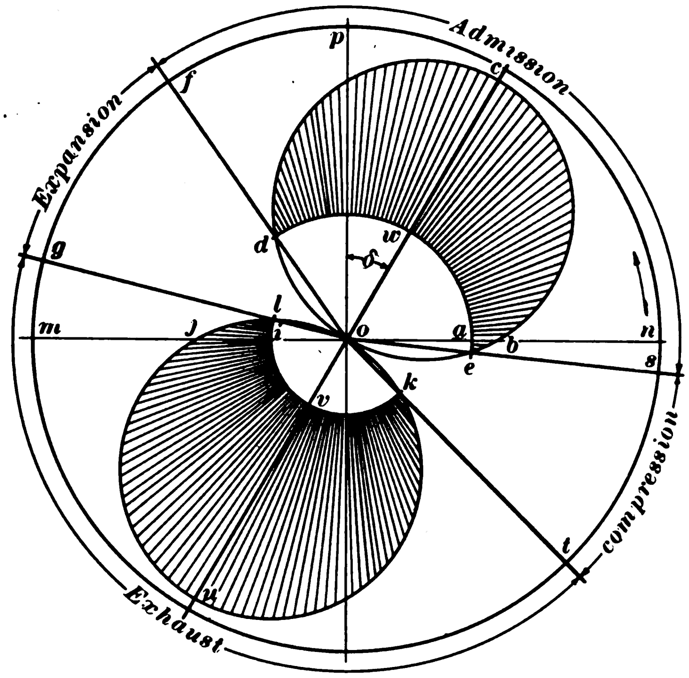

FIG. 5.

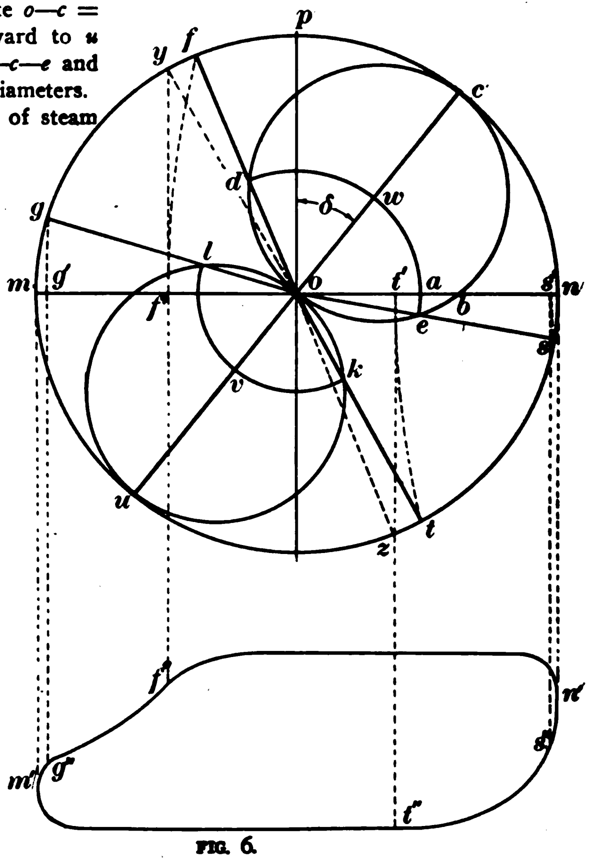

FIG. 6.

When the crank is at the dead center *o—n*, the valve is open the distance *a—b*, which is the amount of lead. At *f* the valve closes, the radial lines in the shaded portion of the circle *o—d—c—e* representing the amount of port opening as the crank-pin travels from *n* to *f*. The expansive force of the steam is being utilized in driving the piston while the crank travels from *f* to *g*. Release occurs at *g* and steam is exhausted from the cylinder during the movement of the crank from *g* to *t*, the radial lines from the arc *l—v—k* to the arc *l—u—k* showing the varying amount of port opening till exhaust closure occurs when the crank is at *t*. Compression occurs during the crank travel from *t* to *s*, the point of admission.

While these events are occurring in one end of the cylinder, complementary events are taking place in the other end, and it is not necessary to draw the diagram for both ends except for special purposes.

To draw the valve diagram and approximate indicator diagram when cut-off is to occur at three-quarter stroke, release at 98 per cent, and compression at 99 per cent of the return stroke:—Suppose the eccentricity *r* of the valve to be 2¼ inches and the connecting rod four times the length of the crank. Lay off *n—f'*, Fig. 6, as three-quarters of *n—m*, and with a radius equal to four times the length *o—n*, draw the arc *f' f*; *f* is the position of the crank-pin for the required cut-off. Take *m—s'* equal to 99 per cent of *m—n* and with a radius equal to 4 times *o—n*, describe the arc *s'—s*. Draw *o—s* which is the crank position for compression. Bisect the angle *f—o—s* by the line *o—c* and make *o—c* = 2¼ inches. Prolong *o—c* backward to *u* and draw the valve circles *o—d—c—e* and *o—l—u—k* on *o—c* and *o—u* as diameters.

The chord *o—d* is the amount of steam lap, which is equal to 1 1-16 inches. With *o—d* as the radius, draw the lap arc *d—w—e*; then the amount of lead *a—b* is about ¼ inch. The point of release is obtained by making *n—g'* equal to 98 per cent of *n—m* and drawing the arc *g'—g*, as before; then *g* is the point of release. The exhaust lap is the chord *o—l*, practically ⅞ inch. By drawing the lap arc *l—v—k* and drawing the line *o—t* through the point *k*, the point of compression is obtained.

The indicator diagram may be constructed by drawing the admission and exhaust steam lines and projecting the points *n*, *f'*, *g'*, *m*, *t'* and *s'* to *n'*, *f''*, *g''*, *m'*, *t''* and *s''*. The distance between the admission and exhaust steam lines depends entirely upon the pressure of the steam supplied to the engine and the back pressure.

The effect of the angularity of the connecting-rod may be noticed in this diagram. When the piston has traveled three-quarters of its stroke, from *n* to *f'*, the crank-pin is at *f*; but if the connecting-rod were of infinite length, the crank-pin would be at *y* and the crank position would be *o—y* instead of *o—f*. A similar effect may be noticed on the return stroke.

An inspection of Fig. 7 will show the effect of making cut-off occur at equal periods in each stroke. Suppose cut-off takes place at three-quarter stroke, or at *r* in the forward stroke and at *t* on the return stroke. When the piston is at *r*, the crank is at *f*, and assuming admission to occur at *s* in the head end, the center of the eccentric is along *o—c*. Extend *o—c* backward to *c'* and draw the valve circles as before. The chord *o—d* from *o* to the point where the valve circle meets the crank at the cut-off position is the steam lap for the head end of the valve, and, by drawing the lap arc, *d—w—e*, lead *a—b* is obtained for the head end. The lap for the crank end is the chord *o—d'*, which is considerably shorter than the lap for the head end. By drawing the crank end lap arc with the radius *o—d'*, the point of admission *s'* may be found by drawing *o—s'* through the point *e'*. It is evident that admission occurs earlier in the crank end than in the head end, and the lead *a'—b'* is considerably greater than the lead *a—b*. Hence, the effect of equalizing cut-off by giving the valve a greater amount of lap on one end than on the other is to make the lead unequal and to cause admission to occur earlier in the crank end. The effect of the angularity of the connecting-rod cannot be entirely eliminated without the aid of special links, as any change made to equalize one event will make other events unequal.

In the design of a valve gear, certain constants are assumed and others are found by drawing the valve diagram. The constants are s and i, Fig. 3, δ, r, the lead, and the crank positions at admission, cut-off, release and compression. The first four constants may be assumed, but only three of the crank positions can be taken and the fourth is found from the diagram. The valve may have overtravel, but r must be less than the sum of $s + p + b$, Fig. 3, or live steam will flow directly into the exhaust port; and the exhaust port e must be wide enough to that when the valve is at its extreme travel, the exhaust opening will be at least equal to the steam port p.

Suppose the crank positions at cut-off and compression, the angle of advance δ and the eccentricity r, are assumed; to find the points of admission and release and the amount of steam and exhaust lap and lead, one proceeds as follows: Draw the crank circle m—p—n, Fig. 5, and lay off the angle c—o—$p = \delta$. Extend o—c backward to u, making o—c and o—u each equal to r. On o—c and o—u as diameters, draw the valve circles. Draw the lines o—f and o—t for the given crank positions, and with o—d and o—h as radii draw the lap arcs; then the crank positions o—s and o—g for admission and release may be drawn. The steam lap will be the distance a—b and the exhaust lap i—j.

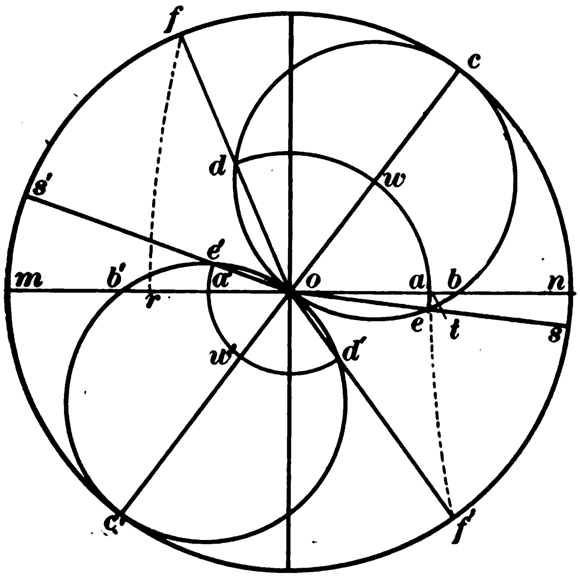

FIG. 7.

Given the crank position at release, the steam lap, the lead, and the eccentricity r, to find the remaining constants and crank positions:—With the given lap as radius, draw the lap arc d—w—e, Fig. 5, and make a—b equal to the lead. With r as radius, draw a circle about the center o and erect a perpendicular from b to meet the crank circle at c; then o—c is the diameter of the valve circle, which fixes the position of that circle. The crank positions for cut-off and release may now be drawn. The exhaust valve circle may be drawn as before and by drawing the given crank position o—g, the lap arc and crank position for compression are easily obtained. Other problems may be similarly solved.

◆

STORAGE BATTERY EXHIBIT AT ST. LOUIS.

BY CLOYD MARSHALL.

Storage batteries will have a more conspicuous place in the electrical exhibits at St. Louis than in any previous exposition, because the use of batteries has extended into every branch of the industry. Besides the displays of the storage battery companies, installations will be made in the several telephone exhibits, in the laboratory of the National Bureau of Standardization, and in some of the lighting and generator exhibits. The principal installation of storage batteries showing their various applications is now being made in the Southwest corner of the Electrical Building.

The Electric Storage Battery Company will have a space in Section 20, and will have a working battery regulating on a changing load to show exactly what results can be obtained from the use of a battery in railway or other fluctuating work. This battery will be installed in a model battery house, constructed on exactly the same lines as a regular battery house, forming part of a power house or sub-station equipment. The battery house will be of fire-proof and acid-proof construction, properly ventilated and with acid-proof brick floor. A small booster will be operated in connection with this battery, and a complete switchboard will be installed with recording instruments to show what work the battery is doing on the fluctuating load, and also how constant the load is maintained on the generator.

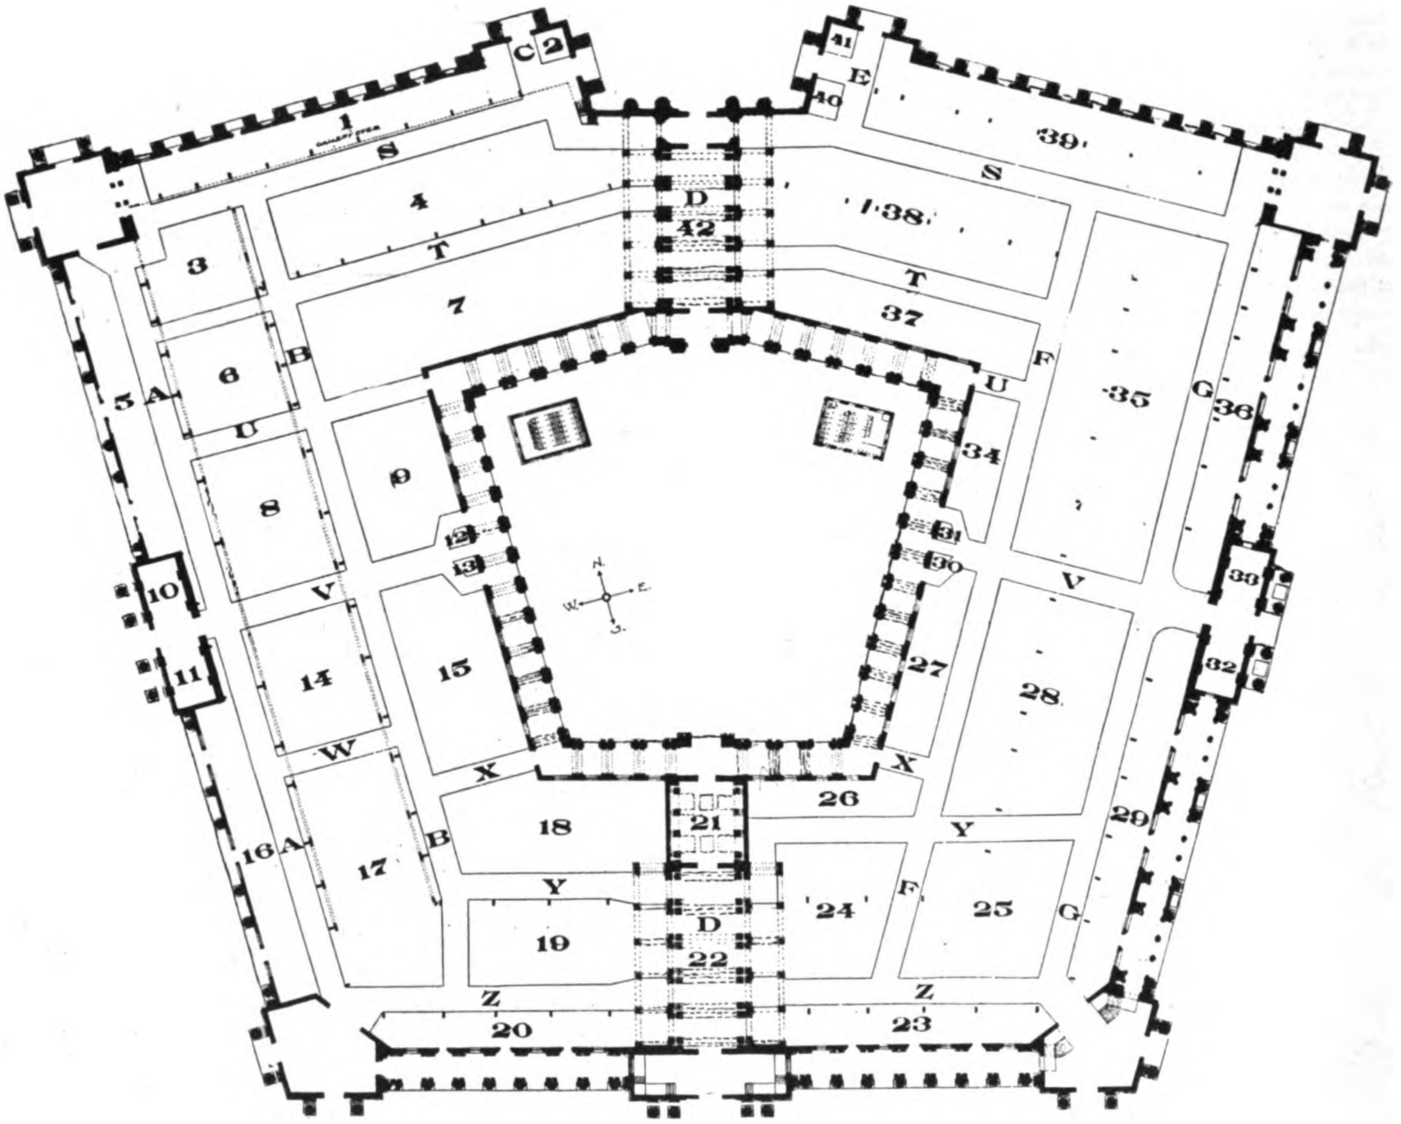
The fluctuating load will be provided either by switching on or off banks of lamps, or starting up a motor load with brake attached. A railway booster of about 100 kilowatts complete with switchboard and regulator will be shown, the motor being connected so that the machine can be run light; a complete line of switchboards for Edison work, isolated plants, railway booster equipment and line batteries; a set of three motor-driven end-cell switches connected up complete with motor control and indicator apparatus, such as is used in Edison work; complete cells erected of type "H" for lighting service; complete "G" type cells for railway work, such as are installed for the St. Louis Transit Company; complete cells of smaller type, set up to show the various types and capacities. A complete exhibit of vehicle batteries for automobile and locomotive work will be shown as well as a collection of photographs and curves showing existing plants and results obtained by same.

On the wall space at the back of the exhibit will be a large map of the United States, approximately forty feet by twenty-five feet, which will indicate the location of each of the electric battery installations, amounting to some 1600 or 1700. These will be shown by a different colored spot of isinglass about one inch in diameter, which will be illuminated by incandescent lamps mounted behind the map, the different colors being as follows: Red lamps for railway plants; blue lamps for Edison plants, white lamps for telephone and telegraph plants and green lamps for isolated plants.

The Gould Storage Battery Company and the Gould Coupler Company are preparing a complete exhibit in Section 16, showing the various adaptations of storage batteries to engineering work. It contains a battery of 60 Gould accumulators, type "O," No. 515 in lead lined, glass-covered tanks. The cells will be mounted in two rows of two tiers on a suitable rack of angle iron or wood. An induction motor is coupled to a double generator or rotary transformer. The purpose of this combination is to use the induction motor to drive the rotary transformer as a direct-current generator, charging the batteries in connection with a booster set. This represents a direct-current power station operating with a regulating battery in connection with a booster set; also, when the induction motor is disconnected, to operate the rotary transformer to represent a rotary sub-station in connection with battery and booster set; also to drive the rotary from the induction motor as a direct-current generator in which the series winding would be reversed to demonstrate a station with constant output (in wattage) in connection with the battery, the batteries taking all the fluctuations below and above a predetermined average, independent of any booster; also to drive the rotary from the induction motor as a direct-connected generator to demonstrate the train lighting system in connection with a suitable motor-driven counter e.m.f. booster, of the railroad type "G."

A booster set is being installed which is to demonstrate a power station regulation within 2 per cent above or below a predetermined average in connection with the battery, and for demonstrating a booster set operating with battery to show an equally close regulation operating with the rotary transformer disconnected from the induction motor as a rotary sub-station. By slight alterations in the connections, it represents an exciter booster system. With the combination of storage battery, motor-generator and booster set and a variable load on an artificial consumption circuit, a very close booster regulation will be obtained. Upon a switchboard about fourteen feet long will be mounted the various instruments, switches, etc., necessary for handling and manipulating the regulating system mentioned above.

A unipolar generator will drive a direct-current motor, taking its current from the bus-bars to which are connected the batteries in series with the booster set. The unipolar generator will be used to charge the two "U" type cells shown in the same group at from 3000 to 5000 amperes. By a suitable change in the connections, the two powerful "U" type cells will be discharged through the unipolar generator operating it thus as a motor to drive the direct-current motor as a generator to charge the battery set, after the battery is once thoroughly developed and charged to illustrate its working capacity and the close regulation obtained by the booster set in charging the two big "U" cells through the motor-driven unipolar machine and to illustrate the large capacity of the "U" cell in charging the battery through the unipolar machine and its motor run as a generator, thus illustrating the conservation of energy principle, the losses in translating apparatus being made up by an occasional charge from the motor generator set. A motor-driven direct-connected generator will be utilized in showing some other regulating systems in connection with the battery.



INSTALLATION PLAN FOR ELECTRICITY AND MACHINERY, ST. LOUIS EXPOSITION.

A new Gould counter e.m.f. booster is encased in a dust-proof, water-tight compact form for railroad train lighting work. It will operate in conjunction with either the first or second motor-generator set and railroad batteries to be located in the Gould Coupler Company's exhibit, which is installed just south of the Gould Storage Battery Company. The train lighting system is one in which the load on the generator will be kept constant by the automatic distribution of its output, through the medium of the counter e.m.f. booster, to the electric lights and the batteries, according to requirements. If the number of lights burning requires the total energy of the generator, the batteries will receive no charge. If the number of the lights burning is equal only to one-half the capacity of the generator, the remaining capacity of the generator will go into the batteries, the voltage of the generator remaining constant, the booster set automatically furnishing what additional voltage is necessary to charge the batteries, subject, of course, to the amount of power which the generator can furnish to the batteries.

A model trolley road with one or two movable model trolley cars will be shown. There will be introduced sufficient resistant to make the model trolley road charge and discharge the battery according to the floating battery principle.

A group of four elements in lead lined tanks with glass covers is being installed. The largest cell will be the one exhibited at the Pan-American Exposition, which gave a discharge of 27,000 ampere hours at a 2000 ampere discharge rate. It was also discharged at the rate of over 30,000 amperes, which is the largest discharge rate on record.

The Porter Storage Battery Company will show its train lighting system in Section 20, and the Columbus Storage Battery Company will make a showing of small batteries.

In the Edison exhibit, Mr. Edison's new cell is to be demonstrated in a way which will add much to the valuable data already compiled from this type of cell.

Dried-out Motors and Transformers.—An interesting and successful experiment has recently been carried out with a number of transformers and induction motors used in driving the pumps of the Knights Deep mine at Johannesburg, South Africa. During the war the mine became flooded, submerging 12 three-phase, 50-h.p. motors and 36 15-kw. transformers. Two years after, the water which covered the machinery to a depth of 500 to 1000 feet was pumped out and the apparatus removed to the surface. Three of the motors were rewound and the others were dried in an over and then soaked in oil. The transformers were dried out in the same manner and all put back in service.

Abstracts from Foreign Contemporaries

New Mercury-Vapor Lamp.—*The Electrician* of London describes a new form of mercury-vapor lamp, brought out by C. O. Bastian and A. E. Salisbury, possessing several features of novelty. Fig. 1 herewith shows the lamp in its normal position. *E* is a spun copper bell-shaped cover which protects the internal mechanism from wet, and provides a means for suspending the lamp and fixing the tubes and other devices. *G* is an ordinary glass globe. As shown in the illustration, the lamp is not at work and it will be observed that the mercury in the tube *T* connects together the two wires sealed into the glass. Fixed to one end of the glass tube is an iron plunger *C* which acts as a core to the electromagnet *M*. Now, it is obvious that if the switch were closed with merely the column of mercury in the circuit the only result would be to blow the fuse, and therefore the resistance *R*, the electromagnet *M*, the carbon filament lamp *L* and the mercury in the tube *T* are all connected in series. On closing the switch, the core *C* is drawn up by the electromagnet, *T* being pivotted at *P*, and the continuity of the mercury being broken, an arc is formed. It will thus be seen that the tilting of the tube is effected automatically instead of by hand, as in other forms. But the mere tilting is not sufficient to effect all that is necessary, for the resistance *R* has to be short-circuited, and this, again, is brought about automatically. To fill the left-hand bulb of the tube with mercury merely by tilting would be inexpedient, as the tube would have to be brought into a position approximating the vertical. Happily, the pressure of the mercury vapor set up by the arc forces the mercury up into this bulb, and thus cuts out the auxiliary resistance. All these operations occupy but a fraction of a second, and there is no "time-lag" in the starting of the lamp. A more or less successful attempt to overcome the absence of red rays has been made by fixing the carbon filament lamp *L* just above the mercury tube. This lamp is under-run and its radiation is consequently rich in the required red rays. The patentees claim an efficiency of 2½ candle power per watt when the carbon auxiliary is not used, and 1 to 1.5 candle power per watt when the latter is used. Each lamp requires from 40 to 60 volts and 0.65 ampere, and the candle power is said to be 80. Lamps have been run both continuously and intermittently for over 1,500 hours, and the inventors believe that the average life will be about 3000 hours. Although they hope that there will be a demand for the lamps for indoor lighting, the principal object is to provide an electric lamp for side street lighting which will compete successfully with incandescent gas lighting. The efficiency of the lamp is necessarily less than that of the Cooper Hewitt, but it has the advantage of a neater shape.

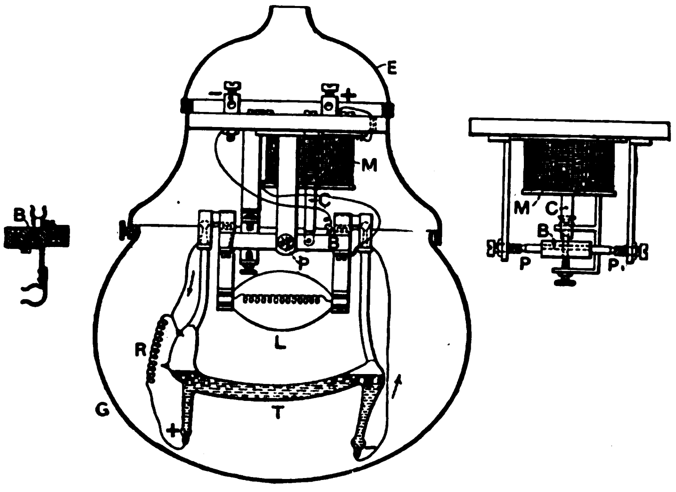

FIG. 1.—MERCURY-VAPOR LAMP.

Bradford Feed Pump.—Fig. 2 herewith shows a new type of boiler feed-pump recently introduced in England and described in London *Engineering*. As shown, the pump is of the direct double-acting type. The distribution of steam in the actuating cylinder is governed by a single valve, which is operated entirely by mechanical means, and which is therefore not liable to stick in the annoying manner that is sometimes experienced with pumps of this nature fitted with an ordinary shuttle-valve. The valve is operated on the "lost-motion" principle by means of a lever connected to the piston-rod as shown, the distribution of steam being indicated by the arrow. There are bored in the liner of the pump cylinder a number of small holes or ports. These are so arranged that when the steam valve reaches its central position, and the steam is cut off from entering the steam cylinder, these ports are beginning to open, owing to the upward or downward movement of the pump-piston. This opening of the ports throws both sides of the pump-piston into communication. The pressure on the pump-piston is therefore equalized, and the expansion of the steam in the steam cylinder is then sufficient to complete the full stroke, thereby actuating the steam-valve, so that steam is admitted to the opposite side of the steam cylinder. Naturally, as is common with this type of pump, the steam is carried practically full stroke, no more work being done by expansion than is required to complete the very small portion of the stroke necessary to operate the valve. The advantage of this design will be apparent, the pump acting with certainty, and a full stroke being obtained with every reciprocation. There is no fear of sticking at any speed and a very regular discharge is obtained owing to the absence of any slowing down at the end of the stroke. The steam valve is of a simple type. The pistons of the water-pump are packed with ebonite rings and all parts in contact with water are of gunmetal.

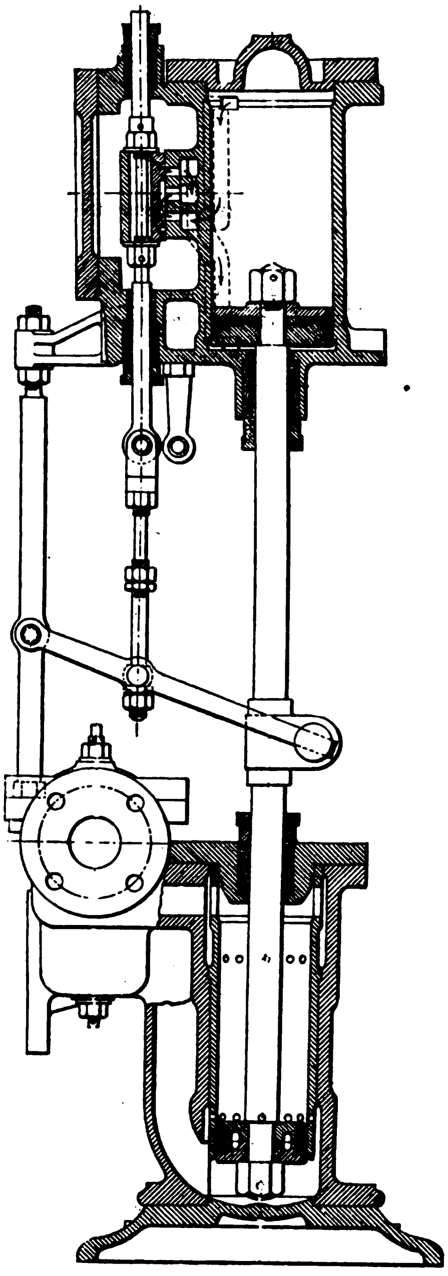

FIG. 2.—BRADFORD FEED PUMP.

Electrical Methods of Measuring Temperatures.—In the third and last of his lectures on the above subject at the Royal Institution, Prof. Callendar demonstrated the applicability of electrical methods for taking indicator diagrams. For this purpose a motor cycle had been rigged up in the lecture room, and five thermocouples had been screwed from the outside into the cylinder wall of its small internal combustion engine. Since the thickness of the cylinder casting is but about ⅛ in., the temperature indications of the thermocouples could be taken to represent also the internal temperatures. One couple was placed near the exhaust, another near the inlet, and the remaining three were fixed near the top, the middle and the bottom of the stroke respectively. First of all, Prof. Callendar determined the temperatures at these various points. He proved experimentally that the temperature at the exhaust side of the cylinder was considerably higher than at the inlet side, but that, by directing a blast of air from a small fan against the exhaust, this order of things might be reversed and the engine rendered more powerful in consequence. The measurement of the temperatures at the three points of the stroke brought out the interesting fact that these temperatures differed but little, the explanation being that the heat generated in the combustion chamber was rapidly transported to all points of the stroke by the piston. Most interesting and instructive were the indicator diagrams of the engine, taken by an indicator of the Hospitalier-Carpentier type. In this indicator the pressure is measured by a flexible diaphragm, which is coupled to a small mirror, which is deflected about a horizontal axis as the flexible diaphragm moves in and out under the variation of pressure in the cylinder. The same mirror is also caused to vibrate about a vertical axis, by being coupled to a small crank driven by suitable connections from the main shaft of the engine. The actual diagram is traced by a ray of light thrown by the moving mirror onto a screen and this diagram can therefore be obtained of practically any size desired. Fig. 3 shows some of the diagrams for which we are indebted to London *Engineering;* the pressure scale, it is stated, is not one of even parts. Perhaps the most striking feature of the diagrams as a whole is the large amount of power absorbed in engine friction. The dots shown in the diagrams near the compression line show the time of the ignition spark. The engine was fitted with an adjustable spring on the automatic inlet valve. In Fig. 3 the diagrams marked *A* were taken with the engine running light at 1430 r.p.m., the suction being throttled and full spring pressure being on the inlet valve. The maximum compression was 39 pounds per square inch, the mean pressure 15 pounds, and the indicated horse-power 0.32. The spark was retarded behind the proper point, both in this and the next set of diagrams marked *B*. It will be seen that the pressure actually falls for some time after ignition, the maximum being near the end of the stroke. In *B* the inlet spring was very weak, and consequently there was occasionally a loss of compression. The engine was run unloaded at 1850 revolutions per minute. The compression varied between 59 pounds and 67 pounds per square inch, the mean pressure was 19 pounds and the indicated horse-power 0.53. In *C* the throttle was half open, and the inlet-valve spring was stiff. As before, there was no load, but the spark was advanced beyond its former position. The compression was 46 pounds, the mean effective pressure 19 pounds, the revolutions 2430, and the indicated horse-power 1.15. This set of diagrams shows a large suction loss, owing to a stiff spring and a slow ignition of the weak mixture at the high speeds. The exhaust line is nearly atmospheric. All these diagrams were taken with a 10-kilogram diaphragm, and the remaining two, *D* and *E,* with a 20-kilogram diaphragm. In taking the diagrams represented in *D* the throttle was fully open, and the inlet spring adjusted to its best tension and the spark advanced. The engine was running under its full load. The speed was 1750 revolutions per minute, the mean effective pressure 78.5 pounds, and the indicated horse-power 2.05. The cylinder was kept cool by a fan fixed on the crank shaft, and as a consequence the compression line was kept low. The temperature of the cylinder at the middle of its length was 120 deg. Cent., and that of the cylinder head 140 deg. on the exhaust side, which was exposed to the blast of the fan, and 230 deg. Cent. at the other side. The diagrams shown in *E* were taken under similar conditions to the foregoing, save that the main fan was shut off and the cylinder was overheated, the engine being on the point of stopping from this cause. The revolutions were 1790, the mean pressure 72.7 pounds, and the indicated horse-power 1.96. The compression line, owing to the hot cylinder, is higher than in the previous set. The temperature at the middle of the cylinder was 300 deg. Cent., and at the head 400 deg. Cent. A small fan was kept running on the exhaust side to keep the exhaust valve from burning. The temperatures noted were measured with thermocouples, as previously stated. The experiments are of very great interest, particularly in view of the enormous powers claimed for their engines by makers of motor-bicycles. Apparently, of the 2.05 horse-power indicated, about half a horse-power was absorbed in engine friction. Professor Callendar finds that the engine generally stops from inefficient lubrication when the temperature of the walls reaches 300 deg. Cent.

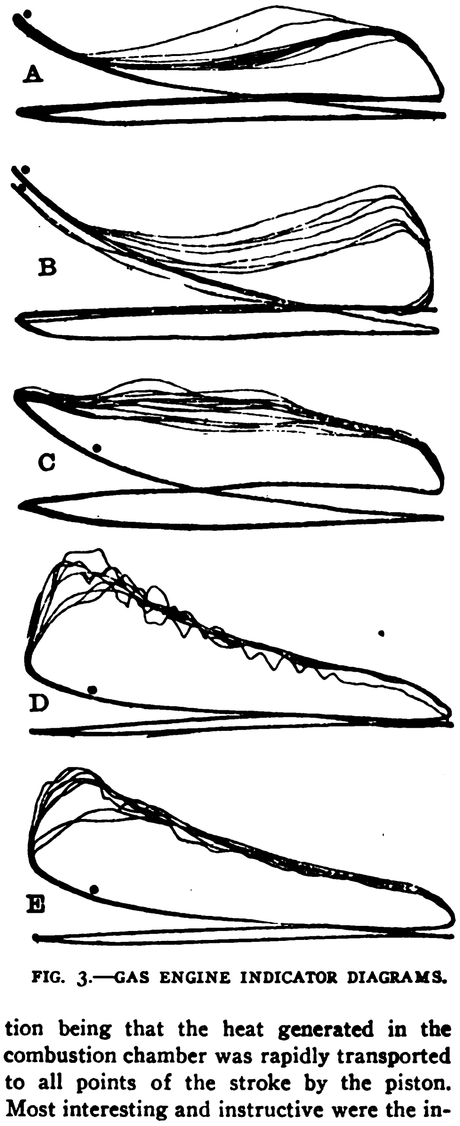

FIG. 3.—GAS ENGINE INDICATOR DIAGRAMS.

Electromagnetic Track Brake.—*The Electrician* of London gives the particulars of an electromagnetic brake for railways which the British Thomson-Houston Company is about to bring out. The general principles on which the brake is designed are clearly indicated in Fig. 4. It will be noticed that the brake proper is suspended from a stiff bracket, which is fastened to the side of the truck, by means of compression springs and wrought-iron eye-bolts. By using compression springs the advantage is secured that, even if a spring should break, the brake shoes are kept clear of the track. The brake shoe itself consists of a substantial steel casting with a cored recess, containing the magnetizing coil. This recess is closed at the top by a water-tight brass cap. A steel core extends through the coil, providing two magnetic circuits, each of which is completed by the action of rail immediately under the brake shoe. Wearing plates of cast steel are bolted to the underside of the shoes in such a manner that they can be renewed without removing the shoe from the truck. The magnetizing coil is supplied with current from the motors, when these are acting as generators, the current being led to the coil by means of flexible wires in duplicate, introduced through bushed holes into the recess of the cast steel frame of the shoe. It may be mentioned that the track brake is entirely independent of the ordinary hand brake. For single trucks two shoes are used, the coils of which are connected in parallel, and for bogie cars four track brakes are employed, two in series and two groups in parallel. The efficiency of the brake as an emergency and service brake has recently been demonstrated by a series of tests carried out under actual working conditions. A four-wheel double-deck car with two motors was used. The weight of the car was about 9 tons, and it carried five or six persons, engaged in the trials. When traveling at the rates of 25 and 14 miles an hour, the car was brought to a standstill in 4 and 1.6 seconds respectively, the stopping distance being 25 and 5.3 yards. In

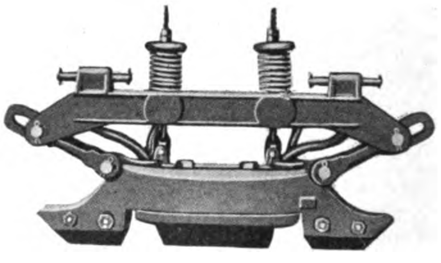

FIG. 4.—ELECTROMAGNETIC TRACK BRAKE.

the former case the car was on a down grade of 1 in 13, and in the latter case the car was running on a level grade. The first test represents extreme conditions; while the second test corresponds to the case of a car traveling at a moderate speed and obliged to pull up suddenly. A low and even speed can be maintained when the car is coasting down the steepest grades, and if necessary, the car can be stopped by further movement of the controller handle, and held at rest by the wheel brake.

The Inflammability of Twin Flexible Cord. —A joint contribution by J. Herzog and C. Feldman to the *Elektrotechnische Zeitschrift* gives the results of some experiments undertaken by the authors to determine the safety factor of twin flexible cord, such as is commonly used in connection with electric lighting installations. The tests were made with rubber-covered wire suitable for use in dry rooms, and designed for pressures up to 125 volts. Each conductor of the twin cord was composed of 24 copper strands 0.2mm. in diameter, the sectional area of the two conductors being, therefore, 2 × 0.75 square millimetres. The insulation consisted of a cotton covering, a thickness of Para rubber tape, and two braidings of cotton thread over all. In regard to insulation, the wire complied with the standards adopted by the Verband Deutscher Elektrotechniker. On the other hand, however, the composition of its conductors did not conform to these standards, which specify 0.75 square millimetres as the smallest permissible section, but fix 0.3mm as the minimum diameter for the copper strands. Referring to the accompanying diagram, curve *A* represents the temperature increase of the wire under a load of 20 amperes; four minutes after switching on the current the temperature was found to have risen by 70° C. Curve *B* was plotted from observations made with a load of 25 amperes; after four minutes the temperature rise had attained nearly double the previous value. With 30 amperes (curve *C*) an excess temperature of 150° C. was imparted in two minutes. Finally, as shown by curve *D*, the increase of temperature due to a current of 35 amperes amounted to 200° C. after 2 minutes 15 seconds duration. To prevent the ignition of the insulation before the completion of the observation, the current was reduced from 35 amperes to 32 amperes; the temperature increased within another minute to 240° C., and the wire began to glow. At this point the current was again increased to 35 amperes, and after the lapse of a further 30 seconds the insulation fired. The increase of temperature, it may be mentioned, was ascertained by measuring the resistance of the wire, assuming a constant temperature coefficient of 0.004. Now, the German safety rules allow a maximum continued load of four amperes for conductors of 0.75mm. cross-section, causing the temperature of the same to rise about 10° C. At the same time, the fuse must be designed to blow under the effect of double the maximum permissible current (in this case eight amperes) within the space of two minutes. But even four times this fusing current is insufficient to ignite the flexible cord within two minutes. The experiment also shows that the conductor is capable of carrying continuously a current of 20 amperes without its insulation being fired. Even supposing a 10-ampere or 16-ampere fuse were accidentally or purposely inserted instead of the 4-ampere one, these would be blown within two minutes by the passage of 20 amperes or 32 amperes respectively without ignition resulting. It is, consequently, wrong to suppose that the current due to a short-circuit between the conductors can fire the insulation of the wire over its whole length. But the case is different when one considers local inflammability. For instance, should broken strands of the core penetrate the insulation and cause the formation of an arc, to maintain which only a relatively small current is necessary, the phenomenon would involve a far greater element of danger. The small excess current might not suffice to blow the regulation fuse, while the insulation would be fired at the point of arcing. To avoid this danger, insistence on good material and workmanship is recommended. Further, it is pointed out that shop-window dressers should be warned against fastening flexible wire to draperies by means of pins, as also against the practice of knotting the flexible cord, etc.

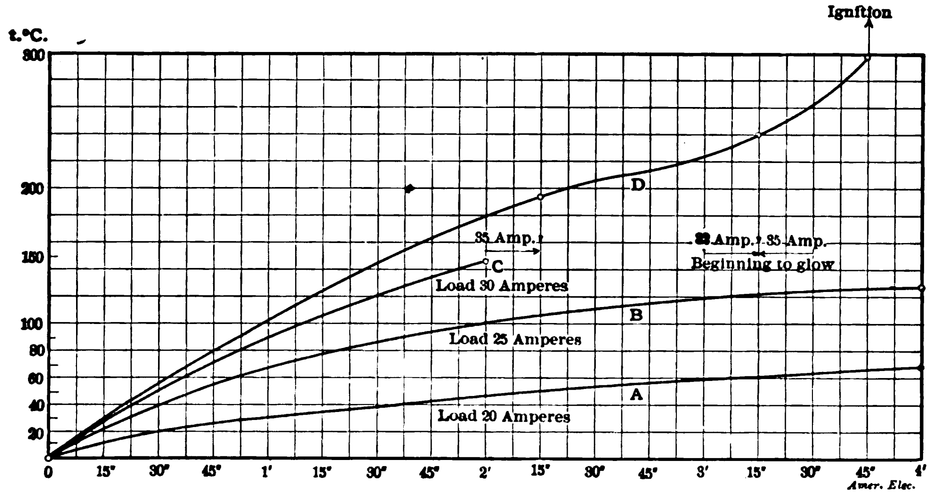

FIG. 5.—CURVES OF TEMPERATURE INCREASE IN TWIN FLEXIBLE CORD.

Three-Phase Electrolytic Rectifiers.—Emile Mors contributes to *L'Industrie Electrique* a description of an electrolytic device for the conversion of three-phase current into direct current. The apparatus involves the use of the electrolytic valve, and the connections used in this particular instance are shown by Fig. 6 herewith. Each of the wires of the three-phase system is connected to two electrolytic valves, in each of which there are two plates, one of aluminum and the other of some other material. As is well known such apparatus only allows current to pass in one direction. The two electrolytic valves on each wire are oppositely connected. It will be seen that the aluminum electrodes are connected to one of the wires through which the direct current is to flow, while the other is connected to the three plates of other material. With this arrangement the current in the rectified circuit is always in the same direction, and the curve of e.m.f. has undulations of exceedingly small amplitude. The author states that with a pure sine wave in the three-phase system the variation from the mean would be under 15 per cent. After trying this apparatus in its sub-stations at Clinchy and Courbevoie, the Société du Nord-Lumière has now decided to use them at these stations for converting three-phase current at 25 periods and 110 and 220 volts to direct current. In both cases the voltage obtained is considerably higher than the effective pressure of the currents applied, which the author states has not previously been the case in other attempts in the same direction, because the higher part of the curve of three-phase current has not been utilized. This increase in voltage in the case of three-phase current at 215 volts allowed of 230 volts being obtained on the direct-current side. This is used to supply six arc lamps in series. The efficiency as measured by two Aron meters has varied between 75 per cent and 78.5 per cent and the apparatus does not heat more than 20° C. over the surrounding air.

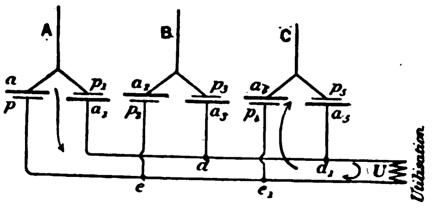

FIG. 6.—THREE-PHASE ELECTROLYTIC RECTIFIERS.

Oil Switches for High Tension Work.—The *Elektrotechnische Zeitschrift* publishes a report of an interesting paper read by Herr Volgelsang before the Elektrotechnische Gesellschaft zu Köln, in which the author deals with oil switches for high tensions. After reviewing the changes which have been made in the designs for high-tension generating plants since the first transmission scheme was carried out, the author goes on to say that modern practice has discovered two ways of constructing high-tension switches which can be relied upon to satisfy the more exacting requirements. One of these methods consists in the employment of the horn-break type of switch, while the other embodies the principle of interrupting the circuit under oil. Each has its advantages and disadvantages; the horn-break is only effective with heavy currents—the greater the current the more reliable is its action—a peculiarity which renders it especially adapted for use with fuses. On the other hand, the space which is required for its proper function is considerable. The author then discusses the oil switch—incidentally describing a type constructed by Voigt and Haeffner, Frankfort-on-Main, which is exceedingly simple. A three-pole switch is provided with six contact jaws, to engage with which there are three blades, so that each pole is interrupted at two points simultaneously. The oil is contained in a removable vessel of tin. The quiet action of this type is somewhat surprising, the interruption of the circuit being unaccompanied by noise. Experiments have shown that the formation of an arc under oil, just as in air, depends very largely upon the speed of the break. The author is of the opinion that the advantage of providing a large number of break points, especially in oil switches designed for very high tensions, will be more appreciated in the future, and thinks this principle better than that of employing extra long breaks under oil. He also points out that oil fuses are much less satisfactory in action than oil switches, because in their case one point of interruption only per pole can be provided. Moreover, at the moment of interruption the particles of melted metal along the path of the fuse assist the formation of an arc. For this reason oil fuses are used only for moderately high pressures, that is up to 3000 volts, and for relatively small currents. Within this limit oil fuses have proved thoroughly reliable. On the other hand, combination oil switches, in which the ordinary switch blades are replaced by fuses, have met with considerable success, especially in mines; but the practice of employing automatic cut-outs, instead of fuses, in conjunction with oil switches is quickly gaining favor, and it would almost seem that the use of oil switches with automatic releases in place of ordinary switches and special fuses has solved the difficulty hitherto connected with the breaking of high-tension circuits. The advantages of such an arrangement are obvious, especially in that the danger of fire which, in unfavorable circumstances, attends the blowing of tigh-tension fuses is avoided. In regard to oil switches with maximum current releases, the action is always indirect, being effected either by direct current through the medium of a relay or by alternating current through a rectifier. The latest phase in the development of this class of apparatus is the construction of automatic oil switches and cut-outs which can be operated from a distance. It is probable that this type of switch will find extensive employment for central-station work.

Measuring Alternating Current Potentials by the Aid of Condensers.—In a contribution to the *Elektrotechnische Zeitschrift,* Prof. W. Peukert deals with the use of condensers as an aid in the measurement of high potentials. He describes a modification of the principle whereby the range of a voltmeter may be increased by introducing a capacity into the circuit. Messrs. Siemens & Halske use a condenser for this purpose having a dielectric composed of porcelain plates; but the results, the author says, may be rendered independent of the periodicity by employing an air capacity. Since the voltmeter is also an air capacity, two similar condensers are in series the potential of the current being divided between them. Let a capacity C_1 (Fig. 8) be connected in series with an electrostatic voltmeter across an alternating current circuit having a potential E; also let the capacity of the voltmeter be C_2 and the potential at the two capacities be e_1 and e_2 respectively, then $e_1 \div e_2 = C_2 \div C_1$, or $(e_1 + e_2) \div e_2 = (C_1 + C_2) \div C_1$. But $e_1 + e_2 = E$ and $E \div e_2 = (C_1 + C_2) \div C_1$; hence $E = e_2\ (C_1 + C_2) \div C_1$. If now the capacity, C_2, of the voltmeter be known, one may vary the range of the instrument at will through the choice of C_1. For instance, if $C_1 = C_2$ then $E = 2\ e_2$, the range being doubled. It follows that the sensitiveness of the instrument may be varied within wide limits by means of this arrangement. Or, suppose one has an electrometer whose range is 200 volts and wishes to measure a pressure of 1500 volts, the capacity of the condenser required may be easily determined. Let the known capacity of the electrometer equal C, and that of the condenser to be discovered,, C_x, then $1500 = 200\ (C_x + C) \div C_x$; whence $C_x = 2C \div 13$. The air capacity employed consists of two metal plates, insulated from each other by glass stays, one of these plates being fixed while the other is adjustable by means of a screw motion. The capacity of such a condenser is, within certain limits, inversely proportional to the distance separating the plates, and one can, therefore, vary the capacity within these limits. In the above formula the capacity of the voltmeter is assumed to be constant, but this assumption would not hold in practice. On the contrary, one would have to find the relation between the capacity of the voltmeter and the potential at its terminals That is to say, one must determine its capacity for any potential. The measurement of what is, after all, the very small capacity of the voltmeter may be made by connecting it in circuit with a high non-conductive resistance (graphite resistance of several megohms) across a known potential. If E represent the latter and e_1 the potential indicated on the voltmeter, then the relation existing between these potentials and the potential, e_2, on the resistance is $E^2 = e_1^2 + e_2^2$, whence $e_2 = \sqrt{E^2 - e_1^2}$. Further, if R be the non-inductive resistance, then $e_2 \div R = i_0$, the charging current of the condenser, from which and the potential, e_1, the capacity may be calculated when the periodicity is known. By varying the resistance, R, the different deflections on the voltmeter are obtained and thus one is enabled to determine the capacity corresponding to any potential. In concluding, the author remarks that condensers have been successfully employed for the purpose described, both with electrometers and voltmeters, in the laboratory with which he is connected.

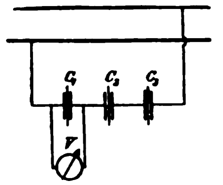

FIG. 7.

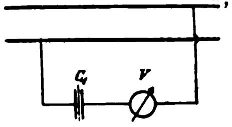

FIG. 8.

Phase Meter.—If an alternating current wattmeter be arranged so that for a varying load the current in the movable coil and the current in the fixed coil are constant, the instrument would be suitable, not for measuring the power, but for determining the power factor. For this purpose the arrangement shown by Fig. 9, taken from the *Elektrotechnische Zeitschrift,* is used. The fixed wattmeter coil is made of manganin so as to represent a distinct resistance, having a temperature coefficient practically equal to zero, and its terminals are connected to a voltmeter for control. Since the resistance of this wire is constant within wide limits, the voltmeter reading may be taken to determine the current in the fixed coil; if this reading is constant the current is also constant. In order to make the current constant and independent of the current in the consuming apparatus, a liquid resistance is connected in parallel with the fixed coil of the instrument. By manipulating the liquid resistance, the current J_1 in the fixed coil can be maintained constant while the current J changes. The current i in the movable coil is maintained constant by means of a rheostat W in series with it. Under these circumstances the reading of the wattmeter is directly proportionate to the power factor, so that the phase difference may be easily found.

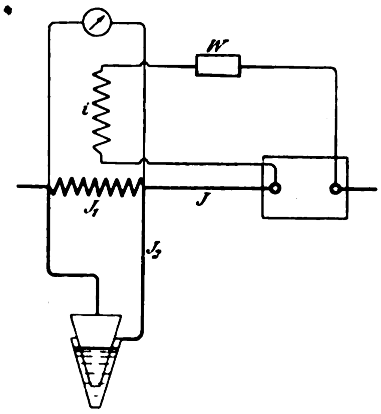

FIG. 9.—PHASE METER.

Frequency and Slip Meter.—*The Electrician* of London contains a note on a new device brought out by A. Bianchi, of Milan, for measuring the slip of induction motors. The whole apparatus is self-contained in a box of small size. A small electromagnet, with a polarized armature, is connected in shunt to the line through a contact-breaker. The latter consists of a disc of insulating material having (for a bipolar machine) one metal contact piece on its periphery, the disc being directly rotated by the rotor of the induction motor to be tested. Every time this contact piece passes beneath the brush, the shunt circuit referred to is closed and the electromagnet is energized. Since the frequency corresponding to the speed of the rotor is lower than the frequency of the line, it follows that contact is made each time at a different point of the primary wave. Each successive contact corresponds to a slightly advanced value of the line wave. The electromagnet is, therefore, energized by a current wave of the frequency v, equal to the difference of the frequency of the line and the frequency corresponding to the rotor speed. Since the armature of this electromagnet is polarized, it will be actuated in accordance with this wave of comparatively low frequency. The number, N, of the revolutions of the rotor is recorded by a speed counter and the frequency, v, is recorded by means of the electromagnet. The slip in per cent is calculated from the equation: $\text{Slip} = 100\, v \div v + (pN \div 60)$ and the impressed frequency is $v + (pN \div 60)$. In these equations $2p$ is the number of poles. If the induction motor has more than two poles, the rotating disc must have more than one contact; in fact, the number of contacts must be equal to the number of pole pairs. In Bianchi's apparatus, six different contact rings are provided, allowing motors with nearly every number of poles between 2 and 36 to be tested.

Direct-Current Voltage Transformer.—M. Aliamet describes in a recent number of *La Revue Électrique* the Lanhoffer system for varying the voltage of a direct-current generator. As is well known the voltage that can be obtained at the terminals of a direct-current generator cannot be varied within very wide limits, since the upper limit and the lower limit are very clearly defined. If the ratio of the highest and lowest voltage under which a dynamo can be operated successfully is called the coefficient of variation of the tension, this coefficient is generally below 1.5. The machine of Lanhoffer enables one to increase it over 5. It consists, as shown in Fig. 10, of two machines with independent stationary field systems while the two armature cores are mounted on the same axle. The armature winding passes over both cores. The excitation of the field N S is kept constant while the exciting current of the field V V' can be varied and reversed. For this reason a rheostat with a reversing switch is provided in the exciting circuit of V V'. The field N S may be excited either by a separate source of current or a method of self-excitation may be used; in the latter case the exciting current for N S is furnished from a special winding which is wound only around the core A_1 and not around A_2. If the e.m.f.'s induced in the common armature circuit by the field V V' are of the same sign as the e.m.f.'s induced by the field N S, the machine V A_2 V' acts as a booster; if the e.m.f's are of the opposite sign, this machine acts as a negative booster. The same arrangement may be used as a direct-current voltage transformer with the ratio of transformation being variable within rather wide limits. In this case, of course, a second commutator must be provided which is supplied from the external circuit at constant voltage. This commutator is connected to the armature winding of core A_1 alone. The transformed current is taken up from the brushes b b'.

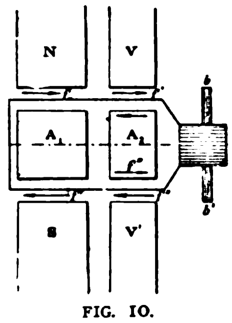

FIG. 10.

SOME RECENT ELECTRICAL PATENTS

Quick-Acting Magnet.—In order to decrease the time element of an electromagnet and make it respond and release promptly, Willis D. Gregory, of Pittsburg, Pa., has devised the type of construction illustrated by Figs. 1 and 2. In Fig. 1 the core of the magnet is cut nearly through at two points, 4, and in Fig. 2 it is shown cut entirely across. These constructions, of course, merely have the effect of dividing the magnet core into several very short lengths; it is well known that a relatively short core will change its magnetic condition more readily than a long one, and the inventor uses several short cores magnetically in series instead of one longer one. The avowed purpose for which this magnet is to be used is to operate the disc of a telephone receiver, but it is not apparent that the soft-iron cores of the ordinary receiver can be shortened enough to make any difference in their responsiveness. It would appear that laminating them, as a transformer core is laminated, would produce the desired improvement quite as well as, if not better than, the method proposed in the patent. Patent No. 753,879.

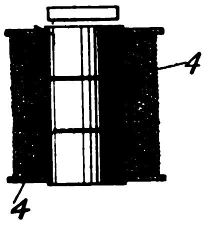

FIG. 1.

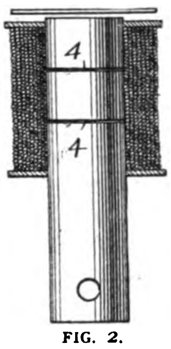

FIG. 2.

Anti-Sparking Dynamo Winding.—It is well known that the field distortion due to armature reaction in a direct-current dynamo or motor, and the sparking at the brushes which usually results if the brushes are not shifted as the load varies, may be corrected by providing a stationary winding so located with relation to the armature that its ampere-turns neutralize those of the armature winding. Such windings have been devised by Fischer-Hinnen, Thomson, Ryan and others, in different forms, but all of the same general character. The latest form of winding for the purpose mentioned is illustrated diagrammatically by Fig. 3, which is taken from a patent granted to Prof. Dugald C. Jackson, of Madison, Wis. It consists of a winding which is practically a counterpart of the armature winding and is located in slots cut axially across the pole-faces and non-magnetic bridges between adjacent poles. This winding is in series with the armature, so that the current in it varies exactly as the armature current and its ampere-turns are always equal to those of the armature. The current traverses the compensating winding in the opposite direction, of course, to that in which it traverses the armature winding, so that the reactive effect of the latter upon the field in the air-gap is neutralized. The arrangement has the obvious advantage that no special form of field magnet or main field winding is necessary; the pole-pieces and interpolar bridges are special, but these constitute a very small proportion of the total structure. It has the disadvantage that two complete armature windings are required, the compensating winding being substantially a duplicate of the armature winding. In view of the

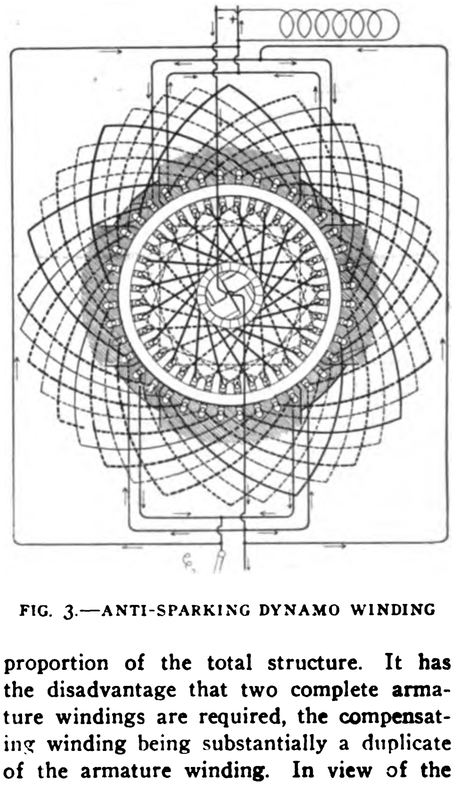

FIG. 3.—ANTI-SPARKING DYNAMO WINDING

well-known "state of the art" it is a mystery how Prof. Jackson succeeded in obtaining a patent for this winding; it is a perfectly obvious arrangement to anyone versed in the subject. Patent No. 743,082.

Three-Wire Balancer.—Motor balancers for preserving equality of potential on both sides of the neutral wire of a three-wire system are too familiar to require explanatory discussion. It is also a matter of common knowledge that the ordinary motor-balancer will not compensate for the increased drop in the "heavy" side of the system when it becomes unbalanced; so that considerable unbalancing of the load produces an objectionable degree of voltage unbalancing. This is also true of the now familiar balancing coil used with direct-current dynamos and of the transformer windings of a rotary converter outfit when the neutral wire of the direct-current distribution mains is connected to the transformer neutral. In order to obviate this disadvantage, Mr. Chas. P. Steinmetz proposes to use a series-wound booster inserted in the neutral wire of the direct-current system and driven by any suitable means, such as a constant speed motor. By properly connecting the field winding of the booster with relation to its armature, it is obvious that the machine can be adjusted to compensate automatically for variations of potential at the distribution center due to unbalancing of the load in either direction. Such an arrangement is shown diagrammatically in Fig. 4 in connection with a rotary converter system. The neutral wire, *s*, of the direct-current system is connected through the booster dynamo *E* to the neutral point of the transformer secondaries, which are connected up Y-fashion for that purpose. The detail at the right of the drawing shows an alternative arrangement of the booster, which is here connected with only its armature in series with the neutral tap and its field excited from the main wires of the direct-current system. The method involved is applicable to the so-called three-wire dynamo and compensating coil, as well as to a rotary converter system. Patent No. 745,460.

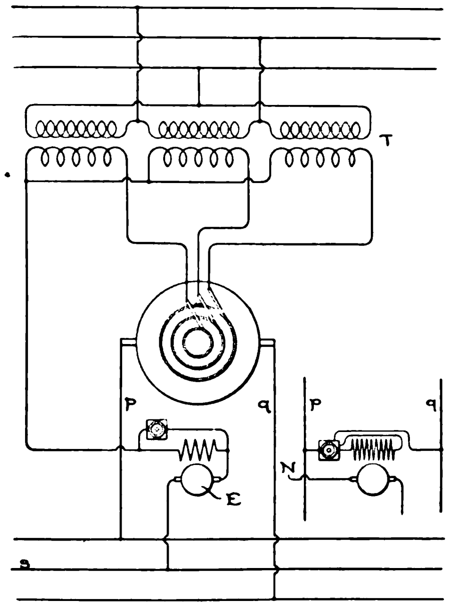

FIG. 4.—THREE-WIRE BALANCER.

NOTES.

The Ohio Electric Light Association will hold its next convention at Sandusky, August 16, 17 and 18, this year. Several papers of an unusually valuable character are promised.

Summer Schools for Artisans.—The third session of the excellent summer school for artisans, established by the University of Wisconsin, will open on June 27th this year. The school has proved of immense value to practical workers who cannot arrange for winter studies. Information may be obtained from F. E. Turneaure, Dean of the College of Engineering of the University.

A Warning.— The General Electric Company requests us to state that some one passing under the name of George E. McCants has been representing himself throughout Texas as the "chief electrician" or some other important official of that company, and that no such person is in the employ of the company. It is scarcely necessary to state that no one of the name mentioned was ever chief electrician of the General Electric Company.

More Factors in the Steam Turbine Field.—The Hooven-Owens-Rentschler Company, Hamilton, Ohio, has arranged to enter strongly into the steam turbine field. A 1500-kw. turbine has already been built and at last reports was about ready for test at the works; this will be exhibited at the St. Louis Exposition. It is also reported that the Warren Electric Manufacturing Company, Sandusky, Ohio, has perfected a line of steam turbines and is now entering orders for turbine-alternator units in outputs of 150 to 750 kilowatts.

The International Association of Municipal Electricians.—At a meeting of the executive committee of this association, held at Brooklyn, N. Y., April 2, the following papers were selected and assigned to be read at the ninth annual convention to be held at St. Louis, September 13 and 14, 1904: "Street Lighting; the Principles Involved and Systems Used," by A. S. Hatch, of Detroit, Mich.; "The Limitation of the Telephone for Fire Alarm Purposes," by Adam Bosch, of Newark, N. J.; "The Inspection of Theatres from an Electrical Standpoint," by William H. Thompson, of Richmond, Va., and "Methods of Testing," by Walter M. Petty, of Rutherford, N. J.

Electric Traction Tests on Swedish Railways.—Electric traction is to be tested on two experimental tracks each 8 km. in length, starting from Stockholm, it being contemplated in a near future to equip the whole of the Swedish state railways. Mr. Dahlander, acting as expert to the commission appointed for the purpose, advocates single-phase alternating current, which, apart from its well-known technical advantages, seems to be specially suitable in this case because of the great distances and relatively small traffic. The power is to be derived from the abundant stores of water power the country possesses, but for the experimental service now being installed, a provisional steam central station has been provided at Tomteboda.

Conventions at the Exposition.—The following societies have all promised to hold conventions at St. Louis during the International Electrical Congress week, and to hold conventions with one or more sections of the Congress: The American Institute of Electrical Engineers, The American Physical Society, The American Electro-Chemical Society, The American Electro-Therapeutic Association and The International Association of Municipal Electricians. The British Institution of Electrical Engineers has also arranged to cooperate under some plan, the details of which have not yet been determined. The Société Internationale des Électriciens, The National Electric Light Association and The Association of Edison Illuminating Companies have promised to cooperate by sending delegates.

To Regulate Electric Wiring.—A bill introduced into Congress some time ago for the regulation of electrical wiring in the District of Columbia, has passed the Senate and is now in the hands of the Committee of the District of Columbia on the House side. This bill makes it unlawful for any person to act as an electrical wiring contractor or to engage in electrical construction or installation, who has not been licensed or is not working under the supervision of some person so licensed. A further provision is to the effect that any person who shall knowingly employ an electrical contractor who has not been regularly licensed would be subject to punishment by a fine of not less than $5 nor more than $100, and in default of payment shall be confined in the workhouse for a period not exceeding six months. Any persons engaged in the business without a license shall be subject to a fine of not less than $5 for each and every offense, or by imprisonment not exceeding one month.

More Technical Light from the Daily Press.—A California newspaper enlightens a waiting world as follows:—

"In support of the statement that the solid globe and its atmosphere rotate in a direction opposite to that of the electric current I cite the case of an electric car. The dynamo in the new power house at Saratoga generates force, which is evidently derived from the inexhaustible reservoir stored in the earth and its air. From the dynamo the current passes eastward along the copper conductor and thence through the trolley to the car motor. When it reaches the bonded rails it at once changes its direction, the rails being in a negative condition. The iron is incapable of becoming permanently electric, as copper wires are when they are termed 'live wires,' but the copper bonds serve to establish a circuit, over which the current is attracted, after the car passes each of them, actually causing the car to move eastward while it passes westward. All the rails when thus united enable the negative tracks in front of the driving wheels to attract and pull the carriage in a direction opposite to the current's course."

A Novel Coherer.—Mr. C. Schniewindt, of Neuenrade, Germany, has devised a new wireless telegraph coherer which consists of a fine wire gauze made from a highly conductive metal, the wires of this tissue being cut through so that the wires, instead of running continuously from one end to the other, are cut into a number of short lengths. One type of apparatus includes a round piece of short wire gauze, separated by a spiral cut into a number of turns, the wires of which form by their terminals the edge of the windings. The spiral form, however, is by no means necessary, the cut being as well made in a serpentine or zig-zag line or even in a straight line, and the bands being connected alternately at one end or the other, as the cut does not run throughout the gauze. By dividing the wire lengths into various short sections, the resistance with respect to the electric current is made infinite. When the electric waves used in wireless telegraphy impinge on a piece of wire gauze thus prepared, the short wire pieces, being in contact with one another. cohere in a way similar to the metallic powder in the coherers so far used. By striking or jarring the coherer, the points of contact may be made to decohere.

Single-Phase Current for Standard Gauge Swiss Railways.—The use of single-phase current for standard gauge railways is being considered in Switzerland, where the Maschinenfabrik Oerlikon some time ago erected a standard-gauge experimental track 700 meters in length with a view to testing the practicability of their own traction system for electric railways, using high tension single-phase current in connection with a distinctive construction of the working wire as well as of the collectors. The collectors consist of bars having a convex curvature with respect to the trolley wire, and capable of rotating in bearings fixed to the car, only in a plane perpendicular to the direction of running, while being pressed against the trolley wire by some outside force. This arrangement allows of readily dealing with any ramification in the trolley wire and of giving the latter any possible position within the arcs of a circle drawn round the rotating point of the collector as centre, with a small and great radius corresponding to the straight lines connecting the centre to the lowest and farthest admissible contact points respectively of the collector and the wire. In order to improve the contact, the collector is developed to a surface. The experimental track is to be enlarged shortly.

The Use of Magnets in Connection with Cranes.—The danger arising from careless handling has been a material drawback to the adoption of magnetic hoisting devices. In the case of a magnet being used alone, there is the risk of the current being interrupted from some cause during the lifting and conveying of the material, and the men in charge of the crane being seriously endangered by the material falling. An ingenious device has recently been patented by the crane-building firm of Ludwig Stuckenholz, Wetter & Ruhr. Such magnets as are to be used, for instance, in transporting rails, tubes, etc., are combined with two pairs of grips or bows closing beneath the magnet. The working of the apparatus is as follows:

The magnets, being, as a rule, traversed by no current, are dropped on the objects to be transported and then excited by applying the current. Simultaneously with the lowering of the magnets the above mentioned tongs or grips will open automatically. After the magnet has lifted the material to be transported, the tongs close automatically, when the magnet may be switched off, leaving the tongs to transmit the lifted goods. This results, on one hand, in a saving of current, and on the other hand in enabling a transport to be made even above the heads of men working underneath without any danger to the men.

Producer Gas Plant Using Brown Coal Briquette Fuel.—An electricity works comprising a 100-horse-power producer gas plant and dynamo recently installed in Hoyerswerda, Germany, appears to be the first central station where the producer gas plant is operated with brown coal briquettes as fuel. The gas engine is identical with those used in connection with lighting and anthracite generator gas, and the producer plant is also quite similar to the usual arrangement, consisting of the generator proper, the dust collectors, the scrubber and the saw dust cleaner. Since the use of brown coal briquettes was adopted (in October last) it has been carried on continuously with most successful results and without any disturbances, the plant working about 14 hours daily; no reserve equipment has been provided until now. Another gas engine of the same output has been installed. Tests made sometime ago showed the cylinder to be free from impurities from tar or paraffine. The brown coal briquettes used were composed as follows:

Carbon	48.32	per cent
Hydrogen	3.35	"
Oxygen and nitrogen	26.54	"
Sulphur	1.09	"
Ashes	5.00	"
Moisture	15.70	"
Total	100.00	per cent

The calorific value is 4853 heat units [calories?] per kilogram (2.2 lbs.). A rough experiment intended for ascertaining the consumption of fuel was made for a period of 10 hours, the briquettes being unloaded from weighed buckets and the output being read on the ampere and voltmeter. This test showed a fuel consumption of 0.65 kilogram per horse-power-hour.

Operating gas generators with brown coal briquettes as fuel proves in many respects more convenient than using anthracite coal. The gas generator is never obstructed by slag, and after the normal intervals of idleness it may be started again without any blowing-in; the door leading to the ashpit may be opened during operation so as to clean the grate, which on account of the absence of any slag is relatively easy.

Incandescent Lamp Combination.—A series of meetings were held recently by the various incandescent lamp manufacturers of this country for the purpose of discussing prices, sales policies, the patent situation, etc. The last-named subject appears to have been the chief topic; the situation had begun to assume complex characteristics, but was cleared up by the licensing of most of the "independent" manufacturers by the General Electric Company and the old Edison Electric Light Company, owners of several important patents relating to manufacturing processes. The manufacturers who have been licensed are as follows: Downward Light Electric Company, New York; the Sterling Electrical Manufacturing Company, Warren, Ohio; the Brilliant Electric Company, Cleveland, Ohio; the Banner Electric Company, Warren, Ohio; the Franklin Electric Manufacturing Company, Hartford, Conn.; the United States Incandescent Lamp Company, St. Louis, Mo.; the Standard Electrical Manufacturing Company, Niles, Ohio; Capital Electric Company, Denver, Colo.; Gilmore Electric Company, Boston, Mass.; Liberty Electric Company, Pittsburg, Pa.; Warren Electric and Specialty Company, Warren, Ohio; the Colonial Electric Company, Ravenna, Ohio; Monarch Electric Manufacturing Company, Warren, Ohio; Shelby Electric Company, Shelby, Ohio; Bryan-Marsh Company, Marlboro, Mass.; the Buckeye Electric Company, Cleveland, Ohio; Munder Electric Company, Springfield, Mass.; Sunbeam Incandescent Lamp Company, Chicago, Ill.; Columbia Incandescent Lamp Company, St. Louis, Mo.; Independent Incandescent Lamp Company, Cleveland, Ohio; New York and Ohio Company, Warren, Ohio; Fostoria Incandescent Lamp Company, Fostoria, Ohio; General Incandescent Lamp Company, Cleveland, Ohio; National Electric Lamp Company, Cleveland, Ohio.

It will be noted that the Sawyer-Man Electric Company is not in the combination and that company has already issued a statement to the public to that effect. Four other concerns are not included, although it is intimated that some of them may still come in. It is claimed that over 99 per cent. of the lamp production of the country is represented by the capacity of the "pool" licensees. The present annual consumption of lamps is put at 45,000,000. The total productive capacity of the existing factories is placed at about 65,000,000.

ESTABLISHED 1889.

American Electrician

A Journal of Practical Electrical and Steam Engineering.
WITH WHICH IS INCORPORATED
Electrical Industries.

CECIL P. POOLE, Editor.

Published on the first of each month by the
McGraw Publishing Company,

Central Station News.

In this issue we add a new department which we hope will meet with the appreciation of AMERICAN ELECTRICIAN readers. In this we shall endeavor to present all available information regarding current developments in both commercial and municipal central stations throughout the United States, Canada and Mexico, and our readers are cordially invited to contribute to the department any items of news relating to plants in their vicinity. So far as we know, no systematic effort has heretofore been made to record all of the many changes in plant equipment, policy and officials which occur from time to time, and it is the object of the new department to supply this important deficiency. Aside from its news function, this feature of the paper will, we believe, serve an excellent purpose in indicating the general trend of central station development.

◆◆◆

The Municipal Plant Question.

It has several times occurred that shortly after the publication, in this or some other journal, of a report showing favorable conditions in a municipal electric lighting plant we have received communications from readers in which the favorable report was quoted as a refutation of what our correspondents were pleased to call our "prejudiced utterances" against municipal ownership. We were unusually favored in this respect recently as a result of the commendatory remarks published in our Notes last month concerning the municipal plant at South Norwalk, Conn., and are thereby incited to state that we have no prejudices whatever on any subject; we have very clearly defined convictions on many subjects, and one of these is the municipal ownership of public utilities.

That a municipal electric light and power plant can be operated at the same cost as a commercial plant operated under identical conditions is a self-evident proposition, and one which we have never attempted to controvert. The whole question hinges on the practicability of establishing the same conditions for the operation of a municipal plant that characterize the operation of a privately owned plant. We have always maintained that *if* politics could be kept out of the control of the plant, a municipal plant could be operated just as any other one is, and with equally satisfactory results; the report of the South Norwalk plant merely vindicates this argument. The superintendent of that plant is allowed to operate it according to his notions of expediency and not according to the bidding of peanut politicians with massive axes to grind and knives up their sleeves already well-ground; consequently it is a success. This state of affairs, however, is about as common in municipal plants as Miss Helen Gould's brand of philanthropy is among millionaires.

Even when the conduct of a municipal plant is not affected by politics, there is a strong temptation for the active management of the establishment to "soldier," on the assumption that the question of profits is not nearly so important as in a commercial plant and that the city "can afford to pay for it" when the balance sheet does not show up as comfortably as it might. This attitude is quickly recognized by the subordinate employees, and the general tone of the work throughout the plant is lowered accordingly. This has been the case in several municipal plants we could mention, where political influences were not applied to the lighting department to an appreciable extent. Hence our contention that the successful operation of a municipal electric light station is, as a general rule, far less probable than that of a commercial plant in the same city. The municipal ownership of public utilities would not be detrimental in the slightest degree to the electrical industry if the plants were conducted on strictly business principles; only the capitalists would be affected, and there are numerous avenues of investment for them. As we have always remarked, however, the "if" is a huge one.

◆◆◆

Specialization.

It is generally recognized now that the fullest measure of success in any avenue of endeavor is to be obtained by specializing—making a thorough study of one class of work and pursuing that exclusively. It has been argued that the huge department stores and gigantic industrial establishments such as the General Electric and Westinghouse Companies are such colossal exceptions to the rule as to vitiate it entirely. The magnificent achievements of Helmholtz and Kelvin are also frequently cited as nullifying the rule. None of these examples, however, is in the least opposed to the maxim stated above. The department stores and industrial organizations are merely aggregations of specialists without whom (or others like them) the whole structure would be a dismal failure. The benefits of specialization are shared by those whose talent for organization enables them to make the best use of the efforts of those whom they aggregate; they themselves are specialists in this very direction. It requires no argument to show that the specialists grouped together in such organizations as those mentioned enjoy an immensely greater success than would be possible if they attempted general instead of special activity. Helmholtz, Kelvin and the few others of their standing are shining exceptions; if all of us had the mental equipment with which those men were blessed industries would suffer for the lack of "rank and file."

It should be remembered that specialization does not consist of knowing one thing perfectly and being an ignoramus on all other subjects. Broadness is as essential to the perfection of success as thoroughness in some one direction; but there is a wide difference between broadness of mental cultivation and a smattering of general knowledge which leads nowhere. The young man who determines to specialize should also determine to learn just as much about everything else besides his chosen occupation as time and opportunity will allow him to acquire; but he should avoid wasting time with the unimportant details of other lines of thought. The very best fireman (in a power plant) that we have ever seen had a fairly good grasp of social economy and a startling familiarity with Roman mythology. Of course, neither was in the least essential to a knowledge of fuel combustion and the evaporation of water in a boiler, but the man's mental development enabled him to consider his work far more intelligently than his fellows could, and to get correspondingly better results.

◆◆◆

Machine Tool Motors.

The application of individual electric motors to machine tools is a problem the solution of which usually upsets the preconceived ideas of the average machine-shop superintendent. The shop which he has operated successfully with a 25-h.p. motor driving all of the tools should not, in his estimation, require any more power for its operation when the tools are individually equipped; in fact, he naturally expects that less power will be required, because of the elimination of shafting and belting, and from these premises he is likely to make seriously erroneous deductions as to the sizes of the individual motors that are to be put in. Consequently, when he is assured by the consulting engineer or manufacturer to whom he has entrusted final responsibility that his motor equipment will aggregate three or four times the amount of horsepower that his old single motor developed, he is likely either to suspect that he is being "worked" or to insist that errors have been made in the calculations. A careful analysis of the matter will, of course, straighten out his misconceptions, if he has the intelligence of the usual shop superintendent.

The principal reason for the larger aggregate rating of the individual motor equipment as compared with a single motor is that each machine tool must be equipped with a motor capable of driving it at its maximum capacity, even though it may not be worked at that capacity more than once in a week; and when the tool is being worked at half its maximum ability, the motor operating at a slow speed may to some other machine, as is the case when several tools are group-driven by one motor. Moreover, under some conditions and with some systems of speed control, the motor can never be operated at its maximum ability. If the regulation is by means of voltage control, for example, a lathe motor operating at a slow speed may receive minimum voltage and maximum current; when at the highest speed, it will receive maximum voltage but the current will not be anywhere near the maximum, as a rule. Consequently, the machine never receives maximum e.m.f. and maximum current simultaneously, and is therefore never worked at its full capacity. With speed regulation by means of variable field excitation this particular disadvantage is, of course, not encountered. Everything considered, it is an extremely nice problem to determine the distribution of motors and the type of speed control best suited to machine-shop conditions. Each case must usually be treated as a special one.

◆◆◆

Our "How-to-Make" Articles.

Immediately following the editorial pages in every number of the AMERICAN ELECTRICIAN is published an article in which instructions are given in very full detail for the construction of some piece of electrical or mechanical apparatus; in this number, the subject is a three-phase synchronism indicator. Within a few days after each issue of the paper has been mailed we begin to receive requests for information as to how the apparatus described in the number just issued can be modified to fit some special conditions for which it was not designed. If it were at all practicable, we would be only too glad to grant all such requests, but we are compelled to refuse them either because the changes desired are absolutely impossible or because the apparatus was not designed in this office and we are therefore unfamiliar with the basis of its design and cannot afford the time necessary to "work backward" to it and obtain the necessary data for redesigning the apparatus, even if we could spare the time to re-design it for the new conditions.

◆◆◆

The Source of Current for Arc Lamp Circuits.

It is of considerable interest to note that notwithstanding the strong tide of enthusiasm which the many advantageous features of series alternating current arc lighting aroused when its practicability had been thoroughly demonstrated, the old direct-current system of series circuits supplied by constant-current dynamos continues to be manufactured and installed. Open arc lamps are not now used to anything like the same extent as before the advent of the enclosed arc, but the alternating-current system has by no means rendered the direct-current system obsolete. There are several facts and combinations of facts which very probably account for this. In the first place, the direct-current apparatus is simpler and more easily understood and maintained by those in charge of the smaller (and more numerous) central stations than the alternating-current apparatus. A constant-current Brush or Wood dynamo can be handled by anyone who has a little common sense and is at all familiar with electrical machinery, whereas most constant-current transformers and automatic reactance coils have more delicate organisms and, although perfectly simple in construction, are regarded by the uninitiated with some awe.

A more substantial argument in favor of direct-current arcs, however, is that for central stations of moderate size it is much safer to have the constant-potential and the arc-lighting circuits and supply sources distinct; a break-down of one system will then not affect the other. With the arc lighting circuits supplied through transformers or reactance coils from the same generator that supplies the constant-potential circuits, both branches of the service would, of course, be crippled by the failure of a machine, and unless the plant were of sufficient size to justify a reserve unit equal in output capacity to any of the active units, such a breakdown would be most serious. In stations of considerable size, the advantages accruing from the supply of all circuits from a common type of generator, if not from a single primary set of bus-bars, are so plainly obvious as to require no discussion and so great as to subordinate all such questions as circuit power factor, inductive drop and the like. There is the chief field for alternating-current arcs.

CONSTRUCTION OF A THREE-PHASE SYNCHRONIZER.

BY PAUL C. PERCY.

A most useful synchronism indicator may be produced by properly combining two small transformers, three incandescent lamps and a set of connecting plugs and sockets of the type commonly used for connecting up synchronizing lamps. One of the transformers must be three-phase (if the system is three-phase) and the other single-phase. Such an outfit is described in detail herein, and may be constructed with extremely limited facilities in the way of machinery and tools; the greatest care must be exercised, however, in applying and maintaining the insulation of the transformers.

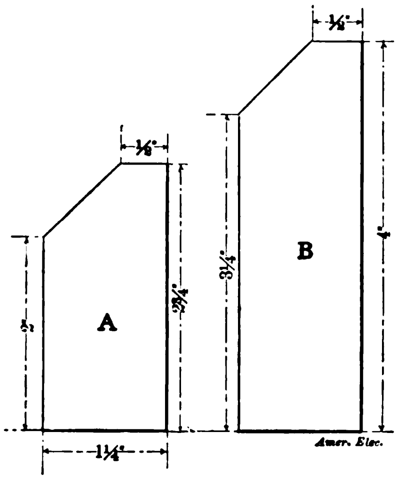

FIG. I.

The single-phase transformer is built up of rectangular strips of sheet steel each having one corner cut off, as indicated in Fig. 1; there must be two sizes of these strips, as the engraving shows, and of the dimensions specified in the sketch. The thickness of the sheet steel may be 25 mils; this would be too thick for ordinary transformer work, but as these transformers are in circuit only a very short time the increased core loss due to the thick sheets is of no importance. There will be required 80 strips of each size shown by Fig. 1, and these are to be built up to form a core of the shape and dimensions shown in Fig. 2. The core is 40 sheets thick and these 40 sheets should compress to about 1 3-16 inches, as indicated by the dimension stated on the edge view of the core.

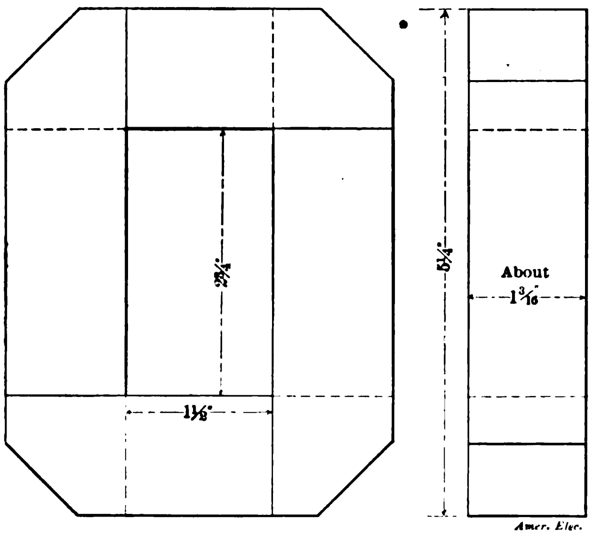

FIG. 2.—COMPLETE CORE OF SINGLE-PHASE TRANSFORMER.

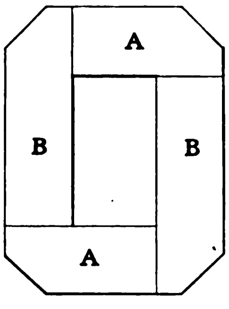

FIG. 3.

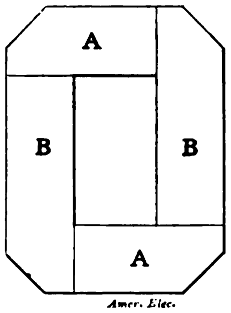

FIG. 4.

The strips must be staggered, so as to break joints, the first layer being put down as shown by Fig. 3, the second layer as shown by Fig. 4, the third layer like the first, and so on.

Before the core can be built up, the coils must be wound, taped and baked. The coils are wound in fibre bobbins, the heads of which are made of 1/8-inch hard fibre of the shape and size shown by Fig. 5. Two of these heads are fastened to the tube of the bobbin, one at each end, by means of thick shellac varnish. The tube consists of a sheet of 1/16-inch fibre 2 3/4 inches wide and 5 1/4 inches long, bent into tubular form so as to fit in the square openings in the heads. The bobbin must be mounted on a square wooden mandrel and the heads backed up by blocks tacked on the sides of the mandrel, so that the wire will not press the heads off the ends of the tube.

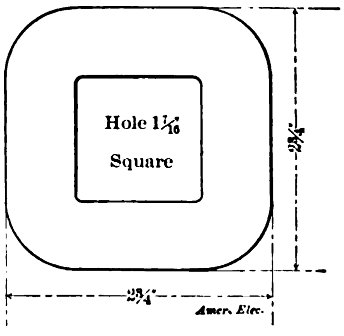

FIG. 5.

The secondary coil is wound on the bobbin first. It consists of 3 layers of No. 20 double-cotton-covered magnet wire in each bobbin (there are two, one on each leg of the core) with 60 turns in each layer: 180 turns in each coil. After winding this coil, it must be covered with six layers of oiled linen 0.01 inch thick, wrapped in one continuous strip the full width of the bobbin between heads (2 1/2 inches). Then four pieces of hard fibre 1-16 inch thick and of the shape and size shown by Fig. 6 must be glued to the inner face of each head so that when the primary wire is wound on top of the secondary the wires cannot pull down between the head and the edges of the oiled linen.

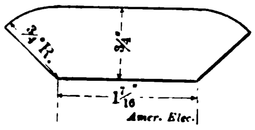

FIG. 6.

The primary winding in each bobbin consists of 8260 turns of No. 36 double-silk-covered wire, the silk covering being 2 mils thick; that is to say, the diameter of the wire measured over the insulation is 4 mils greater than the bare diameter. After winding on the first four layers of the primary, these should be covered with a thickness of the 0.01-in. oiled linen; a layer of this should be put in on top of each four layers of wire throughout the winding; six strips will therefore be required for this purpose. The outside of the complete coil should be covered with six layers of oiled linen and a protecting layer or two of heavy duck, the outer layer of this being heavily varnished. The two primary coils are to be connected in series so that if direct current were passed through them they would both magnetize the core in the same direction as to the complete magnetic circuit. The two secondary coils are also connected in series, and in agreement with each other.

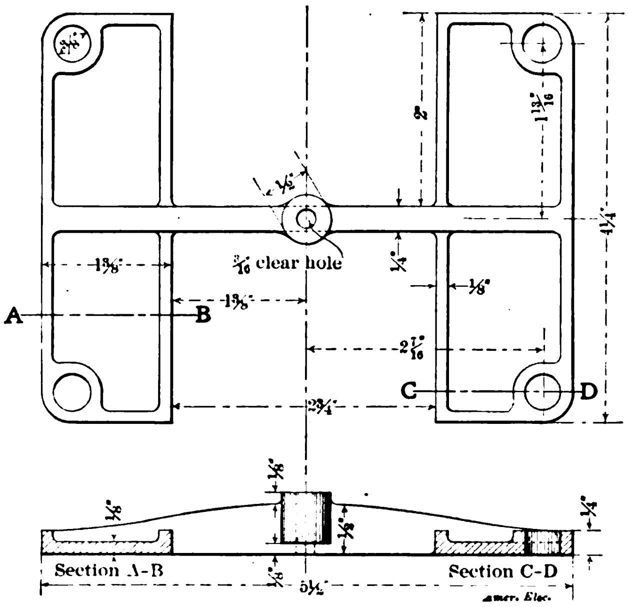

FIG. 7.—CLAMPING PLATE; SINGLE-PHASE TRANSFORMER.

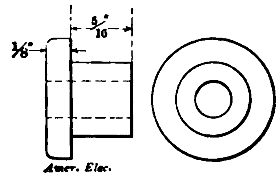
After the core-plates are assembled, with the coils in place, of course, they are to be clamped tightly together by means of two brass plates of the shape and dimensions shown by Fig. 7, and five steel rods 3-16 inch in diameter, threaded at both ends; the clamping plates are to be drawn together by means of nuts on the ends of the rods. The plates must be insulated from the core by means of hard fibre facings 1-16 inch thick, the full size of the plate outlines. The rods in the four corner holes are insulated from the clamping plates by means of fibre bushings, one of which is shown in Fig. 8; the central bolt need not be insulated.

The three-phase transformer core is made up of sheet steel strips of four sizes; the shapes and dimensions of these are given in Fig. 9. The complete core, without the coils, is shown in Fig. 10; it is built up in somewhat the same manner as the core of the single-phase transformer. The first layer is put down as shown in Fig. 11, the second layer as in Fig. 12, the third layer like the first, and so on. The complete core must be 40 sheets thick.



Head ⅝" diam.
Sleeve ⅜" "
Hole 3/16" "

FIG. 8.—TIE-ROD INSULATOR.

This transformer has three sets of coils, and therefore three fibre bobbins. The bobbin heads are ⅛ inch thick, as in the previous case, but of the size indicated in Fig. 13. The bobbin tube is made and the bobbin mounted in the same way as previously described. The secondary coil on each leg consists of 360 turns of No. 20 double-cotton-covered wire, wound in three layers. This winding must be covered with six layers of 0.01-inch oiled linen, as before, and the four cheek pieces glued to the inner face of each bobbin. The primary winding comprises 11,790 turns of No. 34 double-silk-covered wire, with a layer of 0.01-inch oiled linen inserted after each *third* layer of wire, and the whole wrapped like the single-phase coil.

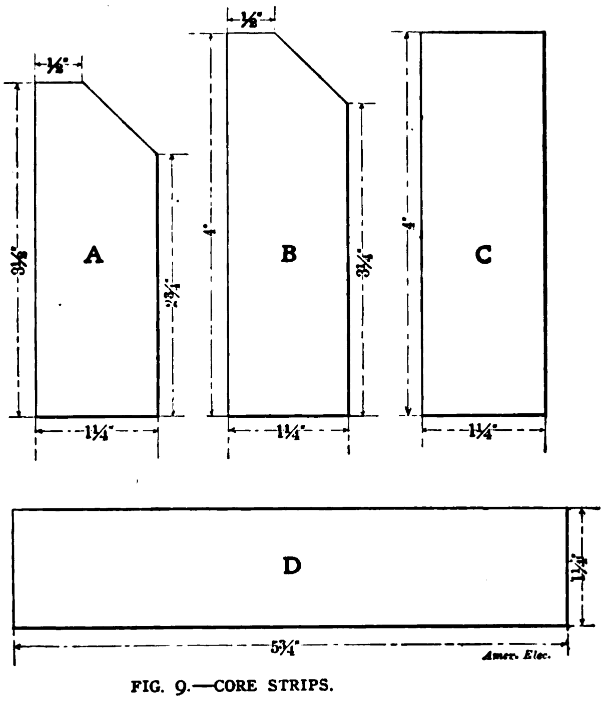


FIG. 9.—CORE STRIPS.

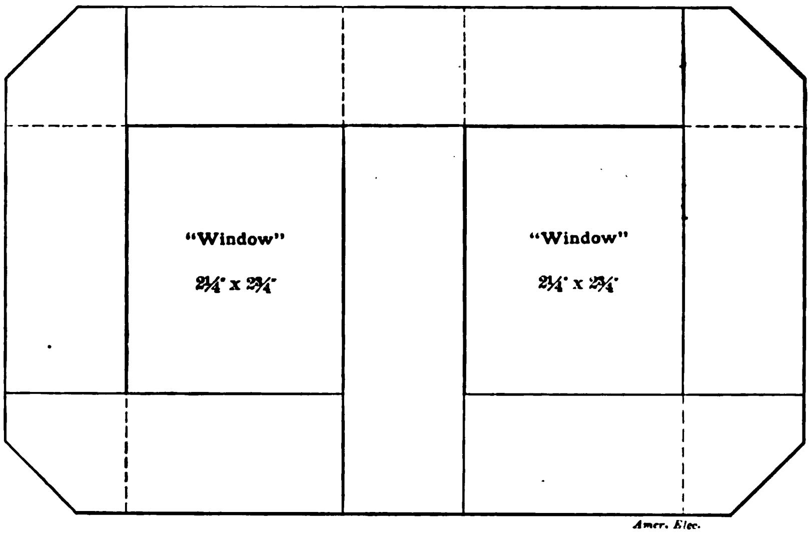

FIG. 10.—THREE-PHASE TRANSFORMER CORE.

The core sheets are pressed together by means of two brass clamping plates of the shape and dimensions shown by Fig. 14, six ¼-inch steel rods and two strips of ⅜-inch fibre carrying a metal strap at each end which is tapped to receive a 3-16 inch cap screw. Fig. 15 shows one of these strips; they go between adjacent coils, and the cap screws pass through the 3-16 inch holes in the clamping plates.

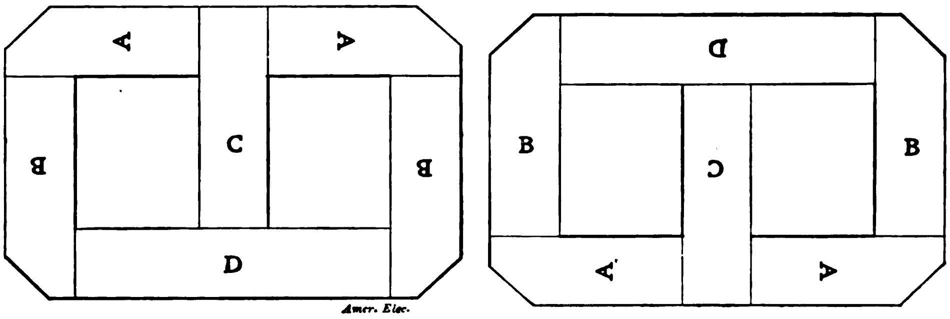

FIG. 11.—ASSEMBLY OF THREE-PHASE CORE STRIPS.—FIG. 12.

The connections of the outfit are shown by Fig. 17. The primary winding of the single-phase transformer is connected to "Phase A" of the bus-bar through a double-pole switch; one terminal of the secondary is connected to the neutral point of the lamp circuit, which is Y-connected, and the other terminal is connected to one terminal of all three of the secondary windings on the three-phase transformer, which are also Y-connected. The free terminals of the three-phase secondaries are connected to the free terminals of the three lamps.

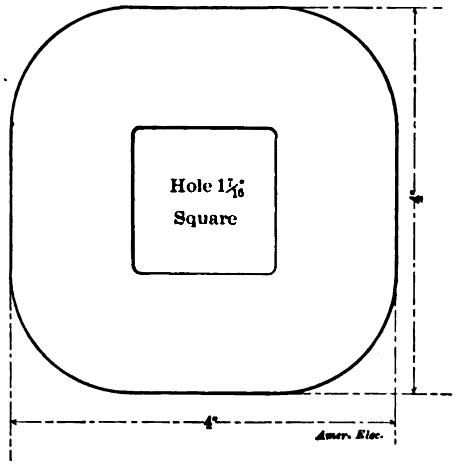

FIG. 13.

The primary windings are connected Y-fashioned, and the three terminals are plugged to the switch of the generator which is being thrown in.

If the connections are properly made with respect to the phase relations of the various coils, the lamps will glow in succession as the phases of the incoming generator agree successively with phase A of the system; this will give the effect of a revolving light, the speed of which will be proportional to the difference between the speed of the incoming generator and that of the machines already in circuit, and the direction clock-wise. As the incom-

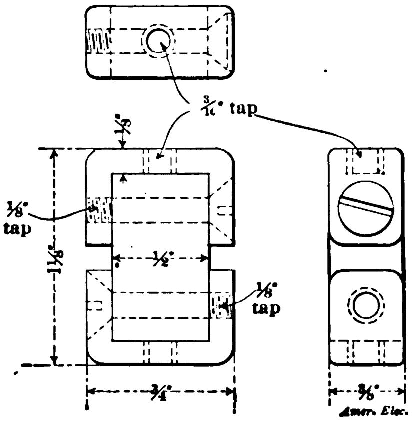

FIG. 15.

ing generator approaches synchronism, the speed of the "revolving light" will decrease, and when exact synchronism is attained, the top lamp (*a*) of the group will glow steadily and the others will remain dark.

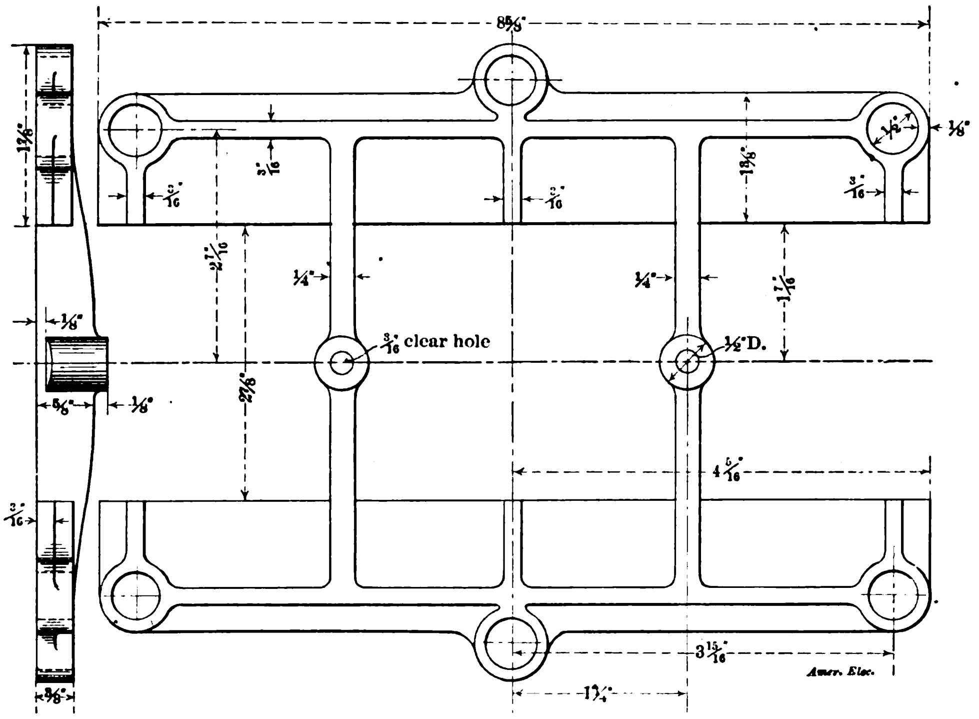

FIG. 14.—CLAMPING PLATE; THREE-PHASE TRANSFORMER.

It should be remembered that the steady glowing of either of the other lamps alone indicates identical speeds at the generators, but not coincidence of phases; if the lamp *b* glow steadily, it indicates that the generators are running at the same speed, but that phase B of the incoming machine is in step with phase A of the system, and the machine must, of course, not be thrown in.

The lamps should be rated at 100 volts and of low efficiency—say 64 watts consumption. The single-phase transformer is designed for a primary e.m.f. of 2300 volts and the three-phase transformer for 1626 volts per coil (2300 volts between free terminals); the secondaries should give 50 volts, but their voltage should be measured and lamps chosen which are of at least twice the voltage of each secondary, and preferably a volt or two higher. It is as well to repeat the warning given in the beginning of this article to the effect that the transformer windings must be most carefully handled and insulated in view of the high primary voltage. It is also essential that the rods which draw the clamping plates together be reliably insulated from the plates and from the core; it will be found a good plan to wrap them with a couple of layers of tape after the core is assembled.

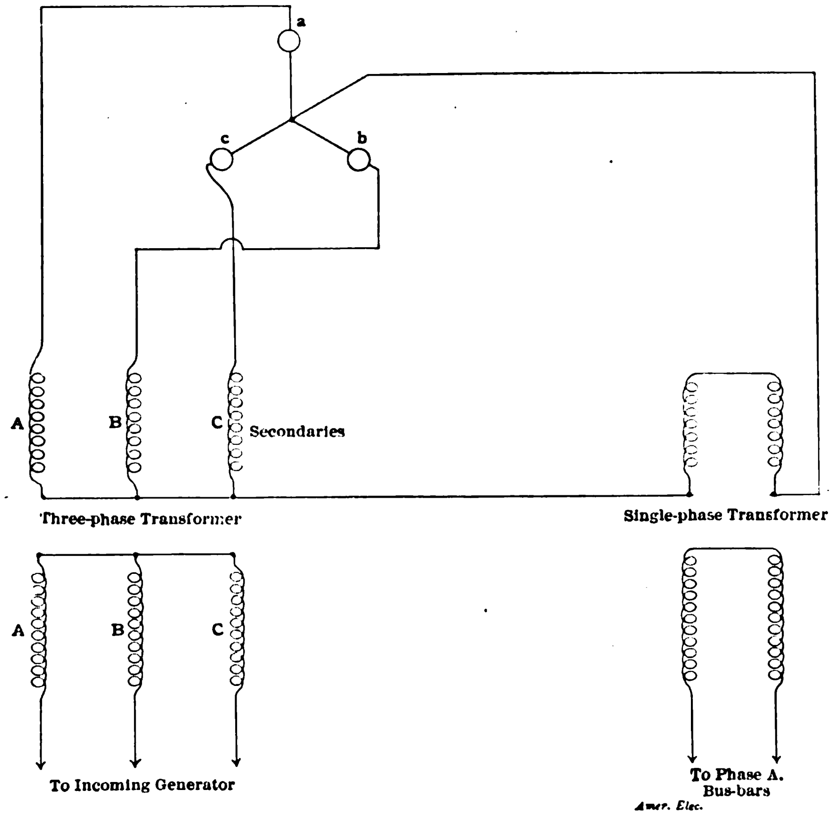

FIG. 17.—DIAGRAM OF CONNECTIONS.

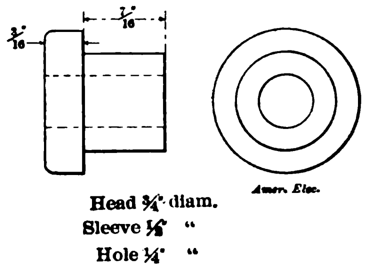

FIG. 16.—TIE-ROD INSULATOR.

PREPARATION FOR THE ERECTION OF AN ENGINE.

BY W. T. EDWARDS.

The principal and most important feature of the installation of a reciprocating engine is the foundation on which it will rest. The size of the foundation and the material of which it is constructed will depend upon varying conditions. The size, aside from the area required to accommodate the bed plate, will depend upon the bearing power of the soil; however, unless the soil is of an extremely low-bearing capacity, an increase over this area will hardly be necessary. In soft, marshy soil it is sometimes necessary to drive piles in order to get a satisfactory foundation, but when such conditions exist it would be wise to have an experienced engineer design and superintend the construction of the foundation.

Undoubtedly, hard pan or gravel is the very best base upon which to start the masonry foundation. Bed rock may be considered excellent, but there is a possibility of vibration being transmitted to the building, or adjoining buildings, which is objectionable, resulting in injury to walls, ceilings, etc., and this is likely to end in strained relations if not law suits between the proprietors of the affected buildings. Moreover, the excessive rigidity resulting from such a non-elastic combination is likely to cause the breakage of anchor bolts. To obviate this trouble, a layer of sand from 4 to 6 inches thick is used between the bed rock and the foundation. This has been very successful. Paper, felt and rubber have also been used for the same purpose with varying success.

The material used in a foundation should be of the best quality obtainable, and the workmanship should equal the material in quality. Concrete at the present time is in high favor for foundations; it is used for the engine foundations in the Manhattan, the Edison Waterside and the Interborough power houses. The ease of erection and the monolithic character it assumes when thoroughly set commends it for the purpose. In the erection of a foundation, concrete has the advantage over almost any other material in that after the forms are built little or no skilled labor is required to construct the foundation. That portion of a concrete foundation which lies below the surface of the ground may be built of rubble concrete; this is the same mixture that is used above the surface of the ground, but it has distributed through it what are called "one man stones," meaning stones that are as large as one man can conveniently carry. These are thoroughly wet before being imbedded and should not be placed nearer each other than 6 inches and not nearer than 4 inches to the surface of the work. The concrete may be made up of 1 part Portland cement, 2 parts clean, sharp sand and 5 parts broken stone or gravel. It is common practice to specify that no piece of stone shall be larger than 2 inches in its largest direction, and that the stones shall be screened, but it is now considered by very good authorities that the broken stone just as it comes from the crusher makes the best concrete, because there are fewer voids.

Using the proportions given, one barrel of cement will do for about two-thirds of a cubic yard of concrete. Concrete should be deposited in layers not more than 9 inches thick and should be thoroughly rammed until a film of water appears over the entire surface. If that portion of the foundation which is above the surface of the earth is to be exposed and it is desired to make it present a more pleasing appearance than it otherwise would, the corners may be neatly rounded by suitable fillets of tin in the angles of the wooden forms. These forms are made of dressed and matched lumber, and should be properly secured to prevent any bulging or twisting due to the pressure of the concrete. One way of securing a smooth finish is to deposit a layer of about 2 inches of cement mortar against the forms, this mortar being placed in position as the work progresses, not added as a plaster when the work is finished. While this material is being placed a workman inserts a tool resembling a spade with a long blade between the concrete and the form and manipulates it in such a fashion as to cause the cement mortar to assume a cream-like consistency against the form. This treatment is given to all surfaces that will eventually be exposed, and produces a surface that will equal some trowelled work. In case any portion of the foundation is light, due to recesses for exhaust or other pipes, corrugated or twisted steel rods may be used to reinforce; these are placed in their proper places while the foundation is being built and the concrete tamped thoroughly around them. There should be no portions detached from the main foundations, such as supports for bearings, as these will prove a source of trouble from unequal settling which will throw the shaft out of alignment. The foundation must be a single mass large enough to accommodate all the parts directly connected together.

In case it is convenient or desirable to have a brick foundation, the bricks should be of uniform texture, hard-burned, free from lime and other impurities; those bricks that are exposed should be of uniform size and have smooth surfaces, straight angles and be free from spalls or other defects. "Salmon" bricks, which are of a light color and soft, should not, under any circumstances, be allowed in any part of the foundation; they disintegrate very quickly. It is essential that the work be done by a skilled bricklayer and that the bricks be laid in a good quality of cement mortar, such as 1 part cement and 2 parts clean, sharp sand.

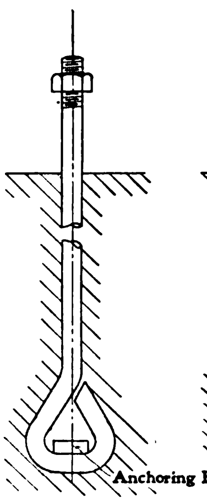

FIG. 1.

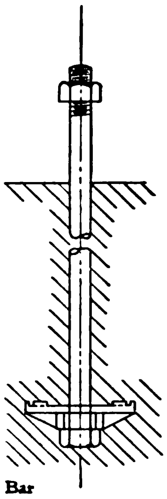

FIG. 2.

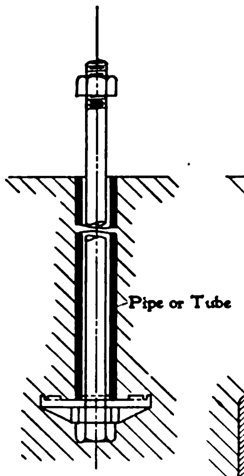

FIG. 3.

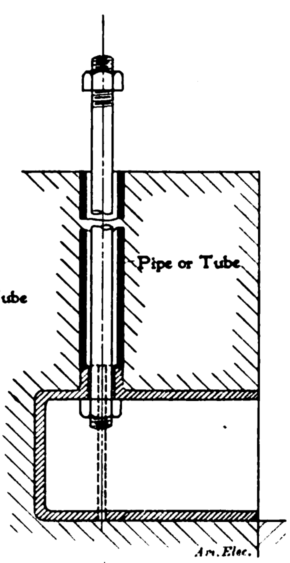

FIG. 4.

Too much care cannot be taken to have the anchor bolts exactly right, for after the foundation is once built it will be almost impossible to readjust the bolts to rectify a mistake. There is a difference of opinion about building the bolts in solidly or placing them in pipes or tubes, so that they may be free to move; however, the best guide is the practice followed on the most important work, and there pipes are used.

There are various ways of anchoring the bolts in position, several of which are shown by Figs. 1 to 4. Fig. 1 shows a stirrup turned on the bolt through which an anchoring bar or rod is passed, the whole being firmly built in the concrete or brickwork, as the case may be. Fig. 2 shows a bolt with a cast-iron washer built in solidly, as in Fig. 1; the bolt may be furnished with a head and nut, or with two nuts, one on each end, as may be more convenient. Fig. 3 shows the bolt passing freely through a pipe from the washer. An arrangement that is sometimes used, though it is a question if it is worth the expense, is shown in Fig. 4; this is a cast-iron box which takes the place of a washer or anchor plate and is made large enough for a man to turn up a nut by hand, reaching in from outside the foundation. In this case the bolts are generally placed in pipes, as such a box is usually put in only where there are likely to be broken bolts. The pipe is held in position on the box by a boss cast concentric with the hole through which the bolt passes. In brick foundations the equivalent of the cast-iron box is obtained by building in "anchor stones," which are about 10 inches thick, over pockets left in the brickwork; the bolts pass through holes drilled in the stones and are secured by means of ordinary nuts and washers.

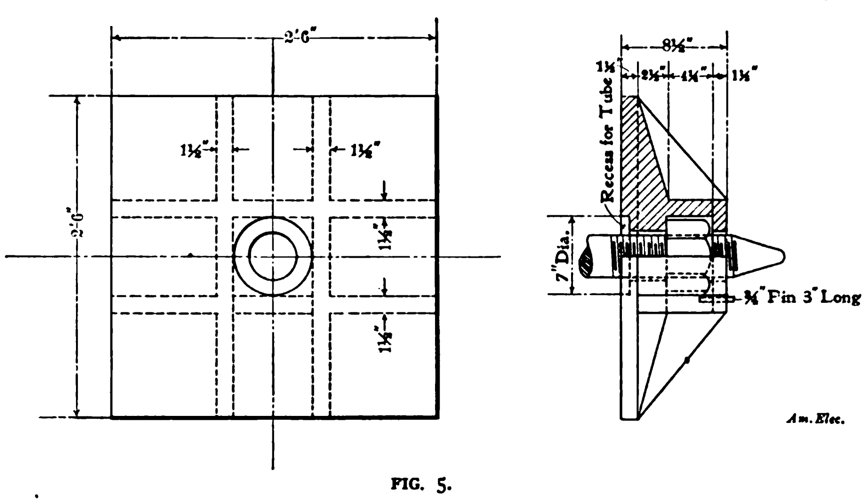

FIG. 5.

Where pipes are used with anchor plates, as in Fig. 3, the pipe is centered by a recess in the upper surface of the plate, concentric with the bolt hole; Fig. 5 shows this construction very clearly. This drawing is the detail of the washers used in the foundations for the engines of a power house in New York City. It will be observed that the nut is held on the under side of the washer in a box which forms part of the casting, and is prevented from falling out by a pin. The nut has a certain amount of freedom in the box, which permits it to adjust itself to the bolt in case there is any irregularity in setting the washers.

A template is indispensable to the correct location of the anchor bolts. It should be accurately laid out to match the bolt holes in the bed plate of the engine. These templates are sometimes furnished by the builders of the engines, but if they are not they should be made of lumber about 1 in. x 4 ins. in cross-section if the bolts are not larger than 1¾ inches in diameter; this will allow for a hole large enough for a 2-in. pipe to be bored in the 4-in. material. The template should be securely braced with diagonal braces to keep it in correct shape. If the engine is on the ground, measurements may be taken directly from the bed plate for making the template, but if not, the template will have to be made from drawings furnished by the builders. In order to avoid possibilities of mistakes, all bolts for any part of the engine should be laid out by one template; if some are at different levels, provision should be made by "stepping" the template to conform to the difference.

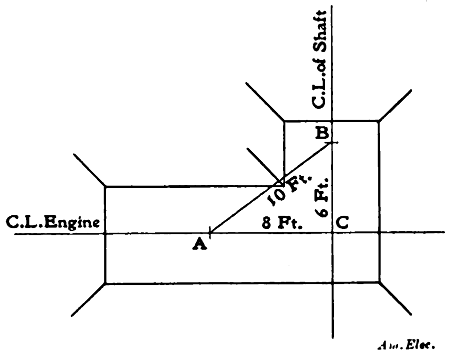

FIG. 6.

It is usually a problem to support the template at the proper height and rigidity, but if the foundation is to be of concrete this becomes quite simple, as it can be supported directly on the foundation forms. When the foundation is to be of brick or stone, scaffolding or horses are used. When the bolts are passed through the anchor plates, thence through the pipes, the top of the template should be placed at a height at which the tops of the bed plate bosses for the bolts will be when the engine is in its proper place. The bolts are given a good full nut and allowed to hang free from the template; sometimes the bolts are held in position at the lower ends, but not always. The pipes may be held concentric with the bolts by means of wedges. When the bolts are built in solid they are hung from the template, as described. If the bolts are not to be put in place until after the engine bed is set, the pipes are held by the template, the top ends of the pipes coming a little under the top of the foundation, and they are preferably plugged to keep foreign matter out. After the engine bed is set, a tap is put down through the pipe and into the nut contained in the anchor plate, so as to clean out the nut for the reception of the bolt.

Too much importance cannot be attached to having a center line from which to work. All work should be done from the center line of the engine and the center line of the shaft, as all the dimensions are laid out from these lines on the drawings. If one has the use of a transit and level and is able to lay out the work with these instruments, or can have the services of someone who can, all will be plain sailing, but if not, the lines may be laid off by means of the triangle method. Measure along the center line that is known to fix the location of the engine, a distance of 8 feet from the point of its intersection with the center line of the shaft; then lay off 6 feet along the line which will represent the center line of the shaft, and move it around until the diagonal from the 8-ft. mark to the 6-ft. mark measures exactly 10 feet; the lines are then perpendicular, to each other, or are 90 deg. apart. Fig. 6 explains it a little more clearly. The center line of the engine bed has been located definitely and it is desired to lay off the center line of the shaft square with, or perpendicular to, this line; lay off from *C*, the intersection of the two lines, 8 feet along the center line of the engine, or to *A*, and 6 feet on the center line of the shaft to the point *B*, and move this line about the center, *C*, until the distance *A—B* measures 10 feet; the lines will then be square with each other.

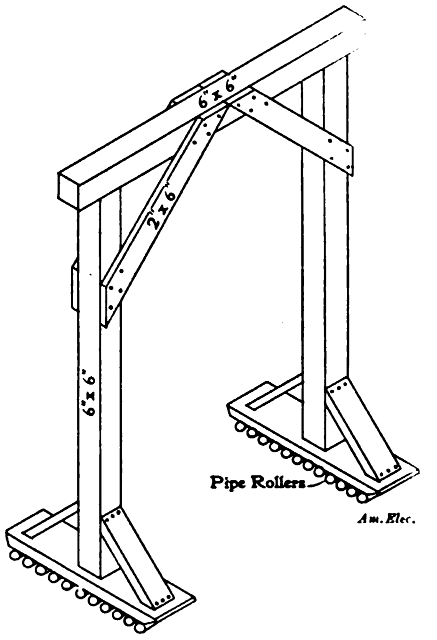

FIG. 7.

The foundation is never brought to the exact height required by the engine; a space varying from ¾ inch to 1½ inches is left for a "joint" either of sulphur, grout or "rust." This practice of having the foundation low gives a chance to level up by means of wedges or screws, or sometimes both. After the engine bed is leveled up, the space between it and the foundation is filled with one of the three named materials; if grout is used it is of neat cement, and as it is difficult to make perfect contact between the bed plate and the foundation in large work, holes are cored in the bottom of the bed plate called "grout holes," through which the grout is poured so that the grout is more completely and uniformly distributed over the surface. If a rust joint is desired, it is made of clean iron chips, which are thoroughly wet with sal amoniac and driven under the bed plate with tamping tools. Sulphur is used only for small work as a rule. When the bed plate is fixed, it is generally filled part full with concrete of the proportions 1 part cement, 2 of sand and 5 of stone; this will prevent the drum-like noise sometimes produced by the large hollow casting. Sand is used for the same purpose and is considered by some to be superior to concrete for the reason that some Portland cements expand on setting, thus exerting strains that have in some cases ruptured the bed plate. Whatever is used for a joint between the bed plate and the foundation, it should be protected from oil as the oil has a deteriorating effect on either concrete or iron joints. No opening should be allowed in the bed plate through which oil could get to the foundation. Sometimes shellac is used to cover the exposed parts of the joint, and this, to a certain extent, protects it from the oil.

It is well to have at least two hydraulic jacks (four are better) and not less than six wooden rollers about 5 inches in diameter; plenty of blocking which ought to vary from ½-in. stuff to 6-in. x 6-in. or 8-in. x 8-in. timbers; pulley blocks and rope of about 4½ inches girth, as well as chain hoists. Everything should be carefully prepared before beginning any work, as time will be saved thereby. A gallows frame may be made as shown by Fig. 7 and used with advantage for erecting the cylinders, shaft, etc. It should be made with a generous base to move on rollers of wrought-iron pipe. If the fly-wheel is solid and it is necessary to force it on the shaft, the clamps shown by Fig. 8 will be found cheap and convenient. The cross pieces may be of oak about 2 inches thick, or of flat iron about 1 inch thick, and if the engine is of the center-crank kind the cross pieces

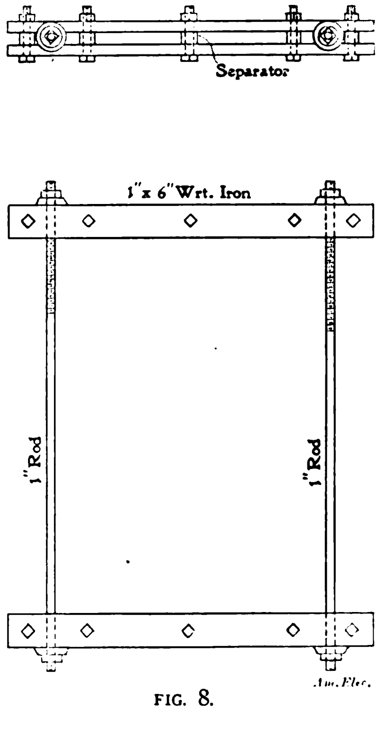

FIG. 8.

should be about 1 inch less in width than the space between the crank discs. The cross pieces should be bolted together in pairs, as shown, with about 1-in. bolts, using separators of pipe between. The rods should be not less than 1 inch in diameter, with two nuts, and each should have about 4 inches of thread on one end and about 15 inches on the other. These 1-in. rods will each have about 25,000 pounds ultimate or breaking strength.

The method of using this clamp is to block the fly-wheel up until it can be entered on the shaft, when it will usually go on a few inches quite freely, but will have to be forced the remaining distance to its bearing; one of the cross pieces is placed against the crank disc, provision being made to prevent the disc from being injured, and the other cross piece is placed outside of the wheel resting on two blocks of hard wood which bear against the face of the hub; the bolts are placed in position and the wheel pressed on by turning up on the nuts. The bolts should be spaced equal distances each side of the shaft and the nuts turned up equally; otherwise the wheel would be strained out of line and cramped or jammed on the shaft. Clamps are better for this work than a jack, as the strain is brought directly on the shaft and the whole is practically self-contained. Some engine builders tap a hole in the outboard end of the shaft to receive the end of a threaded rod about 3 inches in diameter, and about 2 feet 6 inches long; this rod takes the place of the clamp just described, being provided with a heavy nut and a yoke to engage against the hardwood block next to the wheel.

If the fly-wheel is in segments or in halves, the clamps will not be required, of course. If it is in two parts, one part can be lowered into the wheel pit before the shaft is in place and the other skidded over the shaft to its proper position and lowered on to the shaft and the bottom part lifted into place by long bolts passing through the hub. If the wheel is in segments, each part is fitted into the hub, the bolts driven into place and the links put in after the whole is in position. Sometimes the hub only is split, and a wedge driven into the split will open it enough to allow it to be slipped freely on to the shaft.

TABLE I.—SOME RATES OF INCOME FROM TELEPHONE SERVICE.

	Business.			Residence.		
	1-party.	2-party. *	4-party. *	1-party.	2-party. *	4-party. *
Baltimore Independent .	$48	$84	$128	$36	$60	$96
Louisville Bell	96	156	192	60	96	120
St. Paul "	84	144	216	60	96	144
Pittsburg "	125	200	320	100	160	240

Kansas City "	97	150	204	72	120	168

*Total income per line per annum.

In handling the bed plate, it will be found convenient to have it on rollers, as it can be moved directly over the anchor bolts and lowered onto the wedges ready for leveling.

The shaft may be placed in position by means of the gallows frame, Fig. 7, or it may be jacked up and blocked until it can be rolled over the bearings and lowered into place. The cradle for the shaft may be made of two 6-in. x 6-in. timbers and the shaft held in position by chocks. It is very important to follow any heavy work that is being jacked up by a good crib of blocking; this has been the means of preventing some very serious accidents. It is also important to be sure that everything is secure and safe before a block is cast off or a jack released; a little extra caution on these points may be the means of avoiding inconvenient, if not costly, accidents.

The cylinders can be very easily placed in position by means of the gallows frame, or may be blocked up to the proper height for entering the bolts connecting the cylinder to the frame and the whole moved forward by sliding the timbers supporting the cylinder on the blocking. Among the tools necessary is a good level; one that is moderately quick acting is to be preferred, and if it is one with an iron body, so much the better. It should be tested for truth. This may be done by placing the level on some approximately level surface and noting the position of the bubble, then reversing the level "end for end," being careful to have it in exactly the same place it was at first, and again noting the position of the bubble; if the bubble shows the same relation to the center line of the glass that it did at first the level is true; if not, it should be adjusted for one-half the difference.

◆◆◆

THE LEICH FOUR-PARTY SELECTIVE RINGING SYSTEM.

BY A. DALLAM O'BRIEN.

The advantages that accrue to the operating telephone company and to the telephone subscriber from the use of party lines are numerous. From the company's standpoint, the investment in wire plant required per station, where more than one station is connected to a line, is considerably less than in the case of a direct line, and by judicious grouping of the stations the additional circuit material required may, and usually does, in cities at least, amount to only a short length of overhead wiring from the terminal pole to the sub-station. From the standpoint of the subscriber whose use of the telephone is not excessive, the party line offers the required service at a yearly cost considerably below that of an exclusive line, and where the system used is selective there are no attending disadvantages with this decrease in rental. There is, of course, some additional equipment required both at the central office and at the sub-station for the operation of a selective party line system, but the annual charges on this investment represent but a small fraction of the profit due to the increased ratio of stations to lines.

Table I gives some figures showing the yearly charges for direct and party lines, in both the business and residence sections in a number of large cities, the figures given showing the total income derived from the line, from which the cost per station to the subscriber may be obtained by dividing the figures in the table by the number of stations connected to the line. The data contained in Table II was compiled by Mr. L. W. Stanton in connection with a paper read before the National Convention of Independent Telephone Companies, held in Philadelphia in 1902. This table shows the average cost per line for various numbers of stations, the income for the various classes, cost of operation, the interest and depreciation charges, and the net and percentage earnings per line for the different numbers of stations considered.

While the figures in this table may not apply in a great number of cases, their relative values may be taken as being fairly representative of party line practice. In order that party line systems may be made to appeal to the subscriber, they must of necessity be made selective, as signal ringing is very apt to lead to mistakes on the part of the operator and considerable annoyance to the subscriber. Where two stations are connected to a line, it is a very simple matter to render the signaling selective, as one station can have its bell connected from one side of the line to ground while the bell at the other station is connected from the other side of the line to ground and the apparatus at the central office adapted to send the ringing current over either side of the line. With a four-party system, it is obviously impossible to use the same simple means of connecting the stations.

TABLE II.

Number of stations per line.	Average cost per line.	Rental per line per year.	Cost to operate per line.	Interest on investment per line.	Depreciation 10% per line.	Total cost to operate. Interest and depreciation per line.	Net earnings per line.	Net earnings per station.	Net per cent. earned on investment per line. In the Leich system two instruments are connected to each side of the line and at the central office two generators are provided which furnish current at different frequencies. The arrangement of the circuit for a four-party line connected on this system is shown in Fig. 1, but before entering into a description of the arrangement and operation of the system it will be well to consider the principle upon which it operates. There are two types of instrument used with this system, the difference between them being entirely in the arrangement of the ringing circuit. Each type of instrument is equipped with a 1000-ohm ringer, a retardation coil and a condenser. The circuit arrangement of this apparatus, however, differs materially in the two cases. In operating this system there are two different sources of ringing current at the central office, one of which furnishes alternating current at 60 cycles per second and the other alternating current at 20 cycles per second. The division of the instruments into two types is due to the fact that one type is designed to respond to a ringing current of low frequency, while the other is intended for high-frequency current. In the low-frequency instrument, as shown in Fig. 1, a 2-microfarad condenser and a 2000-ohm retardation coil are connected in series with the 1000-ohm ringer, the free terminal of which is grounded. If Z represents the total opposition (impedance) that is offered to the flow of the alternating current, then by using the well-known expression

$$Z = \sqrt{R^2 + (2\pi)^2 f^2 L^2},$$

in which R is the resistance of the circuit to a direct current, f the frequency of the alternating current applied to the circuit, and L the co-efficient of self-induction of the circuit, it will be readily apparent that the impedance of the ringing circuit with the arrangement shown for the low-frequency instrument, will increase directly as the frequency of the ringing current increases, and that a point may be reached where the frequency of the ringing current has become so high and the impedance of the circuit so great that sufficient current cannot pass through the ringer to actuate it and cause an audible signal. With the high-frequency instrument, the arrangement of the ringing circuit consists in connecting a 0.3-microfarad condenser in series with the 1000-ohm ringer, the free terminal of which is grounded, and bridging the ringer with a 1000-ohm retardation coil. The action of a condenser in an alternating-current circuit is directly opposite to that of a retardation coil, the impedance offered to the flow of the alternating current by a condenser being represented by the formula

$$Z = \sqrt{R^2 + \frac{1}{(2\pi)^2 f^2 C^2}},$$

where C is the capacity of the circuit, the remaining symbols having the same significance as before. From this it is evident that the impedance offered to an alternating current by a condenser varies inversely with the frequency of the current, so that with the high-frequency instrument the impedance offered to the 60-cycle current is considerably less than that offered to the 20-cycle current.

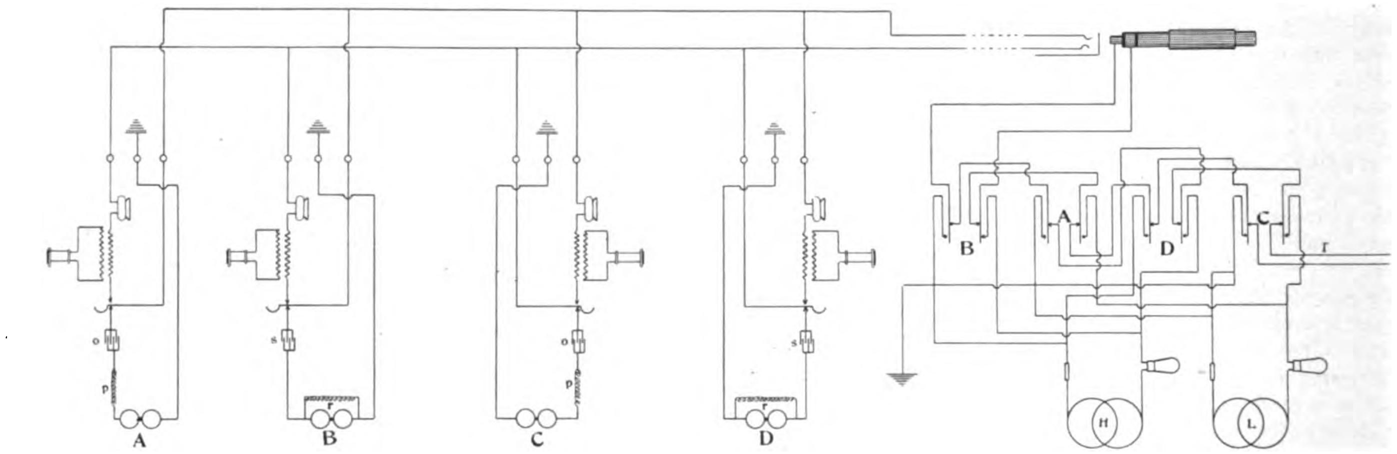

FIG. 1.—LEICH FOUR-PARTY SELECTIVE RINGING SYSTEM.

An inspection of Fig. 1 will show that to each side of the line are connected two instruments—a high-frequency and a low-frequency station from the central office, low-frequency current is sent out over the line and passes through the condenser, bell and retardation coil of the low-frequency instrument, and causes an audible signal. This current is prevented from affecting the high-frequency bell by the condenser which is in series with it and which offers a high impedance to the low-frequency current. The current that does pass through the condenser is diverted to ground through the 1000-ohm retardation coil which offers much less opposition to its flow than does the bell. If it were not for the fact that the actions of a condenser and a retardation coil in an alternating-current circuit are precisely opposite in their effects and that by a proper combination of the two the circuit may be made to act as though neither were present, the 2-microfarad condenser which is in series with the retardation coil of the low-frequency instrument would serve as a bar to the low-frequency current. As it is, however, the only effect of this condenser, so far as signaling is concerned, is to reduce somewhat the impedance offered by the retardation coil.

When a high-frequency current is sent out over the line it readily passes through the condenser and bell of the high-frequency instrument, the impedance of the bridged retardation coil being considerably more to the high-frequency current than that offered by the ringer coils. The low-frequency instrument is not affected by this current, as its ringing circuit offers too much opposition to the high-frequency current to allow a sufficient amount to pass through the bell coil and operate it. It will probably be well to explain that the retardation coil used in connection with the high-frequency instrument varies its impedance to currents of different frequencies through a wider range than do the ringer coils, for the reason that the impedance coil is wound on a laminated iron core and has a completely closed magnetic circuit.

The central office equipment necessary with this type of selective ringing can be varied to suit different operating conditions. Since the ringing current, as previously stated, is of two frequencies, this necessitates the use of two machines. For furnishing the current at 20 cycles per second, the regular two-pole alternating-current machine making 1200 revolutions per minute is entirely satisfactory, or a low-frequency pole changer may be used, and even the hand magneto generator will give satisfactory results. The high-frequency current can be obtained either from a pole changer or a small alternator delivering current at 60 cycles per second; the voltage in any case, with either frequency, should not exceed 90 volts.

Where the volume of party line traffic does not constitute a considerable part of the business handled in an exchange, it is possible to equip each operator's position with a single master ringing key which will determine the kind of current supplied to the cords for signaling purposes. When a master key is used, it is necessary for the operator in signaling the subscriber to first move the master key to the position in which it should be in order that the proper kind of ringing current be furnished to the cords, and then to operate the ringing key on the cord which is being used for signaling. With this method it is necessary to perform two operations in order to signal a party line, and the liability to error on the operator's part is thereby increased; so that it is only in instances where a very small volume of party line traffic is handled that this method is a good one.

The usual practice in large central offices consists in equipping each cord circuit with five ringing keys, all contained in a single mounting but having separate governing push buttons. One key is connected to a source of current—usually the high-frequency generator—and is used for signaling direct lines where the bell at the subscriber's station is not grounded. Each of the remaining keys is adapted to ring a particular party. For instance, key A in Fig. 4 sends low-frequency ringing current out over the ring of the plug, over the line and through the bell at Station A to ground;

key *B* sends high-frequency current in a like manner through the bell at Station *B* to ground, and keys *C* and *D* send low and high-frequency current respectively out over the *tip* conductor of the plug to ground through the bells at Stations *C* and *D* respectively. Thus with this equipment but one operation is necessary at the central office, the liabilities of error are decreased and the number of calls which an operator can handle increased.

A point in connection with party lines, which should be very carefully considered, is the designation of the individual lines, and as the number of stations which are connected to a single line increases this matter becomes more and more important. While opinions differ as to just what letters in the alphabet are suitable for this purpose, yet all exchange managers agree that those letters which are least liable to be confused and mistaken one for the other are the ones that should be used.

It almost necessarily follows that the calling rate per station for a party line is very materially lower than that of a direct line, and thus the number of party lines that an operator can handle does not fall much below the figure for direct lines, and indeed it often happens that the party line equipment in jacks per position may be made greater than that of any other class of service.

The particular impedance coil which is used with this system is so designed that its impedance may be varied to suit unusual line or switchboard conditions. For this purpose the core of the coil is made up of a number of E-shaped annealed iron punchings which can be readily inserted or withdrawn and the impedance of the coil adjusted thereby.

When the instruments are installed for use there are a few precautions which must be observed. The gongs should be in such a position that the bell hammer does not touch either of them when it is in its normal position on either side. It is also necessary to see that the armature of the ringer is in contact with the pole pieces when in either normal position, and it is, of course, necessary that a good ground connection should be obtained.

Instruments equipped with this type of selective apparatus have been successfully operated over lines up to ten miles in length without any adjustment whatever. This system is manufactured and marketed by the American Electric Telephone Company, of Chicago.

◆◆◆

A WAY TO UTILIZE OLD DRY BATTERIES

BY GEO. T. HANCHETT.

There are many cases in testing where a small amount of current is wanted for a long period of time, and at a few volts pressure only. Where the circuit is not to be broken, the most satisfactory arrangement is to draw the current from some power circuit using a resistance in series. In cases where the circuit is to be interrupted rapidly, as in the case of an induction coil, or in driving a small shuttle-wound armature, or similar arrangement, the arc at the point of interruption is beyond control unless special means are resorted to. Moreover if any attempt is made to measure the energy in a circuit thus interrupted, the readings will be entirely erroneous, or perhaps it is better to say the readings will be misleading because the energy of arc at the point of interruption is added to the useful circuit energy, and this is by no means small. For instance, in testing a small shuttle-wound motor, an attempt was made to run the armature with lamps in series across a 110-volt main. The sparking at the commutator was very severe, the potential around the armature was 25 volts and the current .9 ampere: a total power cousumption of 22.5 watts. When the same motor was run on a circuit of 4½ volts, the speed was practically the same, the current was 1.72 amperes, and the power in the armature circuit was 7.74. It was easy to see that the extra watts in the first test were consumed in heating the commutator, which quickly became hot enough to melt the solder.

The common expedient to obtain low voltage when only a high-voltage power circuit is available which will be free from troublesome reactions, is to connect the circuit to be supplied in multiple with a suitable resistance which is connected in series with the line. This resistance is not always easy to obtain, it is usually large and inconvenient, it is a source of heat, and always requires more current from the line than is used in the derived circuit.

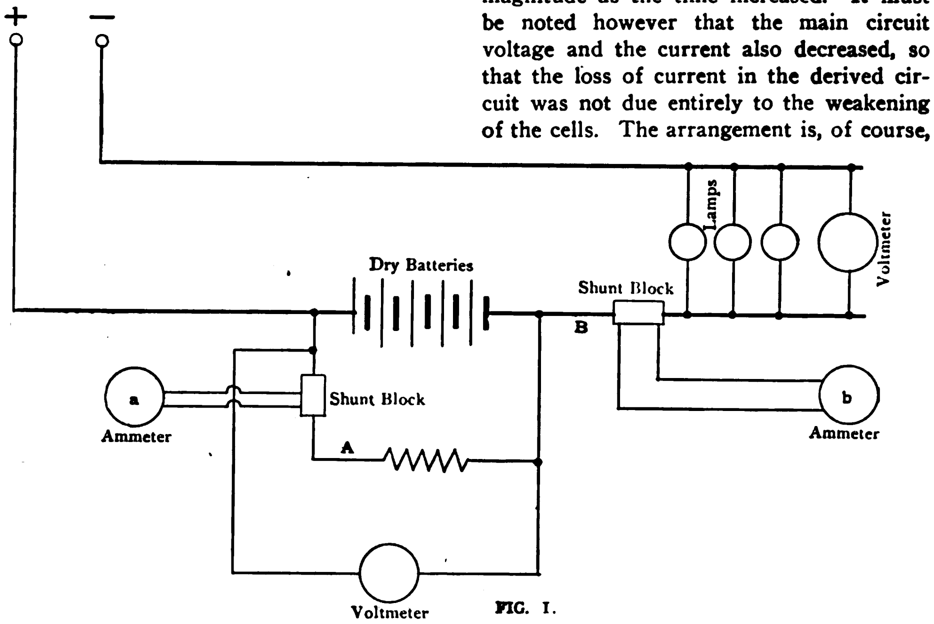

FIG. 1.

A very convenient means of eliminating this difficulty is to use a sufficient number of dry battery cells in place of the resistance, selecting such a number as will give an open-circuit voltage equal to the desired voltage at the work circuit. If the apparatus is so arranged there will be practically no current flowing through the dry cells when the work circuit is closed, so that they will not be a source of heat or trouble, they will form a very compact and convenient substitute for a resistance, having the additional advantage that they are usually easy to secure in comparison; moreover, their condition has very little to do with the result. They should of course be so connected as to oppose current flowing through them, and the reverse current which is sent through them when the work circuit is open tends to depolarize them in case they have been required for any reason to deliver any current to the circuit by virtue of their own voltage. The current in the work circuit may be either greater or less than the current taken from the line, according to the conditions.

In a test where a few volts was demanded, a number of dry cells arranged as shown in the accompanying diagram gave the following results:

Time.	Current in *A*.	Current in *B*.	Volts, V_1.	Volts, V_2.
3.40	2.98	1.9	2.68	114.2
3.45	2.8	1.9	2.53	114
3.50	2.71	1.9	2.48	114.5
3.55	2.65	1.89	2.46	114
4.00	2.62	1.89	2.45	114
4.05	2.59	1.89	2.44	113.5
4.10	2.54	1.88	2.41	113.5
4.15	2.53	1.87	2.4	113.5
4.20	2.52	1.87	2.4	113
4.25	2.5	1.89	2.4	113.7
4.30	2.49	1.9	2.39	113.4
4.35	2.48	1.9	2.38	114
4.40	2.47	1.9	2.37	113.8
4.45	2.46	1.89	2.36	113.4
4.50	2.45	1.87	2.34	113.2
4.55	2.44	1.88	2.34	113
5.00	2.42	1.87	2.33	112.8
5.05	2.4	1.86	2.3	112.2
5.10	2.39	1.86	2.29	111.9

In this case the current demanded in the work circuit was greater than the current taken from the main circuit, and fell off in magnitude as the time increased. It must be noted however that the main circuit voltage and the current also decreased, so that the loss of current in the derived circuit was not due entirely to the weakening of the cells. The arrangement is, of course, of experimental value only and simply consists of a convenient form of resistance which absorbs no energy.

In the case of a three-wire system where the neutral is grounded, a bell circuit might be supplied in shunt to a set of dry cells connected in series with a lamp circuit which was continuously alive, and on the side next to the neutral wire; if the current in this lamp circuit is kept down to a reasonable amount, say that for 1 or 2 lamps, it is probable that very little trouble would be experienced in the battery in a number of years, and the insulation of the electric lighting circuit would not be endangered by the addition of the bell circuit, as the latter would be practically at the same potential as the ground. The greatest value of the battery "resistance," however, is its convenience as a laboratory expedient

Lessons in Practical Electricity

COMBINED CAPACITY AND INDUCTANCE—POWER FACTOR.

As previously explained, any two parallel conductors constitute a condenser; as also explained, capacity, or condensance, produces effects which are opposite to those produced by inductance. Some classes of alternating-current apparatus affect the circuit to which they are connected exactly in the same manner as a condenser would; it is frequently the case, therefore, that an alternating-current circuit contains both condensance and inductance, and a consideration of the joint effect of these is of practical importance.

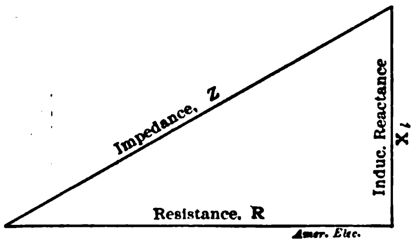

FIG. 1.

Condensance causes the current in an alternating-current circuit to rise and fall *ahead* of the e.m.f. of the circuit; under this condition the current is termed a "leading" current. Conversely, inductance causes the current to rise and fall after the e.m.f. of the circuit rises and falls, and such a current is termed "lagging." It is possible to combine capacity and inductance in a circuit so that their effects on the current phase neutralize each other and allow the current to rise and fall exactly in unison with the e.m.f. of the circuit. This result will be obtained when the inductive reactance and the condensive reactance are numerically equal and are also distributed alike in the circuit.

The inductive reactance, X_l is equal to $2 \pi f L$; the condensive or capacity reactance, X_c, is equal to $\frac{1}{2 \pi f C}$. In these equations f represents the frequency of the e.m.f. in cycles per second, L represents the inductance in parts of a henry,* and C is the capacity in parts of a farad.* The impedance of a circuit containing resistance and inductance is

$$Z = \sqrt{R^2 + X_l^2}$$

and the impedance of a circuit containing resistance and capacity is

$$Z = \sqrt{R^2 + X_c^2}.$$

When a circuit contains both inductance and capacity, the net reactance is equal to the arithmetical difference between the inductive reactance, Xl and the capacity reactance Xc. Therefore the impedance of a circuit containing resistance, inductance and capacity is either.

$$Z = \sqrt{R^2 + (X_l - X_c)^2}.$$

or

$$Z = \sqrt{R^2 + (X_c - X_l)^2}.$$

according to whether X_l is greater or smaller than Xc. It is obvious that when X_l and X are equal, the difference between them is zero, making the impedance, Z, equal to $\sqrt{R^2}$, which, of course, is R. When this is the case, the circuit operates as though there were neither inductance nor capacity present, and the current therefore rises and falls in unison with the e.m.f.

This may perhaps be made clearer by the use of the triangle diagram explained in the February Lesson and a similar diagram showing the relations of capacity reactance, resistance and impedance. Fig. 1 is the diagram showing the relations between resistance, inductive reactance and impedance and Fig. 2 is the corresponding diagram for resistance, capacity reactance and impedance. It will be observed that the line representing capacity reactance projects downward from the horizontal resistance line, while the inductive reactance line projects upward; this indicates the opposite character of the two properties, inductance and capacity, as regards their effect on the e.m.f. and current in the circuit. When a circuit contains both inductance and capacity, the *difference* between the lengths of the lines representing inductive and capacity reactances will represent the resultant or net reactance, X, of the circuit, as indicated in Fig. 3. Here, the capacity reactance, X_c, is one-third as great as the inductive reactance, X_l; the resultant or net reactance, therefore, is two-thirds as great as the inductive reactance, and the impedance line is drawn from the base line to a point two-thirds up the line representing inductive reactance. The dotted line *a* shows what the impedance would be if there were no capacity in the circuit, and the other dotted line *b* indicates what the impedance would be if the inductance were absent. It is obvious that if the line X_l and the line X_c were of equal length their difference would be zero, and the impedance line would be identical with the resistance line, indicating the equality between the resistance and impedance that the formula would indicate under the same conditions.

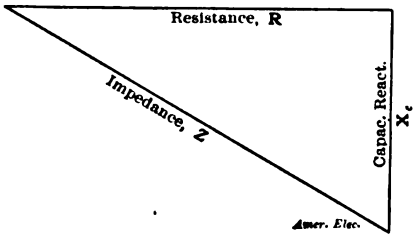

FIG. 2.

When either inductance or capacity alone is combined with resistance in an alternating-current circuit, the current either lags or leads the e.m.f., as already explained. The power developed by the combined current and e.m.f. is the product of the e.m.f. (mean effective value, of course) and the *instantaneous* value which the current has when the e.m.f. is at the point in its rising or falling which corresponds to its mean effective value. This product is always less than the product of mean effective e.m.f. and mean effective current, taken separately; multiplying the e.m.f.* by the current* gives the *apparent* power of the circuit, but the actual or true power is obtained by multiplying the apparent power by a number called the "power factor," which is always less than 1. The triangle diagram affords a most convenient means of considering these relations.

Referring to Fig. 1, if the two lines at right angles are plotted to scale so that their lengths are proportional to the resistance and inductive reactance of the circuit, the length of the diagonal line will necessarily be proportional to the impedance; dividing the length of the base line by the length of the diagonal line will then give the power factor of the circuit. This is also true of Fig. 2, the vertical line being plotted to represent the value of the condensive reactance, and of Fig. 3 where both inductive and condensive reactance are represented. From the foregoing, the following relations result:

$$\frac{\text{Resistance}}{\text{Impedance}} = \text{power factor.}$$

$$\frac{1}{\sqrt{1 + \frac{\text{Net reactance}^2}{\text{Resistance}^2}}} = \text{Power factor.}$$

---

*In practice the inductance is never as much as a henry and the capacity never as great as one farad.

*The mean effective values are always meant unless some other value is specified.

Letters on Practical Subjects

A Belated Credit.

A correct reading of Mr. Ryder's meter was received from Mr. A. V. Youens, Wilkinsburg, Pa., on March 6th, but his name was unaccountably omitted from the list of correct readers published in the April number.—EDITOR.

Mr. Hartwell's Voltage Disturbance.

To the Editor, American Electrician:—

Referring to the voltage trouble mentioned by Mr. Ernest F. Hartwell in your April number, I would suggest that he use a Tirrell regulator connected to the center of distribution and controlling the field rheostat of the dynamo of a small motor-

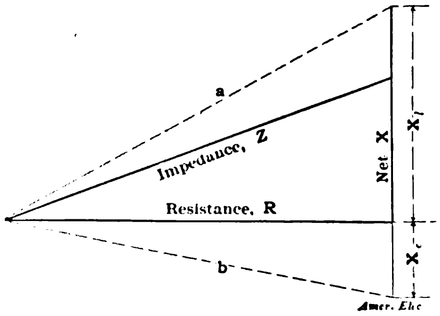

FIG. 3.

dynamo set. The armature of the dynamo end to be connected in series with the feeder and act as a booster, and the field of the dynamo and the entire motor of the set to be connected at the center of distribution. The motor-dynamo set, though small, would be somewhat expensive remedy; perhaps some other reader can suggest a cheaper method of correcting the trouble.

HENRY MULFORD.

Patchogue, L. I., N. Y.

Mr. Mahaffey's Bell Circuit.

To the Editor, American Electrician:—

I enclose herewith a diagram of bell connections (Fig. 1) which I believe to be a correct solution of Mr. Mahaffey's problem published in the last number of the AMERICAN ELECTRICIAN. The arrangement here shown requires about 460 feet of wire. As I understand the problem, the bell at Station A must not ring when either one of the push-buttons at that station is depressed to ring the distant, and the bell at B must not respond to the push-button there. I have therefore used three-point push-buttons or strap keys and a battery at each station. Depressing one of the buttons disconnects the line-wire *a* from the home bell and connects it to the positive terminal of the home battery, thereby ringing the distant bell only. It makes no difference, of course, whether the positive or the negative terminal of the battery is connected to the line-wire *a* when a button is depressed, but it should be the same terminal of each battery so that if the button at Station B and one of those at Station A were pushed simultaneously the two batteries would not be short-circuited on each other.

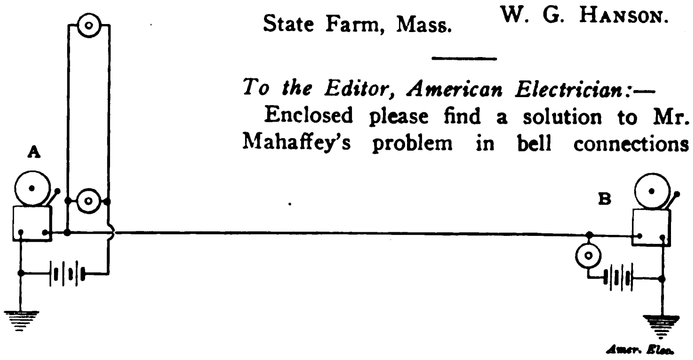

FIG. 4.—MR. GAUSE'S SOLUTION.

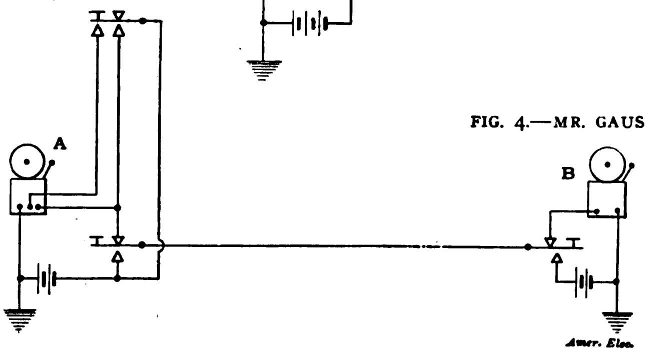

FIG. 3.—MR. HANSON'S SOLUTION.

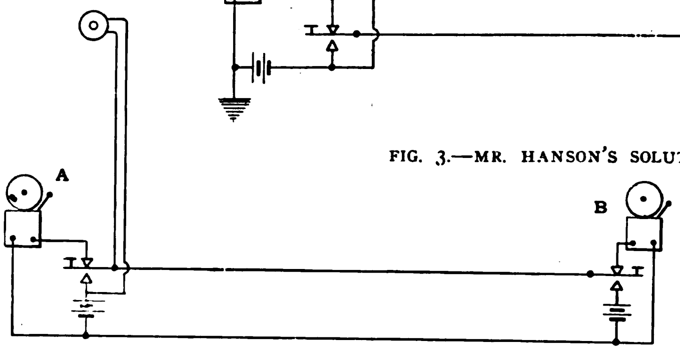

FIG. 2.—MR. LAMB'S SOLUTION.

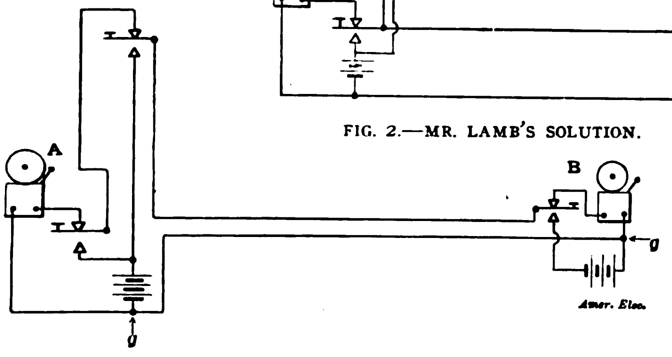

FIG. 1.—MR. PETERSEN'S SOLUTION.

Mr. Mahaffey did not state whether or not a ground return is permissible; if it is, the amount of wire may be reduced, of course, by grounding the two stations at the points, *g, g*, and omitting the lower line-wire.

P. C. PETERSEN.

Washington, D. C.

[The same solution has been sent in by Frederick W. Bender, Elizabeth, N. J.; Frank Carswell, Green Bay, Wis.; H. A. Dresbach, Jersey City, N. J.; H. R. Ern, Chicago; Richard Gessner, Oak Park, Ill.; David Goldblum, New York; P. A. Gould, Saranac Lake, N. Y.; C. H. Hodgkins, Providence, R. I.; C. F. Holmes, Brooklyn, N. Y.; H. Halton, Chicago; R. W. Jackson, New York; H. E. Lane, Philadelphia; J. H. Long, Richmond, Va.; George H. Luft, Highspire, Pa.; J. W. J. Manning, South Boston, Mass.; John J. Marshall, San Francisco; F. V. McAvoy, Floriston, Calif.; Chas. H. Morrison, San Mateo, Calif.; R. E. Noyes, Lincoln, Neb.; G. Peyton, Chicago; F. A. Pim, Los Angeles, Calif.; J. Remey, Buffalo, N. Y.; H. H. Royer, Aurora, Ill.; A. C. Schaedler, Steelton, Pa.; W. H. Shadbolt, Osage, Minn.; L. O. Surles, Chipley, Ga.; F. M. Sutton, Berkeley, Calif.; C. Vanderleith, Brooklyn, N. Y.; E. H. Walters, Waterloo, N. Y., and E. F. Weis, Chicago. It is the correct solution according to the author's diagram, but does not meet the stipulated requirement for the maximum economy in wire, as an inspection of Figs. 2, 4 and 6 will show.—EDITOR.]

To the Editor, American Electrician:—

Herewith I submit a solution of Mr. Mahaffey's problem in bell wiring (Fig. 2). As economy in wire is the chief consideration, I have used two batteries and two double-contact buttons or keys. Depressing either the key or the plain push-button at Station A will ring the bell at Station B, and depressing the key at Station B will ring the bell at A without ringing the home bell.

C. W. LAMB.

Chicago.

[The same solution has been supplied by Chas. H. Dierksmier, Brookline, Mass.; A. R. Treichel, St. Louis, Mo.; Alfred H. Scott and Walter Wynn, of Wilkinsburg, Pa., and H. Wildberger, Jr., Mt. Vernon, N. Y. It involves the peculiarity that one of the push-buttons at Station A rings only the bell at the distant station, while the other push-button rings both the distant and the home bells.—EDITOR.]

To the Editor, American Electrician:—

The enclosed diagram (Fig. 3) is a solution of the bell wiring problem published in your last issue. The two-way keys or buttons normally keep the line closed through the two bells, without battery. Depressing the lower button at Station A disconnects the home bell and connects the battery to the line, ringing the bell at the other station. Depressing the upper key connects the free terminal of the home battery to the line without disconnecting the home bell, and simultaneously short-circuits the vibrator contacts of the bell so it cannot ring. The operation of the two way key or button at Station B is evident from the diagram.

W. G. HANSON.

State Farm, Mass.

To the Editor, American Electrician:—

Enclosed please find a solution to Mr. Mahaffey's problem in bell connections which appeared in the AMERICAN ELECTRICIAN for April. As no restriction in the use of batteries is mentioned, I have used one at each station. Pressing any one of the buttons will connect the free terminal of one of the batteries to the line, putting that battery and the two bells in parallel. The only disadvantage of this method is that both bells will ring when one of the push-buttons is depressed. This was not prohibited, however, in Mr. Mahaffey's statement of the problem.

JAMES H. GAUSE.

Marshallton, Del.

[This solution has also been sent in by Herbert A. Fiske, East Providence, R. I.; L. F. Hammond, New Suffolk, N. Y.; E. S. Lincoln, Brookline, Mass., and J. W. J. Manning, South Boston, Mass.—EDITOR.]

To the Editor, American Electrician:—

The accompanying diagram (Fig. 5) is offered as a solution of Mr. Mahaffey's bell wiring problem which you published last month. The bell connections described by Messrs. McKivitt and Carswell in the March number have been made use of. Depressing either of the two-way keys at Station A will connect the upper line-wire to the home battery and cause the home bell to ring; the vibrator of this bell will also control the distant bell, as the vibrator of that bell is not normally in circuit, while its magnet is. The operation from Station B is the same; the home bell rings and causes the distant bell to ring.

Charlie Potter.

Hoopeston, Ill.

To the Editor, American Electrician:—

The diagram sent herewith (Fig. 6) will, I think, fulfill the requirements of Mr. Mahaffey's letter, published in the April number of the American Electrician.

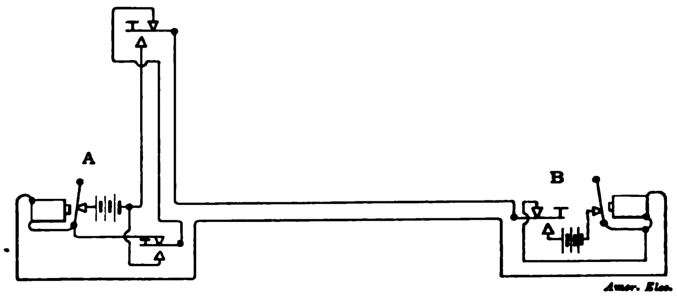

FIG. 5.—MR. POTTER'S SOLUTION.

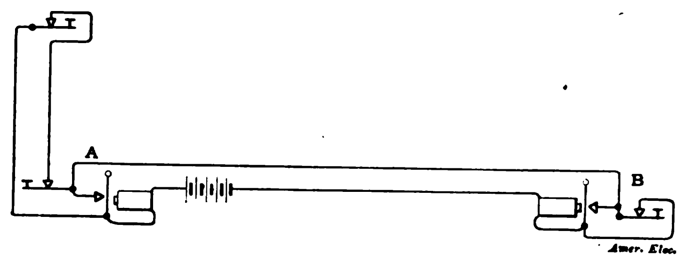

FIG. 6.—MR. SLOCUM'S SOLUTION.

The bells are connected according to the method described by Mr. McKivitt and Mr. Carswell in the March number, and the push-buttons are of the back-contact type. Normally, the magnets of both of the bells are connected in series with the battery, so that a gravity or some other closed-circuit battery must be used. Depressing any one of the push-buttons will remove the short-circuit between the armature and back-stop of the home bell, and that bell will ring; its vibrator will also ring the bell at the distant station, since the magnet of that bell is in circuit and its vibrator is short-circuited by the push-button there. The amount of wire required is about 420 feet.

T. N. Slocum.

Rockford, Ill.

[The same solution was supplied by Charlie Potter, Hoopeston, Ill., as an alternative to Fig. 5.—Editor.]

Size of a 1-Farad Condenser.

To the Editor, American Electrician:—

Referring to page 198 of the April issue, in the middle column near the top, it is stated that the area of a condenser of one farad capacity is 5,555,555,555 square inches or 462,929,293 square feet. This should read 38,580,247 square feet, as 5,555,555,555 ÷ 144 = 38,580,247. I realize that this error does not alter the fact that a condenser of one farad capacity would have to be enormously large, but simply point it out as I believe that you wish to receive the aid of readers in enabling the American Electrician to maintain its high standard of accuracy.

R. Arthur Joslyn.

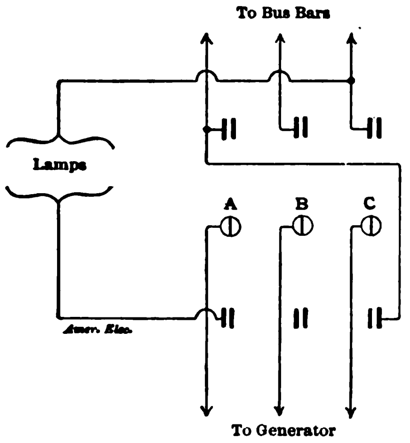
West Lynn, Mass.

[We thank Mr. Joslyn for pointing out the arithmetical error mentioned. It would appear that 12 was used as a divisor instead of 144, which is, of course, the correct one. —Editor.]

Mr. Bailey's Excess Voltage.

To the Editor, American Electrician:—

Referring to Mr. Bailey's synchronizing voltage (page 162, March, 1904) I would suggest that the reason he gets more than the generator voltage is that the two generators are in series; consequently, when they are out of phase, he gets the vector sum of their voltages. In this connection, it may be of interest to point out that synchronizing lamps may be connected up so as to enable one to "synchronize bright" instead of dark, without the use of transformers. The accompanying diagram shows how the connections should be made to obtain this result. The lamps must be capable of taking about double the voltage of the generator.



CONNECTIONS FOR SYNCHRONIZING.

A. E. Ecklund.

Pittsburg, Pa.

[Mr. Ecklund's letter was received before the April number of this paper was issued, but too late for insertion in that number.—Editor.]

Thawing Frozen Water Pipes.

To the Editor, American Electrician:—

In the April issue of the American Electrician Mr. Walter M. Petty states that the idea of thawing frozen water pipes electrically was first suggested in 1900, but was not, so far as he was aware, put to practical use until this year. Many water pipes were thawed in this manner in the upper Mississippi valley during the winter of 1898-99. The method was practically identical with that described by Mr. Petty. The idea originated, as I remember, with Prof. D. C. Jackson, of the University of Wisconsin. In spite of the fact that pipes are usually placed six feet under the surface in this section the trouble was so prevalent that winter that Prof. Jackson and others of the engineering staff at Madison volunteered to instruct electric light superintendents in the work. Later on it was claimed that many leaks developed at pipe-joints, caused by damage from the current.

D. P. Wallihan.

Osage, Iowa.

To the Editor, American Electrician:—

The method outlined by Mr. Petty in the April number of the American Electrician, of thawing frozen water pipes, was, with a few unimportant differences in minor details, used by me in the winter of 1900-1901, in the town of Durham, N. H. About 1000 feet of galvanized iron pipe, including service and main, had been frozen up for six weeks, and local plumbers had given up the job of thawing out as hopeless; where they had dug down to the 1½-inch main, the ice completely filled the pipe.

The apparatus used consisted of one 100-light G. E. oil-cooled transformer, one 100-light and three 20-light Stanley transformers, all connected in multiple, and transforming from 2400 volts to 55 volts. An ammeter, volt-meter and water-barrel rheostat were in the secondary circuit, the whole outfit being installed on an express wagon. Primary taps were made midway between secondary hitches. The secondary connections were made at cellar entrances of service pipes by means of split copper sleeves. The current used varied from 300 to 500 amperes, and in all but the shortest runs (straight across the street from cellar to cellar) the rheostat plates were short-circuited, the volt-meter reading from 40 to 50 volts. This low reading was probably due to the heavy over-load on the transformers. The time required to start water varied from five to twenty minutes; the longest run was about 300 feet, consisting mostly of 1½-inch main.

Arthur Thurston.

Hooksett, N. H.

Queries and Answers

IMPORTANT. No attention will be given to any inquiry which does not give the full name and address of the inquirer.

What is the advantage of using two lamps in series on a 235-volt circuit instead of one lamp of the full voltage? W. G. B.

Lamps of 117 volts rating can be made more efficient than 235-volt lamps.

Please give the formula for calculating the dimensions of an induction coil to give a certain length of spark. G. W.

There is no such formula so far as we know. The dimensions and windings of induction coils are determined empirically from experimental data.

What change would be necessary in an automatic cut-off engine to make the governor cut off at ½ stroke instead of ¼ stroke, and thereby obtain more power from the engine? H.

No change in the engine is necessary. Simply put on the load that it is rated to carry at ½ stroke cut-off and the governor will change the cut-off automatically; that is what it is there for.

Are shunts practical for use with voltmeters? H. M.

Certainly not; a resistance connected in parallel with a voltmeter will not affect the difference of potential at its terminals unless the resistance is so low as to disturb the circuit being measured and cause it to have an e.m.f. different from the one which it is desired to ascertain.

Is there any reason why the gasoline engine described in the February number cannot be built by anyone: I mean any such reason as patents or other restraining conditions? J. M. K.

No; any of the apparatus described in our columns for the purpose of enabling readers to build it may be made for personal use without hindrance, and all except the induction motors may be built to sell if one chooses to do so.

What is the formula for determining the size of wire to use in a three-wire circuit G. R.

The same as the formula for a two-wire circuit, applying it to the outside wires of the system. For the neutral wire a formula is not ordinarily used; the wire is made equal in cross-section to each of the outside wires in most isolated plant work, and of about one-half the cross-section of each outside wire in circuits to be supplied from a three-wire central station.

Please give formulas and instructions for changing the gasoline motor described in the February number from 6 horse-power to 10 or 15 horse-power. A. H. B.

The motor cannot be enlarged by means of any simple formulas; if all of the relative proportions of the 6-h.p. motor are observed in working out the larger machine, the cylinder dimensions may be roughly approximated by applying the maxim that the output is approximately proportional to the product of the cylinder diameter and the square root of the length of the stroke.

A series-wound motor of ¼ horse-power runs at about 2000 r.p.m. at full load, and shows normal heating, etc.; when connected up as a shunt motor the speed comes down to about 1400 r.p.m. and the machine gets very hot; why is this? J. F.

Because the current in the field winding is much greater when it is connected across the circuit than when it is connected in series with the armature, so that the field is very much stronger and the heat produced in the winding is very much greater.

Why does a direct-current constant-potential arc lamp require a "steadying" resistance in series with it? C. M. H.

Because the resistance of the arc decreases with an increase of current, so that any slight increase of current produced by the mechanism would be greatly exaggerated by this property of the arc and cause unstable operation. The resistance of the wire coil *increases* with an increase of current and compensates for the peculiarity of the arc.

What is the character of the current generated in the armature conductors of an induction motor? (2) If it is alternating, what is the relation between its frequency and the primary frequency? (3) Is it practical to vary the speed of an induction motor through a range of 3 or 4 to 1 by means of resistance in the secondary? C. E. F.

Alternating. (2) The frequency in the rotor conductors is proportional to the "slip"; in other words, it is equal to the primary frequency minus the product of half the number of poles and the actual rotor speed in revolutions per second. Thus,

$$f'' = f' - 0.5 \text{ poles} \times \text{r. p. s.}$$

(3) It is possible but not very practical on account of the low power factor and efficiency that result.

What effect does a condenser produce when connected across the contacts of the vibrator of an induction coil? (2) How does the twisting of armature discs on the shaft, so as to "spiral" the slots, prevent humming in a direct-current dynamo or motor? (3) When a single-phase induction motor is started by means of a phase-splitter and then left to run as a purely single-phase machine, why does it continue to run? J. W. J. M.

It affords a path for the discharge of the primary winding when the contacts separate, so that the discharge does not pass across the contact gap, thereby preventing the destruction of the contacts; it also expedites the discharge and thereby makes the demagnetization of the core more sudden and the induced e.m.f. consequently greater. (2) By causing the teeth to enter and leave the edges of the magnetic field gradually instead of suddenly. (3) Because the reaction of the rotor upon the stator produces a rotating field like that of a polyphase machine.

According to the rules of the American Power Boat Association, the horsepower of an engine is computed by the formula

$$\text{H. P.} = \frac{A \times N \times S}{K} \times r.p.m.,$$

in which A = piston area in square inches, N = number of cylinders, S = stroke in feet, and K is a constant. Can this formula be used in designing an engine? (2) It is stated in several text-books on steam and gas engines that it is common practice to make connecting rods two or three times the length of the stroke or four to six times the throw of the crank. The two statements are contradictory; which is correct? (3) What form of reciprocating engine will give the least vibration? G. G. J.

It can be applied if one has appropriate values for the constant K to meet different conditions. (2) The statement should read: "Two to three times the stroke or four to six times the *length* of the crank." (3) Theoretically, a multi-cylinder engine with the cylinders arranged equi-distantly in a circle with their axes radial to the crank shaft.

Why does an induction motor take so much more current when the impressed e.m.f. is reduced one-half than when it is normal? (2) What is the relation between the impressed e.m.f. and the current for a given load? (3) How does the change in impressed e.m.f. affect the speed? (4) Why does the torque of such a motor vary as the square of the impressed voltage? (5) Why cannot shunted ammeters be used for alternating-current work? A. S.

Because the power of the motor is approximately proportional to the product of current and voltage; therefore, if the voltage is reduced the machine must take more current to do the same work. (2) The output is equal to $E\,I\,p\,(1 - s)$, in which E is the impressed e.m.f., I is the current, p is the power factor and s is the slip. (3) The speed will remain approximately the same as at normal voltage. Since it depends upon the frequency and the slip, the only change will be that due to a slight increase in slip. (4) The torque is proportional to the strength of the magnetic field × the current in the rotor conductors. The strength of the field varies inversely as the voltage and the current in the secondary conductors varies directly with the field. Consequently, the torque varies as the square of the field and therefore inversely as the square of the voltage. (5) They can be and are used for such work.

In the formula for transformer windings, why is the counter e.m.f considered equal to the impressed primary e.m.f.? (2) If the two are equal, how can any current pass in the primary windings? (3) What is meant by the "synchronous speed" of a motor? (4) Is it true that two-path armature windings are not suitable for large generators; if so ,why? M. J. McA.

Because the two are so nearly equal that the difference is negligible. (2) The counter e.m.f. due to the cutting of the magnetic flux across the wires is not precisely opposed in phase to the impressed e.m.f. (3) The speed at which the rotor of an induction motor would revolve if there were no "slip"—if it kept up with the rotating magnetic field. A motor never runs at synchronous speed unless driven by some other power than its current, because at that speed no current would be induced in the rotor conductors, and it is this current that makes it run. (4) Yes. Because a two-path winding gives best results with only two sets of brushes (one positive set and one negative set), and in order to obtain sufficient area of contact surface between the brushes and the commutator with two sets of brushes the commutator would have to be made very long and correspondingly expensive; long commutators are also very difficult to build substantially.

1500-KILOWATT ALTERNATOR FOR ST. LOUIS.

The central power plant at the St. Louis Exposition will contain some highly interesting engines and generators, built especially for this occasion and embodying the very latest engineering practice. Among these will be included a slow-speed alternating-current generator built by the National Electric Company, of Milwaukee, and direct driven by a Hamilton Corliss vertical cross compound engine of 2250 horsepower, built by the Hooven, Owens, Rentschler Company, Hamilton, Ohio.

The National alternator will be rated at 1500 kilowatts and will be driven at 83 r.p.m. It will deliver current at 25 cycles and 6600 volts for various purposes about the Exposition grounds. Like all standard alternators built by the National Electric Company, it is of the revolving field type. The revolving field magnet is of large diameter giving additional fly-wheel effect to the engine, and the construction of the field coils is said to make them practically indestructible. All parts are accessible, and the machine is thoroughly ventilated.

The field magnet is made of cast steel in halves, and these are bolted and secured together by shrunk links. The rim of the wheel, to which the cast steel pole-pieces are bolted, is of channel cross section. The field coils comprise 65 turns of 1½ x ⅛-in. copper strap, wound on edge and thoroughly insulated, the outer edge of the coil being exposed to the atmosphere for cooling. Laminated pole shoes are secured to the ends of the pole pieces, and serve to hold the field coils in position. These shoes cover a large polar arc, and distribute the magnetic flux evenly.

The field coils are insulated from the pole-pieces by fuller board, and from the pole-shoes and spider ring by heavy fibre. The revolving field is 16 ft. in diameter at the pole-faces and weighs approximately 50,000 lbs.

The frame is a circular cast-iron housing into which laminated punchings with inwardly projecting teeth are assembled, for the reception of the armature windings. The frame is extremely heavy and stiff, not requiring any external support; it is divided horizontally, the halves being firmly bolted and keyed together. The bolts and keys are contained entirely within the cross section, obviating the use of side lugs. Large open spaces are provided in the sides of the frames, allowing a free passage of air from the ventilating ducts in the core.

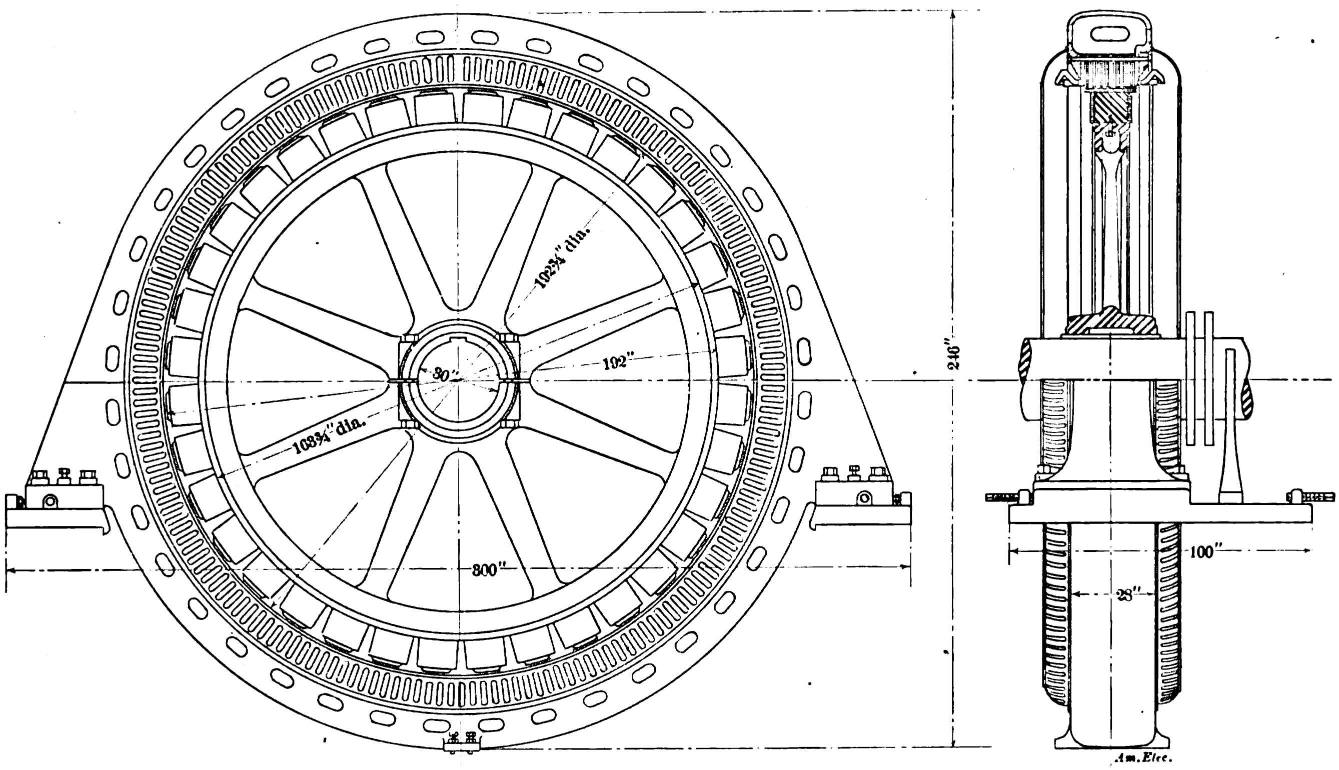


FIG. 1.—ELEVATION AND END VIEW OF 1500 KW. NATIONAL ALTERNATOR.

The armature core is built up of laminated soft steel punchings, which are annealed and japanned before assembling, and ventilating space blocks are inserted at suitable intervals, providing openings extending around the circumference and allowing a free passage for the heat generated in the windings. There are six slots per pole, each 2½ ins. deep x 1½ in. wide, and containing 14 conductors of 0.37 x 0.28 in. compressed copper strand. The internal diameter of the armature is 16 ft. ¾ in. and the axial width of the core 16 ins. Cast-iron collector rings and carbon brushes are used, enabling the machine to be operated with a minimum amount of attention, and this construction also provides a collector gear which will carry a heavy temporary overload.

The net weight of this alternator is 135,000 lbs., and the following are the guarantees for it: Efficiency at 1¼ load 95.5 per cent; at full load, 95.5 per cent; at half load, 94.75 per cent. Regulation, 5.5 per cent on a power factor of unity, and 22 per cent a power factor of zero. The temperature rise is not to exceed 30° on the armature and magnets on a continuous run at full load and 40° on the armature and magnets on a continuous run at 25 per cent overload.

"DELTABESTON" MAGNET WIRE.

An insulated wire which is said to be practically indestructible, and hence especially adapted for armature, field and magnet coils, has been brought out by the D. & W. Fuse Company, of Providence, R. I. This wire, which has been given the name of "Deltabeston," is insulated with practically pure asbestos which has been treated in such a manner that its insulating properties are said to be exceptionally good. It is claimed that its resistance to heat renders it absolutely indestructible so far as any temperature rise to which it may be subjected in commercial service is concerned. Investigation has shown that at a temperature of about 147° C. cotton-covered wire will in time char to an extent that will break down its insulation. It was further ascertained that at 199° C. cotton-covered wire began to smoke in 20 seconds. At 239° C. it was distinctly discolored in 50 seconds and complete carbonization had taken place at 245° C. in 2 minutes and 15 seconds. Deltabeston, the manufacturer says, has been run at a dull red heat representing a temperature in the neighborhood of 600° centigrade without its insulation being destroyed. The company has given the wire severe tests, having had a large number of railway motors in service equipped with it, and the results have been so satisfactory that entire motor equipments are being gradually rewound with it. Deltabeston is made in sizes from No. 4 to No. 18 B. & S. gauge.

HIGH TENSION WALL INSULATOR.

In bringing high-tension lines into stations through the walls of the building it becomes a serious question how best to insulate the wires from grounding. In some cases the line is brought through a hole in the wall; in others, through an elaborate system of tubes placed in the wall; in others through a piece of insulating material of some kind set in the wall; in others, the line enters through an elaborate tower built for the purpose on the top of the building; in still others it is taken directly through the roof of the building.

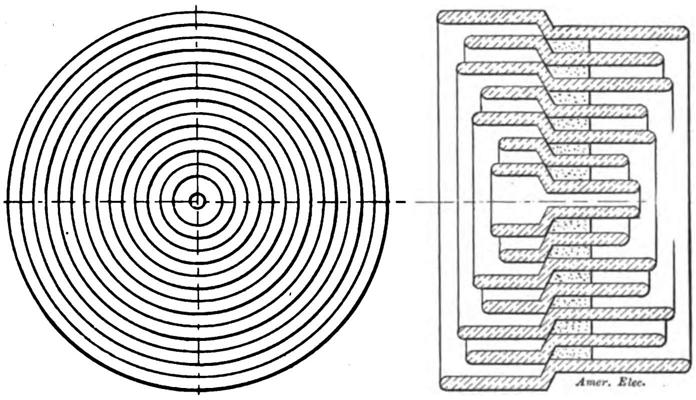

FIG. I.—HIGH TENSION WALL INSULATOR.

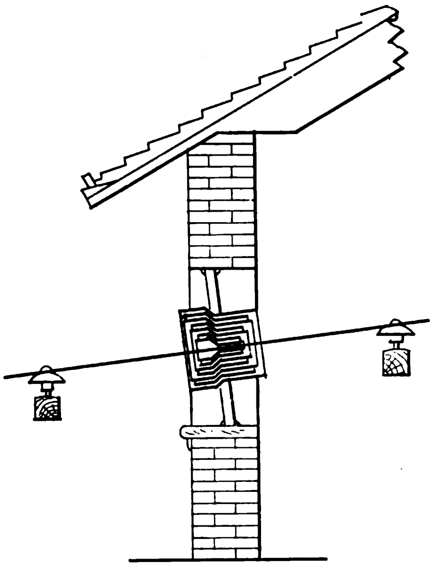

FIG. 2.—WALL INSULATOR IN PLACE.

It is manifestly impossible to prescribe any fixed method for all voltages and locations since this will depend upon a number of conditions. The requirements, however, that must be met are: The maintenance of proper insulation of the circuit; the prevention of the entrance of rain, snow, cold air and dust; the proper mechanical fastening of the line wire, and reliability and simplicity of construction.

In general, wires are best brought through the wall of the building. For high voltages a long insulating tube of small diameter and very heavy wall may be placed over the wire and passed through a slab of insulation set in the wall of the building, the whole being protected from driving rain by an extension of the roof. The insulating tube slopes downward and some form of drip point is provided on the wire just outside the end of the tube. This form of construction has been successfully used for potentials as high as 60,000 volts; but the chief difficulty has been to secure the proper insulating tubes, owing to the fragile nature of porcelain and glass, especially when only one tube is used.

The Locke Insulator Manufacturing Company, of Victor, N. Y., has brought out the appliance shown by Fig. 1 herewith as a solution to the problem. This, it will be noted, is a sort of elastic affair, and can be built up of as many concentric tubes as may be necessary for the insulation of the voltage used. The maker claims that this nest of tubes when cemented together is very strong and substantial, so that fragility is not a part of its nature, and one of the objections lodged against insulators for the purpose under discussion, is overcome. The material used in its construction is a special mixture of clay claimed to withstand high working voltages, so that it combines insulating merit as well as strength. The method of mounting the insulator in the wall of the building is clearly shown in Fig. 2.

INSTRUMENTS FOR DETERMINING INDUCTION CONSTANTS AND ENERGY LOSSES OF ALTERNATING-CURRENT APPARATUS.

BY OUR BERLIN CORRESPONDENT.

A very handy measuring apparatus intended for ascertaining the constants controlling the behavior of alternating-current apparatus has just been brought out by the Siemens & Halske Co., Berlin. As these constants, namely, of self-induction, mutual induction, capacity, and eddy-currents and hysteresis losses, are generally dependent on the number of cycles of the alternating current, measurements should best be made with alternating current, and of the proper frequency. For this purpose the two bridge arrangements represented in Figs. 1 and 2, have been devised. The former measures inductances down to 0.001 henry, while the bridge shown in Fig. 2 has a range of 0.001 to 0.0000001 henry. Both instruments are connected up as shown in Fig. 3, representing a modified Wheatstone bridge. The branches *a* and *b* consist of a manganin wire, divided into the two branches by a sliding contact; the branch *B—C* comprises a self-induction and resistance standard and the branch *A—C* contains the inductance *Lx* to be measured (the resistance of which is *Rx*), and in addition a resistance box *r*. The points *A* and *B* are connected to a source of alternat-

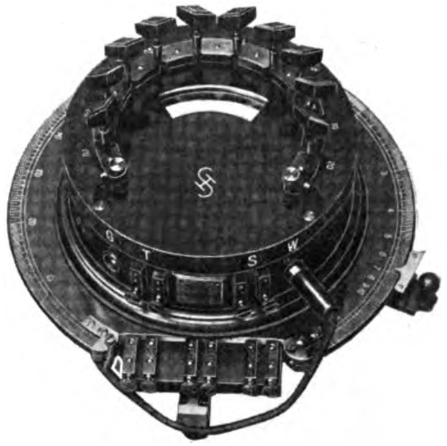

FIG. I.—APPARATUS FOR MEASURING INDUCTANCE.

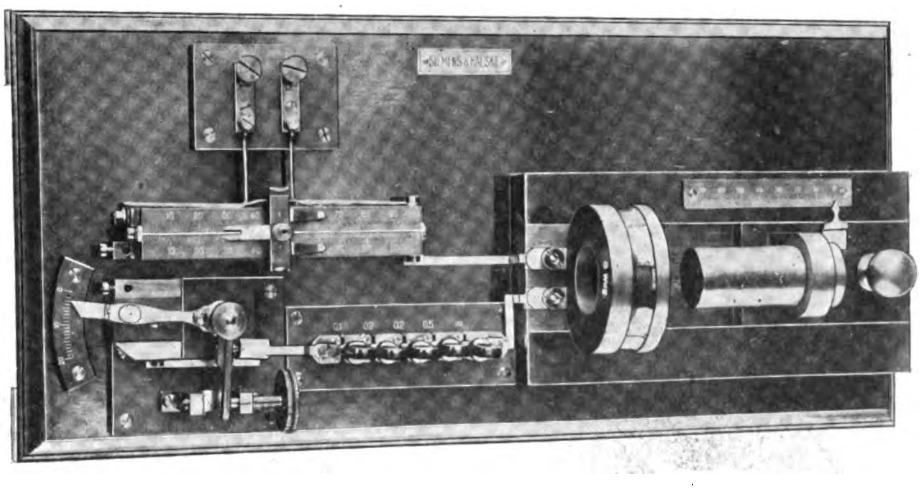

FIG. 2.—APPARATUS FOR MEASURING INDUCTANCE.

ing current following the sine law as nearly as possible, and in the sliding-contact branch an ordinary telephone receiver is inserted. When the sliding contact touches the manganin wire at such a point that no sound is heard in the telephone, the relations

$$\frac{Rx + r}{R} = \frac{a}{b} \text{ and } \frac{Lx}{L} = \frac{a}{b}$$

will enable the inductance Lx to be determined.

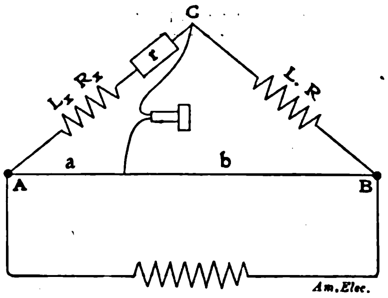

FIG. 3.

When direct current is applied to the bridge, after the above alternating-current adjustment has been made, and the telephone is displaced by a galvanometer, the latter will indicate in the bridge wire the presence of a current which by shifting the plugs in the resistance box r may be made to disappear. This resistance, r, which is finally inserted, represents the resistance loss, and multiplying it by the square of the current gives the watts lost in the tested apparatus by hysteresis, eddy currents, radiation, etc.

As regards the alternating-current source, which in order to obtain a sharp minimum in the telephone should yield a sine-wave current as pure as possible, this is obtained by the use of a special transformer or induction coil and a high-frequency generator, the former producing alternating current of 300 to 650 cycles per second and the latter, a current of frequencies up to 10,000 cycles per second. Fig. 4 is a diagram of the transformer, and Fig. 5 is a view of the actual apparatus. To the center of a circular telephone diaphragm, D, a sack of carbon granules is fixed, the lower part of which rests on a stationary support; this forms the equivalent of a highly sensitive telephone transmitter, or microphone. A tubular permanent magnet, M, surrounds the microphone and one end is in close proximity to the diaphragm, the distance between the two being adjustable. The steel tube carries a coil which is connected in series with the secondary coil, S, of a small induction coil and the external circuit. The primary coil P of the induction coil is connected in series with the microphone and a few storage battery cells, B, in a local circuit, as shown. When this circuit is closed, the diaphragm vibrates at a high rate under the influence of the microphone and the exciting coil in the secondary circuit of the induction coil, in the well-known manner.

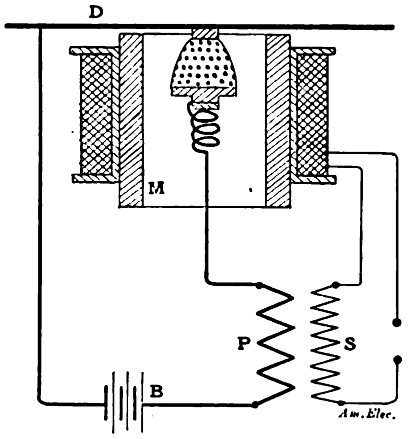

FIG. 4.—DIAGRAM OF TRANSFORMER CONNECTIONS.

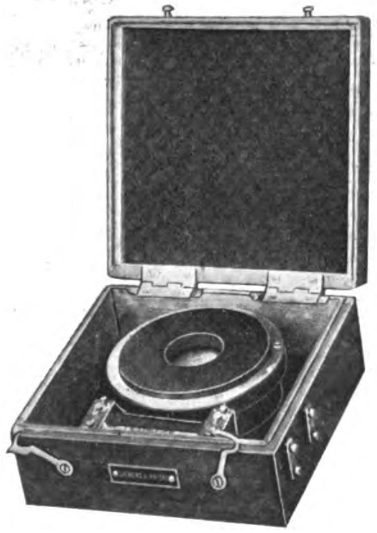

FIG. 5.—TRANSFORMER.

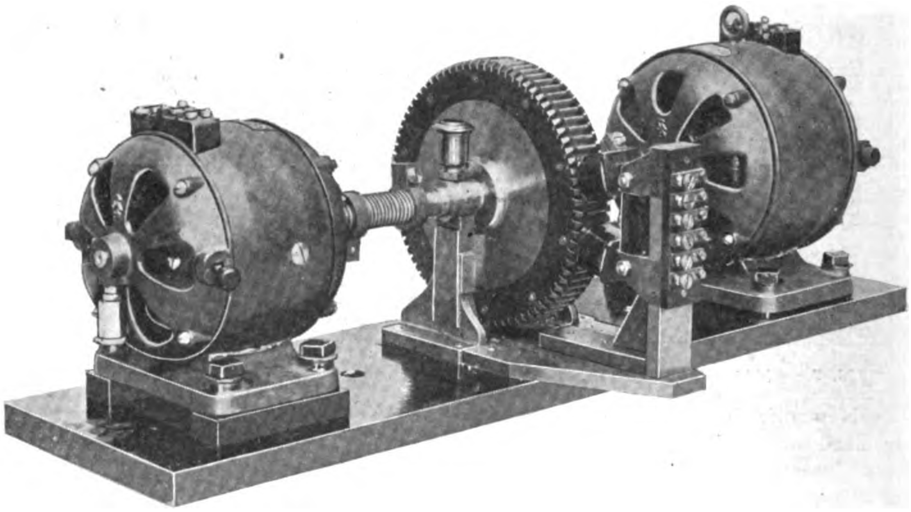

FIG. 7.—HIGH-FREQUENCY GENERATING OUTFIT.

The frequency of the current delivered by the "humming" transformer or induction coil is determined by means of the apparatus illustrated in Fig. 6. This consists of a closed tube, the lower end of which carries a sensitive telephone receiver which is attached to the tube so that all the sound waves produced by the vibrations of its diaphragm are delivered within the tube, and a smaller telescoping tube adjustable within the upper end of the main tube and carrying a flexible ear tube at its outer extremity. The main tube is provided with a graduated scale, which is calibrated so as to read directly in cycles per second. The telephone receiver is connected to the secondary circuit of the "humming" transformer and the listening tube applied to the operator's ear; the telescoping tube is adjusted until the sound is at its maximum, when the index on the graduated scale shows the frequency of the current.

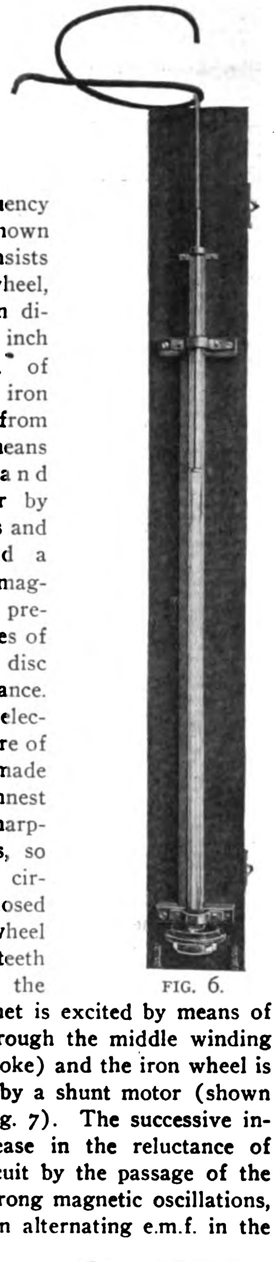

FIG. 6.

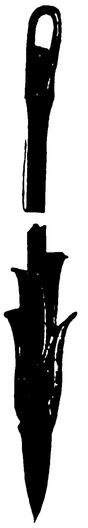
The high-frequency generator is shown in Fig. 7. It consists of a toothed wheel, about 8 inches in diameter and 13-16 inch thick, composed of very thin sheet iron discs insulated from each other by means of varnish and clamped together by hard rubber rings and metal discs, and a laminated electromagnet with its poles presented to the edges of the teeth of the disc at a small distance. The poles of the electromagnet, the core of which is also made from the thinnest sheet iron, are sharpened like wedges, so that its magnetic circuit is almost closed by the iron wheel whenever two teeth are in front of the poles. The magnet is excited by means of direct current through the middle winding (on the magnet yoke) and the iron wheel is revolved rapidly by a shunt motor (shown on the left in Fig. 7). The successive increase and decrease in the reluctance of the magnetic circuit by the passage of the teeth produces strong magnetic oscillations, which generate an alternating e.m.f. in the secondary coils on the magnet poles. The dynamo shown on the right in Fig. 7 is connected to an adjustable resistance and serves to give the motor a steady load, so as to have a constant rate of revolution.

New Apparatus and Appliances

A NEW GUY ANCHOR.

Crouse-Hinds Co., of Syracuse, N. Y., is manufacturing the simple guy anchor shown by Fig. 1 herewith. The anchor is made of forged steel and weighs 22 pounds. The rod is one inch square and five feet long, one end being flattened and pointed, then twisted one-quarter way round. Four wings, each 8 ins. long, 1½ ins. wide and ⅜ in. thick, are riveted on the flattened part, two above the twist and two below. The wings are riveted in such a manner that when open, each wing forms an angle of 90° with the next wing. During installation the wings are closed around the rod; but when an attempt is made to pull the rod out of the ground, the wings, owing to their shape, spread out and offer a wide area of resistance to any further pull. The anchor makes a four-inch hole when being installed, and the only tool necessary for its installation is a sledge hammer. The anchor can be driven in any kind of soil, and a welded ring, to which the guy wire may be fastened, is provided in the end of the rod.



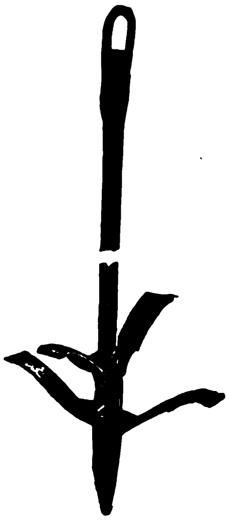


FIG. 1.—GUY ANCHOR.—FIG. 2.

KEELER WATER-TUBE BOILER.

The Keeler water-tube boiler, built by the E. Keeler Co., of Williamsport, Pa., is of the box header type, having a horizontal steam and water drum. The steam outlet is placed in the center of the drum, and is provided with a large-sized dry pipe or separator, while the added flexibility resulting from the long rear header allows for expansion and contraction of the tubes. These are straight and inclined one inch to the foot. The headers are eight inches deep inside, and the throat covers one-half of the circumference of the drum, which is reinforced at this point by three bridges of plate and by the throat flanges. All drums above 36 in. in diameter have triple-riveted double butt-strapped straight seams. There being nothing to impede the rapid circulation of the heated water up through the front header and the cooler water down through the rear header and up through the tubes, the circulation ought to be such as to recommend the boiler for economy and durability. In construction, the wrapper sheet is flanged, this process being patented by the Keeler Company. The boiler is of wrought steel throughout, no cast iron or cast steel being used except for the handhole plates. All the handhole plates are faced in a special machine, and the joint with the header packed with a special rubber composition or metallic gasket. The feed pipe entering the front drum head is carried back into a mud drum. A blow-off pipe is connected to the back end of the mud drum and extended through the rear head of the steam and water drums, whence it can be connected to the main blow-off pipe or left with a separate outlet so the character of the impurities in the feed water can be determined. The front end of the boiler is hung from two heavy channels which rest on wall plates. The rear header rests on expansion plates, thus giving a flexible setting. The front is of sheet steel, with cast-iron doors and frames, and is sectional so that mechanical stokers can be installed without change in construction. The rear header is completely enclosed. An angle-iron frame and sheet-steel tube door are provided for the rear setting wall. Cast-iron side cleaning doors are provided and the cleaning openings so arranged that no cold air is admitted, while if desired the holes in the staybolts are made large enough for the use of a steam blower in front. These boilers are built in units from 50 to 675 horse-power, and also in special sizes to suit space conditions. The standard boilers are built for a working pressure of 150 pounds, but if desired can be built for any pressure up to 250 pounds. The grate surface is carefully proportioned and air space regulated by the class of fuel to be burned.

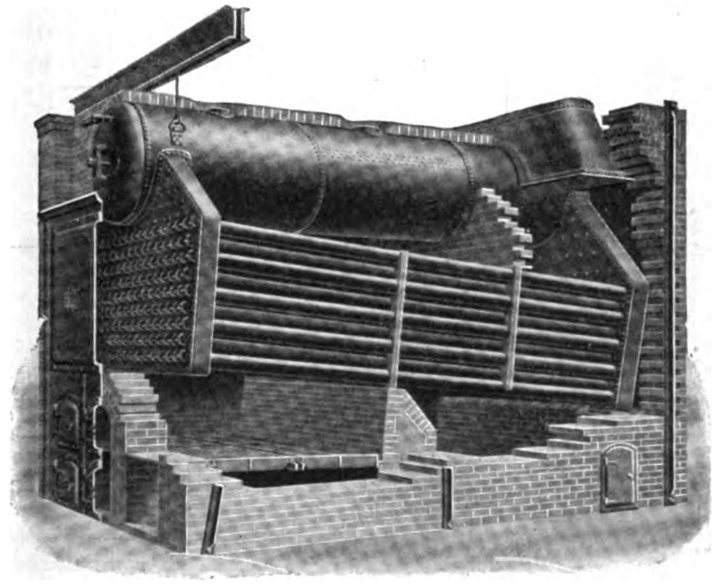

FIG. 3.—KEELER WATER-TUBE BOILER.

IMPROVED "HYLO" INCANDESCENT LAMP.

The Phelps Company of Detroit, Mich., has brought out an improvement to their "Hylo" lamp which is shown in Fig. 4 herewith. It will be remembered in this connection that originally the "Hylo" lamp was provided with a spring base so that when screwed tightly into the socket one filament was in circuit, and when slightly unscrewed the other filament was in circuit. The manner of obtaining these results was open to objection, owing to the looseness of the lamp in the socket. The objection was subsequently overcome by giving the lamp a firm seat in its socket and making the connections to the baby filament and full candle-power filament through the medium of a small double push switch attached to the lamp by flexible cord. In the form now being brought out, three wires run to a small switch as shown by Fig. 4. One wire is attached to the pivot of a switch blade and each of the other two wires is connected to a small copper contact strip which is wiped by the switch blade in pass-

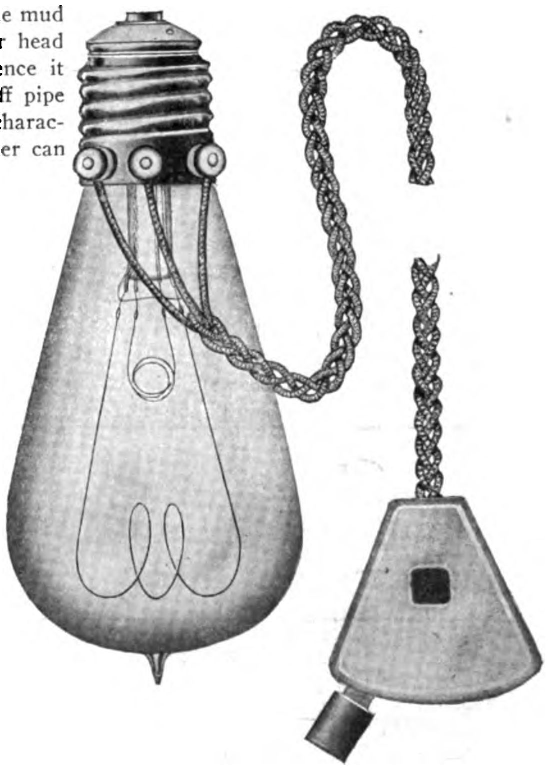

FIG. 4.—"HYLO" INCANDESCENT LAMP SWITCH.

ing. In this way, the switch is first in the off position, a move to the next position places the 1-c.p. filament in circuit and a further movement places the 16-c.p. filament in circuit. The whole arrangement is enclosed in porcelain, carefully designed to meet the Underwriters' requirements.

TRUMBULL PANEL CUTOUT.

Fig. 5 herewith shows a 15-ampere, 110-volt panel cutout brought out by the Trumbull Electric Manufacturing Company, of Plainville, Conn. The particular advantage claimed for this cutout is the fact that it can be used for either the two or the three-wire system and for any number of circuits. Fig. 6 shows three panel cut-outs in a panel box, with connections for two-wire and three-wire systems indicated. In the former, both wires go up one side and continuing over go down on the other, while in the three-wire system, the neutral wire goes up on one side and crossing over goes down on the other, the outer wires terminating at the top. The manufacturer calls attention to the fact that any size of panelboard can be made up from stock with the aid of these cutouts. The individual panels are 3 in. by 6 1-16 in. and when arranged in the box would take up 12⅛ ins. Each additional circuit would therefore add 3 ins. to the length of the box. Each panel includes both switch and cutout, and when used with enclosed fuses conforms to the underwriters' requirements.

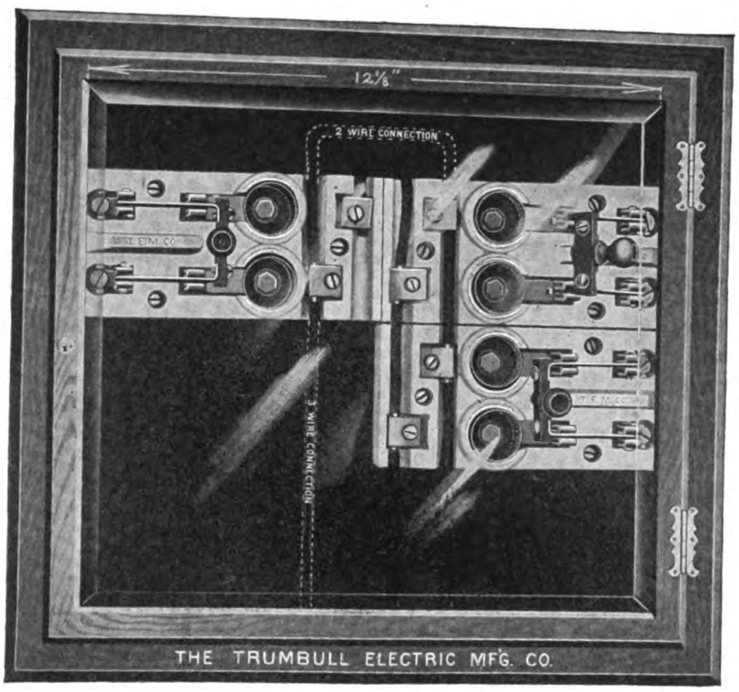

FIG. 6.—TRUMBULL PANEL BOX.

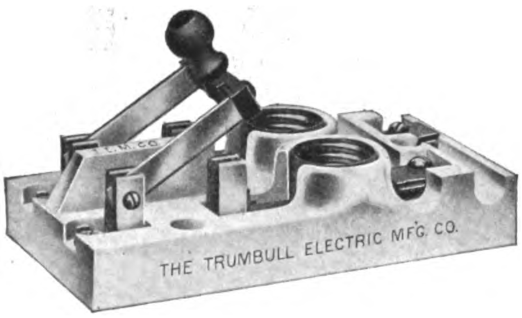

FIG. 5.—PANEL CUTOUT.

MONARCH INCANDESCENT LAMP.

Fig. 7 herewith shows the "Monarch" lamp made by the Monarch Electric Manufacturing Company, of Warren, Ohio. This is simply an improved incandescent lamp adapted for use in any standard socket. The lamps are made in two sizes both for use on either alternating or direct-current circuits. No. 1 has a round bulb 5 in. in diameter and No. 2 has a round bulb 3¾ in. in diameter. The bulbs are sand-blasted so as to give them a frosted appearance, and the voltage range of the lamps is from 90 to 125 and from 200 to 250. The No. 2 is a 25 candle-power lamp and the only fixture that is necessary for use on any standard socket is a polished aluminum reflector finished in dead black on the outside. The No. 1 is a 55-c.p. lamp and is used the same as No. 2 except that for purposes of ornamentation it has a brass or oxidized copper collar fitted with a spring which holds the reflector in place. The lamps are also provided with a ceiling fixture adapted for keyless sockets. The lamp is furnished in two efficiencies corresponding in life to 3.5 and 3.1 watt lamps, their life tests showing, it is said, 600 to 800 hours run. The lamp is equipped with a ventilated collar which is said to prevent overheating and also to prolong the life of the lamp. The reflector of the lamp does not come in contact with the bulb and thus allows of a free circulation of air. The current consumption of the No. 1 lamp the manufacturer says is 120 watts. The current consumption of the No. 2 lamp is the same as the ordinary 16-c.p. lamp but by the use of the reflector it is rated at 25 candle power.

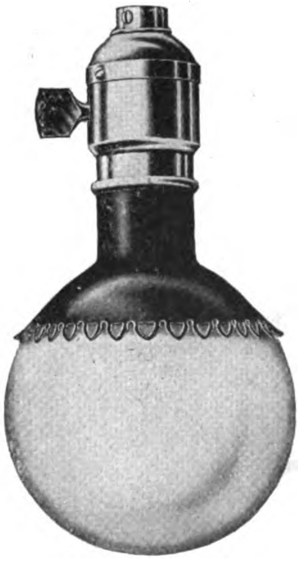

FIG. 7.—MONARCH INCANDESCENT LAMP.

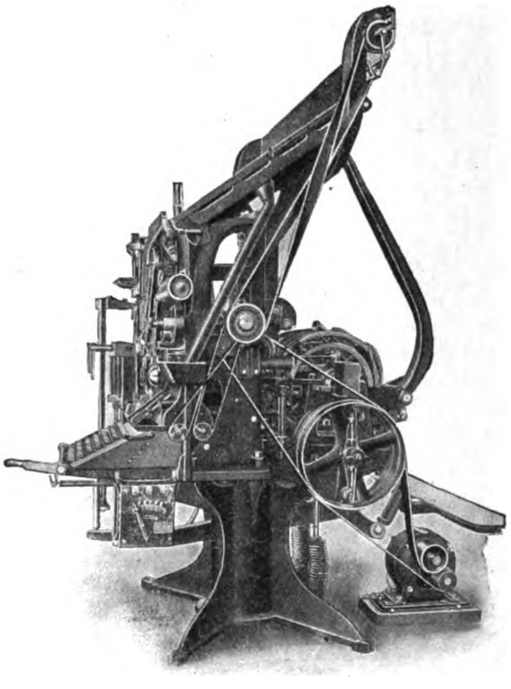

FIG. 8.—MOTOR-DRIVEN LINOTYPE MACHINE.

APPLICATION OF SMALL MOTORS.

The accompanying engraving, Fig. 8, illustrates admirably the fine adaptability of small "protected type" motors to individual driving. The case in point is that of the well-known linotype Mergenthaler machine, and it is driven by a Watson motor, built by The Mechanical Appliance Company, Milwaukee, Wis. The motor is equipped with an idler pulley journaled on an axle which is fastened to the field magnet frame; this arrangement, of course, causes the belt to hug more of the circumference of the motor pulley than it otherwise would and permits the motor to be set close up to the driven machine without entailing belt slippage. The Watson motor, being very compact in design and almost entirely enclosed, is especially well-adapted to applications of the class here shown. The machine itself has been described in our columns very fully and our readers will doubtless remember its construction. The lubrication and brush feed are, of course, entirely automatic, so that the machines need only to be started up and shut down, with an inspection at long intervals to see if the brushes need renewal or the oil well refilling. One of the principal features of the equipment is a special starting box, through which a 20 per cent. variation in the speed of the motor can be obtained.

MILNE WATER-TUBE BOILER AND SUPERHEATER.

The accompanying illustration shows a sectional elevation of the Milne water-tube boiler and also of the superheater connected to the boiler. The boiler is constructed of wrought steel throughout and does not contain any flat, stayed or inaccessible surfaces; all surfaces being cylindrical, of moderate diameter, and accessible through one man-hole. The boiler is a simple combination of four parts; an upper and a lower drum connected by a number of sections of 4-in. seamless drawn steel tubes, to which is coupled an independent feed-water section composed of a single row of tubes. The tubes are staggered and are all curved to a five-foot radius. There are five different bends in a complete set of tubes and the front and the back rows are interchangeable. The feed-water section extends across the back of the boiler, the upper ends of the tubes being expanded into an independent header which receives the feed-water. The furnace is designed with a view to obtaining the most efficient combustion. A fire-brick arch covers the furnace in such a manner, the manufacturer says, as to maintain the high temperature required to ignite and burn the fuel gases, and as the heating surface is situated at the back of the furnace and bridge wall, the highest furnace temperature is said to be maintained and the temperature of the fuel gases not reduced until the combustion is complete. The tubes being vertical, dust and ashes cannot, of course, collect. The gases of combustion travel over a heating surface of about 70 ft. and finally over the feed-water section before escaping. The superheater is of simple form, being composed merely of an upper and a lower steel header, into which the superheating tubes expand. Being situated in the front of the boiler it is accessible for any purpose, and in case of derangement can be entirely removed while the boiler is under pressure. The simple nature of the connections permits easy flooding accompanied by a good circulation in the boiler. The boilers and superheaters are constructed in all sizes up to 1000 horse-power and for any pressure by the Milne Boiler Company, of New York City.

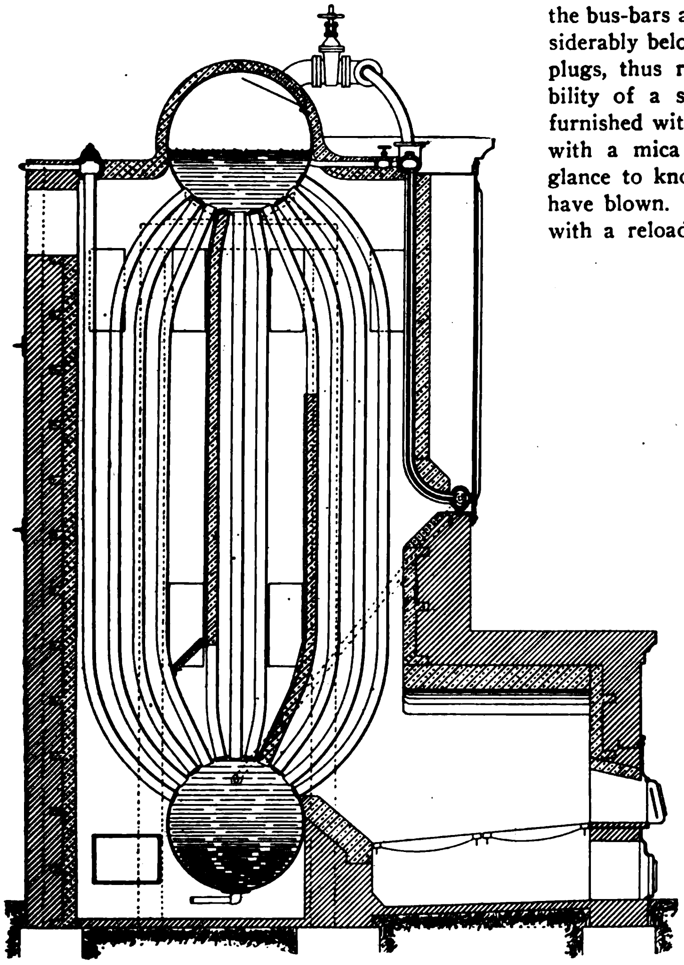

FIG. 9.—MILNE WATER-TUBE BOILER.

FUSE PLUG CABINET PANELS.

The line of cabinet panels manufactured by the General Electric Company is furnished for 125 and 250-volt service, in a variety of arrangements and circuits to meet the requirements of practically all installations. The distinctive feature of these panels is the employment of the well-known Edison fuse plugs on the different circuits. The plug type of panel seems to have an advantage over the cartridge fuse type in that the bus-bars and connections are placed considerably below the level of the tops of the plugs, thus rendering very remote the liability of a short circuit. The fuse plugs furnished with the 125-volt panels are fitted with a mica cap which enables one at a glance to know on which circuit the fuses have blown. The 250-volt panels are fitted with a reloadable type of fuse plug which is easily inserted without danger of shock. These panels are neat in appearance, compact and well finished, and due to the nature of the Edison plug no injury to the panel itself can take place when the fuses blow.

Fig. 10 shows a cabinet panel for twenty-six two-wire double branch circuits from two-wire mains with main and circuit switches, while Fig. 11 shows a somewhat smaller panel arranged for fourteen two-wire single branch circuits from three-wire mains with main and circuit switches. The spacing of the different panels is in conformity with the rules of the National Board of Fire Underwriters.

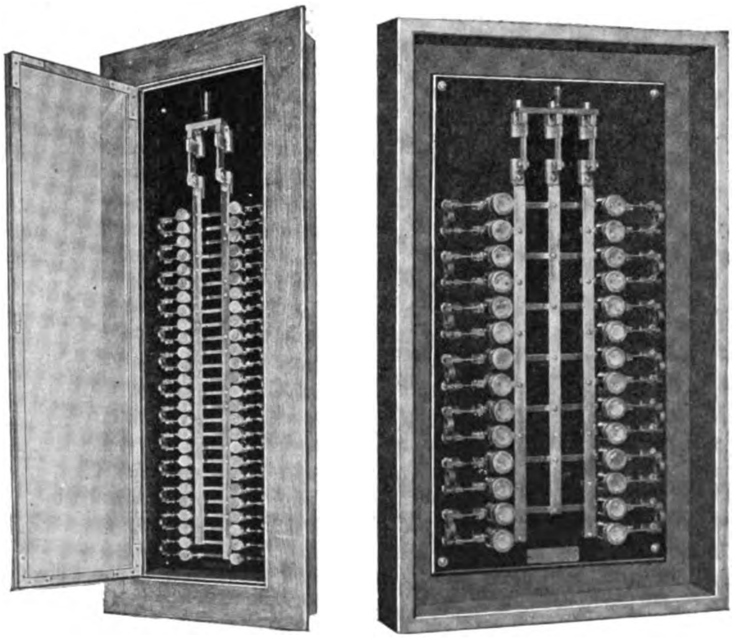

FIG. 10.—FUSE PLUG CABINET PANELS.—FIG. 11.

ALLIGATOR WRENCH FOR ELECTRICAL WORKERS.

The Applied Device Company, of Springfield, Mass., has placed on the market the alligator wrench shown by Fig. 12 herewith. This has a one and three-quarter inch offset, to allow close working to the wall or ceiling. Each wrench is provided with two jaws for right and left hand work. The wrench has a fixed and a flaring jaw, the combination of a grasping jaw and a serrated face, with a bearing jaw having a straight bearing face. In this way it both grasps and releases the pipe with ease and certainty, the curved outline of the pipe finding a tangential bearing in all parts of the opening. The curved jaw first engages the pipe, and then the straight jaw slips under or around the pipe until jammed tightly into the opening between the jaws, the action being entirely automatic. The wrench can be used with any pipe from 5-16 to 1 1-16 in. The tool is made from a forging of tool steel, the teeth being milled and hardened.

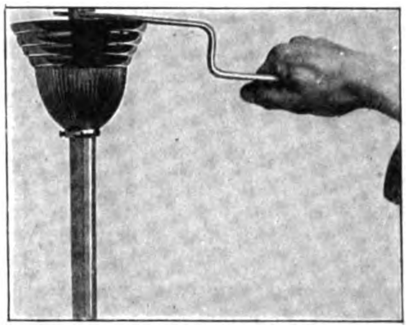

FIG. 12.—ALLIGATOR WRENCH.

BLUE PRINTING OUTFITS.

The General Electric Company has made some recent developments in their electric blue printing outfits. There are designed for the making of blue prints by means of arc lamps, and are capable of making two prints 48 in. x 36 in. or a larger number of small prints at one time. The frames are cylindrical in shape. The sides of the frames are made of curved plate glass, against which the tracings and blue prints are placed; canvas curtains operated by foot levers hold them in position. This arrangement holds the tracing firmly against the glass, insuring good contact between the tracing and blue print. The electric current is thrown on automatically by the foot lever, thus avoiding excessive waste. The frame is light, strong and durable, being constructed of angle iron and sheet steel. Its light weight renders it practically easy to move from one place to another as the occasion demands. By placing thin metal bands horizontally and vertically across the glass to hold the tracings, it is possible to make as many as thirty-two 8-in x 10½-in. prints at one time. This attachment obviates the necessity of removing the tracings until all the desired prints have been made. These outfits can be used on either direct or alternating current circuits, using in either case, the enclosed arc lamps with clear globes. Exposures are governed entirely by the condition of the tracing and the grade of blue print paper employed; the average print, however, is obtained in from one and one-half to three minutes. The General Electric Company, in its own blue printing department, during the month of January, 1904, obtained without the aid of solar light, 110,000 prints from an equipment of twelve frames.

NEW BOOKS.

Testing of Dynamos and Motors. By Charles F. Smith. Manchester, Eng.: The Scientific Publishing Company. Cloth; 240 pages, 5½ ins. x 8½ ins.; 83 illustrations. Price 5 shillings.

The reviewer takes off his hat to Mr. Smith. For completeness, conciseness, directness, accuracy, clearness of exposition and intelligent selection of methods, there is nothing in print in the English language on the testing of direct-current machinery that compares with this little book in the slightest degree. It is worth ten times its price to anyone who has to do with the class of work discussed. There may be errors, of course; there always are in first editions (and sometimes in tenth editions). None have arrested the attention of the reviewer, but no attempt has been made to verify in detail the formulas and examples given; in principle they are correct. For conveying information along the line of least mental resistance the author's style is without a superior within the range of the reviewer's observation.

The "Practical Engineer" Pocket Book. New York: D. Van Nostrand Company and The Derry-Collard Company. Leather, 577 pages, 3¼ ins. x 5¼ ins.; illustrated. Price, 75 cents.

This is the mechanical mate to the pocket book reviewed below, and is considerably superior to it in general quality. It contains many of the tables which are contained by the electrical pocket book, and many more which are equally valuable. The usual steam and mechanical engineering subjects are treated in concise style. There is also an excellent section on gas engines and one very much poorer on oil engines. Some of the gas engine data should be brought up to date: for example, tests of explosive mixtures, the data in the book being the results of Clerk's tests made in 1885 or 1886. Most of it, however, is as near up to date as it is practicable to get it. Like the electrical pocket book, this one contains extremely useful sections on shafting, belting and gearing. There is an unusually small proportion of obsolete matter in the book; in fact, this proportion is practically negligible.

Twentieth Century Hand Book for Steam Engineers and Electricians. By C. F. Swingle; Electrical section by H. C. Horstmann and V. H. Tousley. Chicago: F. J. Drake & Co. Flexible leather; 207 pages, 4½ ins. x 6½ ins.; over 200 illustrations. Price, $2.50.

This is an elementary book intended for practical steam engineers and electrical workers, and is written accordingly in plain language. It covers, as fully as could be expected for its size, boilers, furnaces and settings; boiler feed apparatus; fuel and combustion; properties of steam; evaporation, draft and calorimeter tests; engines, valves, valve setting, governor adjustment, steam indicators and their uses; feed-water heaters, condensers, etc.; electrical instruments and apparatus; circuits and wiring calculation; translating devices; care of dynamos, motors, etc.; storage batteries, lightning arresters, etc. So far as the reviewer has investigated, the subject matter appears to be accurate and intelligently prepared. Some obsolete electrical apparatus has been given probably more attention than it merits, but as some of these relics are still in practical service the information will doubtless be welcome to those afflicted with their operation and maintenance.

The "Practical Engineer" Electrical Pocket Book. New York: D. Van Nostrand Company and The Derry-Collard Company. Leather; 350 pages, 3¼ ins. x 5½ ins.; illustrated. Price, 75 cents.

This is the 1904 edition of this well-known little book, and contains a large amount of valuable data. Many parts of the book, however, appear to have remained unrevised for several years. For example, on page 117 the old Hopkinson curves of magnetic quality of iron are presented; on the next page is an example of the calculation of the magnetic circuit of a dynamo taken from the classic Hopkinson paper read in 1886; on page 122 an ancient discoidal armature and a multipolar field magnet with poles parallel to the shaft are presented as typical of the multipolar dynamo, along with elaborate calculations applying to the design. The whole treatment of the dynamo-electric machine is useless; where it is not out of date it is lamentably perfunctory. The tables of temperature coefficients, specific resistances, and other data involving ohms or volts are rendered useless because one is either not informed whether the unit is the "legal" or the B. A. or the international one, or else the data are in terms of the so-called legal units. The chapter on electrolysis is fairly good. The sections on shafts, gearing and belting are excellent, and the book contains many very useful tables. The section on dust destructors is about the most complete and modern of the entire contents, and there is a little information about elevators which may be useful. The meagre page of platitudes on gas power is unnecessary; the book would have been better off without it.

OBITUARY.

J. L. WEEKS, general manager of the American Steam Gauge & Valve Company, died in Boston on April 2 from an operation for appendicitis. Mr. Weeks was well known throughout the steam and electrical engineering circles and made hosts of friends for his company.

CHESTER D. CRANDALL, general manager of the Western Electric Company, died recently at his home in Edgewater, Chicago. Mr. Crandall was graduated from the University of Rochester in 1879, and shortly thereafter became connected with the Western Electric Company. He has been a prominent figure in Bell telephone work for many years.

THEODORE E. THEBERATH, formerly engineer for the San Francisco district office of the Stanley Electric Manufacturing Company, died at his home in San Francisco on March 29 after a brief illness. At the time of his death Mr. Theberath was connected with the California Gas & Electric Corporation; his last engineering work was the construction of the De Sabla hydraulic-electric plant.

JAMES W. HINKLEY, president of the Consolidated Electric Light & Power Company, Poughkeepsie; vice-president of the Roebling Construction Company, and a director in the Consolidated Car Heating Company, died on April 11 at his home in Poughkeepsie, from apoplexy. Mr. Hinkley was a native of New York State and descended from Puritan ancestry. He was very prominent in businiess circles; in addition to the offices just mentioned, he was president of the United States Casualty Company and director in the International Bank & Trust Company of America, the National Bank of North America and the Poughkeepsie Trust Company, and when the Walker Company was absorbed by the Westinghouse Electric & Manufacturing Company he was its president. He leaves a widow and eleven children, one of whom is Captain J. W. Hinkley, Jr., who is now stationed at Fort Washinigton.

PERSONAL.

MR. A. V. PHILLIPS has been elected president of the Electric Supply & Maintenance Company, Troy, N. Y.

MR. F. V. T. LEE has been appointed manager of the Ft. Wayne Electric Works' new branch office at San Francisco.

MR. FRANK SUTTON, consulting engineer, has removed his offices to rooms 801-804 at 91 Wall Street, New York.

MR. C. C. CRAFTS, of the Westinghouse Company's export department, recently returned from a very satisfactory trip to Mexico.

MR. F. D. PHILLIPS, who was for some time with the Electric Appliance Company, Chicago, has been elected vice-prisident of the Crescent Company, of that city.

MR. E. W. RICE, JR., chief of the engineering department of the General Electric Company, has been elected a director of the company to succeed the late W. C. Whitney.

MR. W. P. FIELD, formerly of the St. Louis office of the Crocker-Wheeler Company, will be put in charge of the company's new office in New Orleans when that office is opened on May 10.

MR. FRED SARGENT, the well-known consulting engineer of Chicago, recently returned from a trip to Europe, where he spent several weeks investigating the steam turbine and central station development in that country.

MR. C. C. STARR, formerly of the firm of John Starr, Son & Co., has been appointed representative of the Canadian Westinghouse Company, Ltd., for the maritime provinces, with headquarters at 134 Granville Street, Halifax, N. S.

MR. P. G. GOSSLER has resigned his position as general superintendent and engineer of the Montreal Light, Heat & Power Company to accept the general managership of the operating department of J. G. White & Co., of New York.

MR. W. A. CALDWELL, formerly connected with the Chicago office of the Standard Underground Cable Company and recently located at the home office of the company, has been appointed manager of the company's new St. Louis office, recently established.

MR. W. H. DOPP, who has been for some time on the staff of the Stanley Electric Manufacturing Company, Pittsfield, Mass., has severed his connection with that company to accept the position of superintendent of the Pope Manufacturing Company's branch factory at Hagerstown, Md.

MR. G. L. CROSBY has been appointed district representative of the Western Electrical Instrument Company for Western Pennsylvania, Ohio and Michigan, and has established headquarters at 426 Williamson Building, Cleveland, Ohio. Mr. Crosby will also handle the General Incandescent Arc Light Company's circuit-breakers.

MR. W. F. BAKER has been appointed contract agent for the New York Telephone Company, to succeed Mr. F. H. Bethell, who has been promoted to the managership of the Potomac Telephone Company. Mr. Baker has been with the contract department for over six years, and during the past two years has been special agent for the Dey Street division.

MR. W. F. WARDEN, president and general manager of the Burt Manufacturing Company, Akron, Ohio, sailed for Europe on April 15. Mr. Warden will visit his company's agents in England, France, Germany, Belgium, Denmark, Norway, Sweden and Russia. Mr. J. Asa Palmer, secretary of the company, will have charge of its affairs during Mr. Warden's absence.

MR. ERVIN DRYER, of the Westinghouse Electric & Manufacturing Company's sales department, has resigned his position there to accept a similar one with the Allis-Chalmers Company. Mr. Dryer is one of the best known and most popular salesmen in the electrical and mechanical field. His headquarters will be at the Chicago office of the company, and the scope of his work will include the sale of steam machinery as well as electrical apparatus.

MR. ARTHUR WARREN, the originator of the Westinghouse Companies' publishing department and the manager of that department from its inception up to February 1 of this year, has organized a similar bureau for the Allis-Chalmers and Bullock interests, with headquarters in the New York Life Building, Chicago. Although Mr. Warren's appointment was very recent, the influence of his department is already being felt throughout trade circles.

MR. E. R. CARICHOFF, who has been prominently identified with the engineering staff of the Otis Elevator Company for several years past, is now on the staff of the International Steam Pump Company and is engaged in installing a very complete lighting and power distributing plant at the new works of that company, which are in course of construction at Harrison, N. J. All of the machinery will be driven by electric power, and many of the tools will have individual motors.

MESSRS. KEMPSTER B. MILLER and S. G. McMEEN, widely known telephone engineers, have embarked in consulting engineering and patent work, with headquarters at 1442 Monadnock Block, Chicago. Mr. Miller is a graduate of Cornell University and has had several years' experience as examiner of telephone patent applications in the U. S. Patent Office, which position he gave up to join the staff of the Western Telephone Construction Company, Chicago, one of the pioneer independent telephone manufacturers. Later he was instructor in telephony for the International Corespondence Schools, from which position he went to the Kellogg Switchboard & Supply Company, where he did notable work in furthering independent telephone interests. Mr. McMeen was long chief engineer of the Central Union Telephone Company. He is a graduate of Purdue University and went to the Central Union Telephone Company immediately after graduating.

TRADE PUBLICATIONS.

ELECTRIC BLUEPRINT OUTFITS. General Electric Company.—This is bulletin No. 4374 devoted to blueprinting frames in which enclosed-arc lamps are used as the source of light.

PORTABLE CRANES. The Franklin Portable Crane & Hoist Company, Franklin, Pa.—A handsomely executed catalogue of pocket size, containing illustrations and tabular data of the well-known Franklin portable crane.

STANDARD FAN MOTORS. The Robbins & Myers Company, Springfield, Ohio.—Catalogue No. 38, illustrating and describing the line of Standard ceiling and desk fan motors built by this company and described in the March number of the AMERICAN ELECTRICIAN.

LIGHTNING ARRESTERS. Garton-Daniels Company, Keokuk, Iowa.—Catalogue No. 40 of standard size, in which the features of the well-known Garton lightning arresters are clearly explained with the aid of handsomely executed half-tone engravings.

"P-K" LIGHTING SPECIALTIES. H. T. Paiste Company, Philadelphia.—This is supplement No. 11 to the Paiste catalogue No. 10 and is devoted to "P-K" lamp sockets, plugs and receptacles, show-window receptacles, baby knife switches and rosettes.

NAME PLATES. Crowe Metal Manufacturing Company, Chicago.—A catalogue of standard size, containing *fac simile* illustrations of the various styles of name plates made by this company. The styles shown in the catalogue are all tasteful, and in many cases artistic in design.

ARC LIGHT SWITCHBOARDS. General Electric Company.—This is bulletin No. 4362, containing an illustrated description of the carrier bus arc light circuit switchboard panels manufactured for use in conjunction with Brush arc lighting dynamos. Connections are made by means of plug connectors and sockets.

HIGH-SPEED AUTOMATIC ENGINES. Ames Iron Works, Oswego, N. Y.—This is the latest catalogue of the well-known Ames automatic center-crank engine which is widely used for electric light service. The catalogue is well executed and the details of engine construction are fully illustrated and described.

PIPE TOOLS, DRILLS AND FORGES. John V. Gibbons, New York.—A well prepared catalogue of convenient size, devoted to pipe cutting and threading tools, pipe wrenches, hand drills, portable forges and steam specialties.

DIRECT-CURRENT MOTORS. Bullock Electric Manufacturing Company, Cincinnati, Ohio.—Bulletin No. 1023 superseding bulletins 1021 and 1022 and devoted to the Bullock type B motor, which is built in the bipolar type up to 7½ horse-power and in the multipolar type from 7½ to 25 horse-power.

ELECTRIC LIGHT AND RAILWAY EQUIPMENT. Railway & Electric Equipment Company, Philadelphia and Buffalo.—A vest-pocket pamphlet containing a list of generators, motors, engines, boilers, cars, rails, rotary converters and other power plant and railway equipment which the company has for sale.

DIRECT-CURRENT DYNAMOS AND MOTORS. The Holtzer-Cabot Electric Company, Boston, Mass.—Bulletin No. 300, containing a well-illustrated detailed description of the Holtzer-Cabot "Type M" direct-current dynamos and motors. These machines are built in outputs ranging from 1 horse-power to 160, with corresponding dynamo ratings.

THE S. K. C. SYSTEM. Stanley Electric Manufacturing Company, Pittsfield, Mass.—A nicely executed book entitled "A Synopsis of the S.K.C. System," and, as its title indicates, taininig illustrated descriptions of the various pieces of apparatus which are included in the system. These are too well known to require specific mention.

INTERIOR TELEPHONES. The Lambert-Schmidt Telephone Manufacturing Company, Weehawken, N. J.—Catalogue No. 11, containing profusely illustrated descriptions of the several types of interior telephone apparatus made by this company. The mechanical work on the catalogue is of almost as high a grade as that which characterizes the Schmidt apparatus.

INTERCOMMUNICATING TELEPHONE DIAGRAMS. The Holtzer-Cabot Electric Company, Boston, Mass.—Bulletin No. 149, containing diagrams for connecting up all of the various intercommunicating telephone systems manufactured by the Holtzer-Cabot Company. The bulletin also contains very useful information in addition to the diagrams and the remarks pertaining thereto.

DIRECT-CURRENT CRANE MOTORS. Westinghouse Electric & Manufacturing Company.—Circular No. 1077 containing an illustrated description of the new line of Westinghouse direct-current crane motors, which are series-wound machines known as "Type L." The controllers used in connection with these motors were described in the New Apparatus department of this paper.

CORLISS ENGINES. Murray Iron Works, Burlington, Iowa.—Catalogue No. 55, in which are illustrated and described the Murray Corliss engines. These are built in several forms of frame, including the simple and box girder frames, Tangye frame and the rolling mill type of frame. The catalogue also includes illustrations and data relating to boilers and feed-water heaters built by this company.

HAND-GEARED BLOWERS. Buffalo Forge Company, Buffalo, N. Y.—This is a pocket-size folder containing illustrations and brief descriptions of the Buffalo hand-operated blowers known as Nos. 99 and 100 and Buffalo portable forges equipped with these blowers. The fan shaft is mounted in ball bearings and is geared to the crank shaft through two sets of special gears which are completely enclosed and also mounted on ball bearings.

ELECTRO-MECHANICAL SPECIALTIES. Engberg's Electrical & Mechanical Works, St. Joseph, Mich.—A nicely executed catalogue of standard size, containing illustrated descriptions of engine and generator sets, switchboards, search lights, electro-hydraulic valves and other specialties. The generating sets are very compact, consisting of a single cylinder vertical engine, of the automatic cut-off type, of course, direct-connected to a six-pole direct-current dynamo.

DIRECT-CURRENT MOTORS. Sprague Electric Company, New York.—Bulletin No. 216, containing an illustrated description of the Sprague Company's latest line of motors which is known as the M. C. Type. These are all four-pole machines, except the smallest size, which is bipolar, and are wound for outputs ranging from 5 horse-power to 20 in slow and moderate speeds, with open frames, and correspondingly reduced outputs with semi-enclosed and entirely-enclosed frames.

THREE-PHASE TRANSFORMERS. General Electric Company.—Bulletin No. 4370, containing illustrations and a description of the G. E. three-phase air-blast transformers which are of the so-called shell type. The advantages of a three-phase transformer over three single-phase transformers are graphically presented by several of the illustrations, and the construction of the three-phase apparatus is also clearly shown. These transformers are built in sizes ranging from 150 to 1100 kilowatts.

RAILWAY MOTORS. General Electric Company.—Bulletin No. 4361, devoted to the G.E.-70 motor, which is somewhat similar to the G.E.-74 machine recently brought out. A distinctive feature of the new motor is in the construction of the field-magnet frame. The frame is an octagonal box divided horizontally, but the dividing line is not through the center of the motor as in the ordinary type of machine; it is considerably above the center line. The armature shaft bearing housings are cast with circular flanges which fit into suitable spaces in the ends of the lower part of the field-magnet frame.

ELECTRIC HEATING APPARATUS. Simplex Electric Heating Company, Cambridge, Mass.—This is catalogue No. 12 and contains 82 pages of illustrated descriptive matter relating to the large line of electric heating apparatus manufactured by the Simplex Company. The line includes chafing dishes, coffee urns, tea pots, milk warmers, ornamental griddles, sauce pans, ovens, broilers, waffle irons, and almost every other form of cooking utensil; immersion coil heaters, heating pads, curling-iron heaters, glue pot heaters, soldering irons, sterilizers, smoothing and pressing irons and other laundry utensils. Radiators and foot warmers are also included in the line, and the company supplies all of the necessary fittings, such as switches, plugs, connectors, etc.

◆ ◆ ◆

BUSINESS NEWS.

CURTIS STEAM TURBINES are to be installed in the station of the Nice Gas & Electric Company, Nice, France.

THE MAXFIELD-FRANCKE COMPANY has removed its main offices from 120 to 136 Liberty Street, New York.

BALL ENGINE COMPANY, Erie, Pa., reports a continuance of good business in its well-known lines of automatic and Corliss engines.

FORT WAYNE ELECTRIC WORKS, Fort Wayne, Ind., have established a Pacific Coast office in San Francisco, at 69-75 New Montgomery Street.

ELECTRICAL EQUIPMENT AND SUPPLY COMPANY, Pittsburg, Pa., has been appointed representative of the Yost Electric Manufacturing Company for Pittsburg and vicinity.

WILLIAM S. BROWN, New York representative of the Chase-Shawmut Company, of Newburyport, Mass., has removed his offices from 39 Cortlandt Street to 3 West 29th Street.

GARTON-DANIELS COMPANY, Keokuk, Iowa, reports that its business for the first three months of the current year is considerably greater than that of any similar period in previous years.

HUGO REISINGER, New York, importer of electra carbons, has been awarded the contract by the Louisiana Purchase Exposition Company for all of the carbons required by the Exposition.

G. M. GEST, New York and Cincinnati, has been awarded the contract by the Bell Telephone Company of Cincinnati for the installation of a large conduit system in Cumminsville, a suburb of Cincinnati.

BROWN-CORLISS ENGINE COMPANY, Corliss, Wis., reports among recent sales two large tandem compound condensing Corliss engines, ordered by the Phillips Insulated Wire Company, Pawtucket, R. I.

THE STANDARD UNDERGROUND CABLE COMPANY, Pittsburg, Pa., has established a branch office in the Security Building, St. Louis, Mo. The company now has seven district offices throughout the country.

GOULD STORAGE BATTERY COMPANY will remove its offices on May 1 from 18 West 34th Street to the New Century Building, 1 West 34th occupying the entire eighth floor of the New Century Building.

THE NERNST LAMP COMPANY has removed its Boston office from 131 State Street to 501 Atlantic Avenue. Mr. George C. Ewing will continue as district manager, and the office will carry a complete stock of Nernst lamps and supplies.

WESTERN TELEPHONE MANUFACTURING COMPANY, Chicago, Ill., has leased commodious quarters in the Atlantic Building, 42 West Jackson Boulevard, and removed its factory and office from 73 West Jackson Boulevard to the new quarters.

HYATT ROLLER BEARING COMPANY, Harrison, N. J., has broken ground and let contracts for a 75-foot addition to its new machine shops, this addition being rendered necessary by increased business notwithstanding the new shops have been completed only six months.

THE MURRAY IRON WORKS COMPANY, Burlington, Iowa, advises us that the Murray Corliss engine at the St. Louis Exposition grounds was started up on April 10 and was the first one of the group of engines in the intramural railway power station to be put in operation.

THE ELECTRIC STORAGE BATTERY COMPANY, Philadelphia, now has Exide battery stations in twelve cities distributed throughout the country. Each of these stations is in charge of an experienced storage battery man and stocked with a full line of automobile battery material.

SCOTT & HAUGER, Rockwood, Pa., have been awarded the contract for installing a complete electric light plant at the Markleton Sanitarium, Markleton, Pa., to replace the one recently destroyed by fire. The generating equipment will consist of Erie engines and Milwaukee generators.

ELECTRICAL TESTING LABORATORIES is now the title of the company heretofore known as The Lamp Testing Bureau. The company has moved into its new office and laboratories at 80th Street and East End Avenue, New York, and is prepared to do testing and standardization of all classes of instruments and electrical apparatus.

THE D. & W. FUSE COMPANY, Providence, R. I., has brought out a remarkable insulation for magnet wires, which is designed to supersede the ordinary cotton covering now used. The new insulation is a preparation of asbestos and is said to be indestructible and at the same time the full equal or superior in insulating properties of the standard double cotton covering.

THE F. BISSELL COMPANY, Toledo, Ohio, reports large sales of its automatic time switches. These compact devices are meeting with much favor for the control of lamps in display windows. The use of the switch enables the store proprietor to leave his lights burning when the store is closed for the day and have them extinguished at a predetermined hour later in the night.

KELLER, PIKE & CO., Philadelphia, have established a branch office in Baltimore, Md., at 211 North Calvert Street. This office will be in charge of Mr. John S. Dobler, of Baltimore, who has had a wide experience in electrical contract work. The firm has just been awarded the contract for the complete mechanical and electrical equipment of the new Camden County court house.

THE H. W. JOHNS-MANVILLE Company is constantly in receipt of highly commendatory letters relating to its Kearsarge gaskets. A recent letter from Missouri states that Kearsarge and rubber gaskets were applied simultaneously to two different engines, an equal number of each to each engine, and that up to date the Kearsarge gaskets have each outlasted fifteen other gaskets.

THE BRISTOL COMPANY, Waterbury, Conn., is sending its World's Fair exhibit to St. Louis. The company's booth will be located in space No. 36, near the main entrance of Electricity Building, and will contain a complete line of the well-known Bristol recording instruments in various styles and sizes. There will also be exhibited a full line of Bristol steel belt lacing.

NEW JERSEY ASBESTOS COMPANY, Camden, N. J., reports that its "Gladiator" asbestos-metallic goods have met with much success. The company makes a complete line of asbestos-metallic packings, gaskets, etc., composed of asbestos sheeting with fine brass wire spun into the center of the threads of both warp and woof, the fabric being rendered water-proof by a coating of India rubber solution.

GOLD CAR HEATING & LIGHTING COMPANY, New York, has taken a large suite of offices in the Whitehall Building, 17 Battery Place, New York, and has transferred both its New York and Chicago offices to these headquarters. The company announces that it has made an arrangement whereby it has the exclusive sale in the United States of the new Edison storage battery for car lighting purposes.

THE REEVES ENGINE COMPANY, Trenton, N. J., reports among recent sales the following: A 400-h.p. vertical cross-compound engine to the Drew-Selby Company, Portsmouth, Ohio, and a similar engine to Platner & Stoddard, Dayton, Ohio; a large vertical cross-compound engine for the Trenton Mills and Elevator Company, and three simple horizontal engines to the Construction Railroad Company, New York. All of these are for driving electric generators.

B. F. STURTEVANT COMPANY, Boston, Mass., has made generous recognition of its publication department in the allotment of space in its new building at Hyde Park. A portion of the basement about forty feet square will be devoted to a press room and a storage space for paper stock and printed matter, and a complete equipment of type and printing presses will be installed. Immediately above the printing room will be offices for the artists, clerks and others in this department.

THE STANDARD VITRIFIED CONDUIT COMPANY, New York, since completing its large plant at South River, N. J., is in splendid position to take care of its rapidly growing business. The company's manufacturing plant has been crowded continuously since it began operations in 1902, and the new plant with its fine equipment of machinery and greater facilities in every way will relieve the pressure considerably. The company is manufacturing single and multiple-duct conduit, and the factories now have a capacity of about 40,000,000 feet per annum.

CROCKER-WHEELER COMPANY, Ampere, N. J., will open a branch office in the Hibernia Bank Building, New Orleans, on May 10. Although the company has fifteen branch offices throughout the country, including one at St. Louis and one in Atlanta, the New Orleans office has been found absolutely necessary in order to take care of the steadily increasing business in the South and Southwest. The company recently increased its capital stock from $1,000,000 to $2,000,000 and is now one of the largest electrical manufacturers below the financial plane of the General Electric and Westinghouse companies.

NATIONAL ELECTRIC COMPANY, Milwaukee, Wis., has inaugurated a new department which will undoubtedly be a blessing to those connected with the company. This comprises two pleasant dining rooms, a butler's pantry and a kitchen, the object being to supply dinner to those engaged in the executive and engineering departments of the company at the company's expense. While there will be no charge to the employees for the dinners, the company frankly confesses that its motives are not entirely philanthropic; it is believed that this arrangement will result in closer touch, and consequently more efficient co-operation, between the various members of the executive and engineering staffs.

THE FOOS GAS ENGINE COMPANY, Springfield, Ohio, recently gave an interesting demonstration of its "special electric" gas engine at its works. A number of representatives from well-known electrical manufacturing companies were present at the tests. The engine was built for the Foos exhibit at the St. Louis Exposition and is of the four-cycle type with throttling speed regulation. On the occasion mentioned, the visitors were shown some twenty gas engines for ordinary service on the testing floor and a hundred or more ready for shipment. Among the electrical manufacturers represented at the tests were the Fort Wayne Electrical Works, the Crocker-Wheeler Company, the Thresher Electric Company, the Akron Electric and Manufacturing Company and the Jenney Electric Manufacturing Company.

CENTRAL STATION NEWS

ALABAMA.

JACKSON.—Mr. B. H. Warren is said to be interested in the establishment of an electric light plant here.

MARION.—The Marion Light & Power Company recently added a duplicate alternator to its equipment.

HUNTSVILLE.—Mr. A. B. Coryell is now superintendent of the Huntsville Railway, Light & Power Company.

CULLMAN.—Mr. A. Dreher, Jr., has been made purchasing agent of the municipal electric light plant of Cullman.

DEMOPOLIS.—It is the intention of the Demopolis Electric Light & Power Company to extend its plant by the addition of a brick engine room 37 ft. x 75 ft.

SELMA.—The Selma Lighting Company is contemplating enlarging its plant and for this purpose will install a new boiler, engine, steam pipe line and accessories.

TALLADEGA.—The Talladega Light & Power Company has let the contract for the construction of a dam at Choccolocco Creek, about eight miles from here. The dam, it is said, will cost $25,000 and will increase the capacity of the present plant considerably.

ALASKA.

DAWSON CITY.—The Dawson Electric Light & Power Company, Ltd., is considering the installation of underfeed stokers.

STEWARD.—Articles of incorporation have been filed by Mr. George E. Dickinson and George Sohus for the Steward Electric Company.

ARKANSAS.

PINE BLUFF.—The Pine Bluff Light & Water Company intends to install a new engine direct connected to an alternating-current generator.

HARRISON.—The Harrison Electric Lighting & Ice Company has added a day circuit to its service; the current is supplied upon a meter basis exclusively.

MALVERN.—Mr. Joseph Brown is now superintendent and chief engineer of the Malvern Light & Power Company. It is understood that the company contemplates installing a new dynamo and boiler.

MONTICELLO.—The present officers of the water and light plant are reported as follows: Mr. Patrick Henry, president; Mr. George A. Knox, secretary; Mr. J. J. McClay, treasurer; Mr. D. A. Tramwell, chief engineer, and Mr. W. J. Kinney, chief electrician.

CALIFORNIA.

LOS GATOS.—Mr. J. D. Farwell is now manager and superintendent of the Los Gatos Light & Power Company.

LODI.—Cary Bros. have completed arrangements for connecting their plant with the American River power line.

MARTINEZ.—The Contra Costa Electric Light Company is considering the construction of a seven-mile line to Concord.

FERNDALE.—It is understood that the Ferndale Electric Light Company contemplates installing an entire new outfit.

SAN FRANCISCO.—Mr. J. F. Lawless has succeeded Mr. A. Pollock as manager of the San Francisco Gas & Electric Company.

BERKELEY.—The contract for lighting the city for two years beginning April 1 has been secured by the Berkeley Electric Company.

SANTA PAULA.—The city contract of the Santa Paula Electric Company provides for forty 16-c.p. incandescent lamps on a moonlight schedule.

FULLERTON.—The City Attorney has been advised to prepare advertisements offering for sale a franchise privilege for electricity for light and power purposes.

EL PASO.—It is reported that an electric power plant will soon be established here by the Southern Pacfic Company for operating the machinery in its railroad shops.

SANTA CLARA.—The city electric light plant is now being supplied with high-tension current by the Standard Electric Company over a long-distance transmission line.

VISALIA.—The Mt. Whitney Power Company, of this place, is erecting a second power plant, the equipment to consist of three 500-kw. units driven by a Stillwell-Bierce & Smith-Vaile turbine.

SAN FRANCISCO.—Articles of incorporation have been filed by the Century Electric Corporation, composed of F. L. Greenwood, C. M. Wood, and others. The new company is capitalized at $250,000.

LOS ANGELES.—The Edison Electric Company of Los Angeles is installing a gas plant at San Pedro. Contracts for the apparatus have been closed. The company is now doing business in ten or a dozen cities and towns in Southern California.

SAN FRANCISCO.—Mr. Theodore E. Theberath, electrical engineer, died at his home in this city on March 29, after a brief illness. He was sent to the coast as engineer for the San Francisco district agency of the Stanley Electric Manufacturing Company and of late years has been in the employ of the California Gas & Electric Corporation. He was 40 years of age at the time of his death.

SAN FRANCISCO.—It is stated by an official of the California Gas & Electric Corporation that while the water supply and electric power plants owned by the South Yuba Water Company and the Central California Electric Company have not yet been taken over, the option held will probably be exercised very shortly. This deal and the taking over of the Standard Electric Company were arranged for at the same time and the financing of the one depended upon the other.

YREKA.—It is reported that the Little Shasta Power Company, which was recently incorporated, is to be a sub-company of the Siskiyou Electric Power Company, who have signed contracts to deliver at Montague all of the power required by the former company. The Terwilliger power line has been purchased by the Little Shasta Company, who will supply current for light and power throughout the Little Shasta Valley. Among those promoting the enterprise are Mr. W. H. Roberts, Mr. M. T. Jones and Mr. J. F. Reisser.

SAN FRANCISCO.—The new equipment to be installed by the San Francisco Gas & Electric Company in their plant at Station "A" includes one General Electric 11,000-volt, rotating-field, engine-type generator, a Union Iron Works vertical engine and five Babcock & Wilcox boilers. The generator will be direct-connected to the triple expansion engine. Two of the engines from Station "B" will be moved to Station "A," formerly owned by the Independent Electric Light & Power Company. This will have a capacity of 15,000 kilowatts or more and is to be made the principal generating station for the city. The changes will enable the company to dispense with steam engines at the old stations. Charles C. Moore & Co. secured the contract for the new boilers and the moving of six Heine boilers from another station, together with the remodeling of the boiler plant. The boilers will all be equipped with B. & W. marine oil furnaces and the Charles C. Moore & Co. oil fuel system will be installed. The five new B. & W. boilers will have forged-steel drums and superheaters, and two special Goubert oil heaters will be used. The auxiliaries will also be supplied through Charles C. Moore. Instead of extending the electric motor system for condensing apparatus, etc., steam-driven pumps will be used throughout. The plant will be equipped with two compound duplex Snow feed pumps, each having a capacity to feed a 16,000-h.p. boiler plant.

COLORADO.

MONTROSE.—The Montrose Electric Light & Power Company expects to double the present capacity of its plant.

ROCKWOOD.—Work is being pushed on the large power plant of the Rockwood Power Company. It is expected that this plant will supply electricity for power and light to enterprises and towns in five counties. The reservoir, it is said, will be the largest in the state.

VICTOR.—It is reported that plans are under way for the erection of an electric plant to be owned by individuals of the city on a co-operative plan. Mr. C. L. Varney is chairman of the Ways and Means Committee appointed by the citizens at a mass meeting held recently.

LAKE CITY.—The present officers of the Hinsdale Electric Light & Power Company are reported as follows: President and manager, W. F. Green, of Lake City; secretary, C. H. Meyer, Gunnison; treasurer, Miss Ida V. Meyer, Gunnison; chief engineer, A. C. Johnson, Lake City.

DURANGO.—The Durango Light & Power Company is contemplating a change from 55-volt secondary distribution to 110-220 volts, three-wire system; each block in the business section to be supplied through one transformer, and every two blocks to be supplied through one transformer in the residence section.

CONNECTICUT.

WALLINGFORD.—The Borough Electric Works are adding a new 225-kw. machine to their equipment.

WOODBURY.—It is said that the reservoir and electric light plant which it is proposed to construct here will cost $15,000.

PUTNAM.—The Putnam Light & Power Company expects to erect a new station at Mechanicsville and will extend its lighting and power service to that town.

HARTFORD.—The report of the special committee appointed to consider the matter of street lighting recommended the rejection of all bids received and, after further investigation, advertising for new bids.

GLASTONBURY.—The Glastonbury Power Company has been incorporated, under the laws of Connecticut, with an authorized capital stock of $350,000, the object of the company being to develop the water power of Roaring Brook for electric purposes. The project calls for the immediate development of 1600 horse-power. A steel and concrete power station will be erected and two reservoirs built. The incorporators are Lewis W. Ripley, Henry S. Goslee, D. Willard Williams, James S. Williams, J. H. Hale and Frank D. Glazier.

DELAWARE.

DOVER.—At a recent meeting of the Town Council, the Water and Light Committee recommended that $8,500 be expended for improvements to the water and light plant.

DISTRICT OF COLUMBIA.

WASHINGTON.—A bill has passed the Senate and is now in the hands of the District of Columbia Committee in the House, providing for the regulation of electric wiring in the District of Columbia.

FLORIDA.

JACKSONVILLE.—A 500-kw. generator will soon be added to the equipment of the electric light plant here.

BARTOW.—New dynamos and engines are about to be installed in the city electric light plant.

TAMPA.—The suit for $25,000, recently instituted by Mrs. Lila Hunnicut against the Tampa Electric Company for the death of her husband, has been thrown out of court.

Readers are cordially invited to contribute to this department items of news relating to plants in their vicinity.

GEORGIA.

AUGUSTA.—Mr. James W. Jackson is now president of the Augusta Railway and Electric Company, and Mr. C. G. Goodrich is vice-president.

GAINESVILLE.—The city water and light plant is to be furnished with a complete new equipment for 75 or 100 alternating-current enclosed arc lamps.

ELBERTON.—The City of Elberton is preparing to install a new dynamo and water-wheel governor, and it is thought that a higher dam will be built.

GREENSBORO.—A franchise for the construction and operation of an electric light plant has been granted to R. L. West, of Atlanta, and T. B. Rice, of this place.

SAVANNAH.—The Savannah Electric Company is considering the matter of extending its lines to Tybee, Ga., for the purpose of furnishing lighting current to that town.

COLUMBUS.—Upon the recommendation of the Lighting Committee, the proposition of the Columbus Railroad Company to furnish street lighting for 1905, 1906 and 1907 has been accepted.

IDAHO.

GRANGEVILLE. — The Grangeville Electric Light and Power Company will build a line to Denver, Cottonwood and Dewey.

BURKE.—The Canyon Creek Electric Company has placed an order for a 100-h.p. motor to take the place of the engine now in use.

COEUR D'ALENE.—The Consumers Company, of this place, has received the machinery for the addition which it is making to its electric plant.

NEZPERCE.—The Nezperce Electric Light and Power Company is considering the erection of a line to Greer and also one to Mohler, both in this State.

MOSCOW.—It is expected that the Moscow Electric Light and Power Company will soon establish transmission lines to Pullman and Genessee, and will use water power from Asotin.

LEWINSON.—Attorney J. H. Smith, representing Judson Sanford, is asking the City Council for a 25-year franchise for the construction of an electric line over the streets and alleys of the city.

POCATELLO.—The American Falls Power, Light and Water Company is arranging for the construction of a new generating station and substation, which will be duplicates of those already in operation.

MOSCOW.—Mr. Francis Jenkins, of this city, is reported to have purchased the right to utilize the Elk Creek Falls, about fifty miles above Lewiston, and will build a large plant for the generation and transmission of power.

NEZ PERCE.—Judge Stearns and Mr. E. A. Eitsen, who have been obtaining the rights of way along the proposed electric road between this point and Lewiston, report that with the exception of three places all have been secured for the entire distance. The three places that have withheld right of way are delaying on account of rights sold to the Northern Pacific Company five years ago.

ILLINOIS.

PARIS.—New boilers have been added to the equipment of the municipal electric light plant.

OTTAWA.—It is estimated that the proposed electric light plant for Ottawa will cost $8,000.

MT. OLIVE.—Several improvements to the municipal electric light plant are contemplated.

WASHINGTON.—The Eagle Electric Works have substituted enclosed arc lamps for open arc lamps.

LOCKPORT.—It is proposed to enlarge and improve the municipal electric light plant in the near future.

SULLIVAN.—An addition of five arc lamps has been made to the lighting circuit of the City Light and Water Works.

CHARLESTON.—Mr. E. C. Jenks is now manager and superintendent of the Charleston Gas and Electric Company.

LINCOLN.—The Lincoln Water and Light Company recently installed a new power line.

HILLSBORO.—The Hillsboro Electric Light and Power Company is engaged in building a 12-mile transmission line.

BATAVIA.—Mr. A. R. Augustine is now superintendent of the municipal electric light and water plant of this place.

GREENUP.—The Municipal Electric Light Plant is said to be contemplating changing from direct to alternating current.

CORNELL.—The Cornell Electric Light Company is preparing to enlarge its electric plant and install a steam heating plant.

QUINCY.—The Council has under consideration the granting of a franchise to the Independent Gas and Light Company.

EFFINGHAM.—Bids will be received May 17 for lighting the streets and alleys here with about sixty arc lights of 2000 candle-power each.

WHEATON.—It is expected that the equipment of the municipal plant will be increased by the addition of a 150-h.p. engine and boiler.

O'FALLON.—The O'Fallon Electric Light, Power, Heat and Water Company is putting all its arc lights on alternating-current circuits.

NUNDA.—The Union Light and 'Phone Company expects to increase its equipment by the addition of a new engine, boiler and dynamo.

ATHENS.—The Burnett-MacMaster Electric Light Company is planning to increase the capacity of its plant by adding another 100-h.p. boiler.

GREENVILLE.—The Greenville Electric Light, Heat and Power Company recently installed 38 140-cycle constant-potential arc lamps for street lighting purposes.

CHICAGO.—The Commonwealth Electric Company proposes to extend its plant and for this purpose has purchased property on Chicago River adjacent to its works.

RIDGEFARM.—It is reported that a company was recently organized by C. O. Linn and William Henderson for the purpose of erecting an electric light plant here.

CHICAGO.—It was recently voted by the stockholders of the Lake Street Elevated Railroad to change the name to the Chicago & Oak Park Elevated Railroad Company.

HENNING.—Mr. Robert Wilson, of this place, recently bought the plant of the Potomac Electric Light Company and it is stated that he will at once extend the line to Henning.

WOODSTOCK.—The municipal plant recently adopted alternating-current series arc lamps and the erection of additional alternating-current lines for street lighting purposes is contemplated.

ASHLEY.—The municipal electric light plant, which began operation last year, is making a good showing. Mr. G. Johnson is manager and chief electrician and Mr. Z. Johnson is chief engineer.

ALPHA.—The Alpha Electric Light and Power Company is considering extending its service to an adjoining town, for which purpose it will be necessary to erect from five to eight miles of new lines.

MATTOON.—The Mattoon Heat, Light and Power Company considers the flat rate system unfair to its meter customers and announces that after June 1 the meter system will be used exclusively.

MT. MORRIS.—The Mt. Morris Electric Light and Power Company is now operating a direct-current day circuit and expects to install a new boiler and a direct-connected unit during the coming summer.

STERLING.—The Sterling Gas and Electric Light Company is replacing the old poles in the down-town district with new ones of uniform size. When this work is completed the apparance of the business section will be greatly improved.

QUINCY.—The Quincy Gas and Electric Company has made improvements in the equipment of its power plant involving an expenditure of $25,000. The improvements will include a 2000 horse-power engine and boiler and a new dynamo.

MARSEILLES.—Mr. W. D. Boyce, head of the water power industry here, announces that arrangements have been about completed to rebuild the dam which was recently destroyed by high water. It is estimated that the work will cost between $150,000 and $200,000.

HIGHWOOD.—Contracts for the new power station to be erected by the Chicago and Milwaukee Electric Railway have been let. The building, which will be of brick and steel construction, will cost about $150,000. The plant will have a capacity of about 1500 kilowatts.

PINCKNEYVILLE.—Bids are wanted May 2 for the construction of an electric light plant, and for power and attendance in operating the city water works pumping station. The operating company will be granted a franchise for a term of fifteen years. Thirty-five arc lights are required for the city lighting.

CARMI.—The municipal electric light plant is to be considerably enlarged. It is said that a new set of machinery will be installed which will be the duplicate of the present equipment, and that new motors and pumps are to be added. A day circuit has been added to the service and electric power will be furnished to drive the flour mills.

CHICAGO.—In his annual message to the Council, Mayor Harrison urges the passage of a law by the next Legislature providing for municipal ownership of the gas and electric light plants. He also proposes that the sanitary district water power be turned over to the citizens and that a portion of the $5,000,000 bonds be used to extend the electric lighting plant, lower the tunnels, etc.

CHICAGO.—The Commonwealth Electric Company recently acquired from the Joseph W. Drexel estate, in consideration of $65,000, 195,000 square feet of land on the south side of the Chicago river adjacent to its works, which will be used for extensions. Other real estate in that locality to the value of $565,200 has been purchased by the company, which has already expended in buildings and power plant from $2,000,000 to $2,500,000. It is estimated that within the next six or seven years it will expend at that place altogether $8,000,000.

INDIANA.

PLYMOUTH.—Mr. Fred Eich is now manager of the Plymouth Electric Light Company.

NOBLESVILLE.—Bids for a ten-year contract to light the city are being advertised for.

FLORA.—The Council has decided to construct water works and an electric light plant to cost about $20,000.

MARTINSVILLE.—The Martinsville Light, Heat, Power and Water Company expects to add to its boiler plant soon.

FT. WAYNE.—The Ft. Wayne Electric Light and Power Company will begin at once the reconstruction of its plant.

ATTICA.—The City of Attica is contemplating a general extension of its incandescent light system for residence lighting.

BICKNELL.—J. H. Barr & Co. are reported to have secured a franchise to erect an electric light and power plant in Bicknell.

RICHMOND.—It is reported that 187 street arc lamps are to be installed by the municipal electric light and power plant.

JASPER.—The electric light plant of this place has been purchased by the Town Board and will hereafter be operated by the city.

NEW HARMONY.—Bids will be received May 16 for furnishing material and construcing an electric light plant at this place.

CLAY CITY.—It is reported that a new engine is to be installed in the electric light and power plant some time during the year.

MICHIGAN CITY.—The Michigan City Electric Company is said to have obtained considerable new business, which will necessitate an extension of its lines.

MISHAWAKA.—The municipal lighting and power plant is considering the advisability of installing enclosed arc lamps to replace the open arcs in use at present.

MOORESVILLE. — The Mooresville Electric Light Company has been bought out by the Public Service Corporation, and Mr. B. V. Hubbard is now manager of the plant.

Readers are cordially invited to contribute to this department items of news relating to plants in their vicinity.

NEW HAVEN.—All bids opened on April 5 for the construction of an electric light plant have been rejected, and new bids will probably be called for again in May.

ELKHART.—It is reported that Mr. C. G. Conn has purchased the interests of the Elkhart Power Company and has applied for a franchise to install a new electric plant here involving an expenditure of $1,000,000.

ROANOKE.—The Town Council has made arrangements with the Ft. Wayne and Southwestern Traction Company for lighting the streets and business houses with electricity. The sub-station of the company will be moved to Roanoke.

FRANKLIN.—Mr. Taylor O. Ballard has resigned the superintendency of the Franklin Light and Power Company and has been succeeded by Mr. P. F. Morgan. It is Mr. Morgan's intention to make a number of improvements in the plant.

BOONVILLE.—The City Light and Power Company has been incorporated with a capital stock of $12,000. The incorporators are: John F. Hepp, S. W. Hart, J. F. Katterjohn, John E. Madden, Dorsey Reed, Louis J. Meyer and William Roth.

VINCENNES.—The Vincennes Light & Power Company was recently incorporated with a capital stock of $200,000. It is understool that the Edward M. Deane Company, of this city, is the parent concern which has taken over the light and power company.

BLUFFTON.—It is reported that the city electric light and power plant, which was installed at a cost of $35,000, has been accepted by the council from Contractor R. S. Ashe, of Richmond. The plant provides a street lighting system and an incandescent system and furnishes power for motors.

NEWBURG.—The equipment of the Newburg Electric Light and Power Plant will be increased during the coming summer by the installation of a new generator, engine and boiler, and it is expected that a complete system of water works will be put in some time this year.

ELKHART.—It is reported that negotiations have been recently closed between the St. Joseph & Elkhart Power Company and the South Bend Electric Company, whereby the latter company acquires the surplus power of the former. As the Buchanan hydraulic development is now furnishing power to the South Bend Electric Company under similar arrangements, all of the important electric power plants of the St. Joseph River Valley will be operated in harmony.

INDIAN TERRITORY.

ATOKA.—The new electric light and power plant, recently completed at this point, is now in operation and the town is well lighted.

ARDMORE.—The Ardmore Ice, Light and Power Company has been incorporated with a capital of $125,000. A. Ruemmeli, of St. Louis, Mo., and Henry Brann and L. P. Anderson, of Ardmore, are among the incorporators.

IOWA.

MASON CITY.—The recent election held in this city resulted in a vote to install an electric light plant.

CRESTON.—General repairs and extension of its pole lines are being considered by the Creston Gas and Electric Company.

CHARITON.—It is stated that the management of the city electric light plant is planning to reconstruct its lines this summer.

ALTA.—The entire municipal plant here is to be enlarged and improved in order to enable it to give more satisfactory service.

ACKLEY.—The Ackley Electric Light, Power and Heating Company is considering the addition of a 100-h.p. boiler to its equipment.

ROCK RAPIDS.—The city is enlarging its electric light plant and may possibly adopt alternating current in place of direct current.

LE MARS CITY.—The Le Mars City Water and Light Company has changed over to direct current enclosed arcs and raised the voltage of the system.

DENISON.—The Denison Electric Light and Power Company proposes to make additions to its plant so as to increase the capacity of the plant throughout.

DES MOINES.—Mr. J. R. Lovejoy is now president of the Des Moines Edison Light Company, which is reported to have a paid-in capital stock of $1,250,000.

SANBORN.—The Sanborn Electric Light Company is reported to be owned now by Mr. J. H. Boyd, president, and Mr. M. A. Gorman, general manager of the company.

PERRY.—The contract of the Perry Electric Light, Power and Heat Company with the city covers 8 arc lights of 1400 candle-power and 140 incandescent lamps of 25 candle-power, on moonlight schedule.

FT. DES MOINES.—Contracts have been awarded for the installation of an electric light system for Fort Des Moines. Current will be supplied by the Des Moines Edison Light Company, of Des Moines, Ia.

FORT DODGE.—Mr. John Eddy has just been made superintendent of the gas works of the Fort Dodge Electric Light & Power Company. He began work with the company some time ago as section foreman and has advanced steadily to his present position.

SIOUX CITY.—Mr. L. L. Kellogg, general manager for the Sioux City Gas & Electric Company, visited Philadelphia recently to attend the annual meeting of the United Gas Improvement Company. The projected improvements in the Sioux City plant will be made in accordance with Mr. Kellogg's recommendations.

NEVADA.—It is said that the Nevada Electric Light Company has completed arrangements for the erection of an addition to its power plant. A 150-hp Corliss engine will be installed as soon as practicable, and it is understood that other machinery has been ordered which will greatly A 150-h.p. Corliss engine will be installed as soon

KANSAS.

SALINA.—The People's Light, Heat and Power Company contemplates a complete reconstruction of its plant, of which Mr. G. H. Smedley is superintendent.

ELSWORTH.—The Ellsworth Electric Light Company has added a new generator to its electrical equipment and is considering the installation of a new steam plant.

GREAT BEND.—The Grimes Light, 'Phone and Power Company expects to install a new alternator between now and fall. Mr. C. E. Stromquest is now manager of the company.

WINFIELD.—A bond issue of $30,000 for electric light was recently voted for by the citizens, besides $89,000 for water works and $15,000 to be used in prospecting for gas.

McPHERSON.—The McPherson Water and Electric Works recently completed the installation of new machinery and boilers and the efficiency of the plant has been considerably increased thereby.

BURLINGAME.—It has been decided to enlarge and improve the electric light plant here and additional bonds to the amount of $6,000 have been voted for this purpose and to pay a small outstanding indebtedness.

JUNCTION CITY.—The Junction City Electric Railway Company, which now operates a railway line between this city and Fort Riley and also supplies the lighting service for the city, is preparing to extend its lighting service to Fort Riley. It is reported that the quarters and barracks at the Post will have about 5000 incandescent lights and 43 arc lights will be required for the streets. The improvements consist of an addition to the plant and the installation of new machinery costing about $100,000. Under its contract with the government, the company is to deliver the current to a certain point on the reservation and the government will control the distribution beyond that point.

TOPEKA.—A charter has been granted to the Kansas City & Topeka Railway Company, of this city, with a capital stock of $2,500,000. The board of directors is reported as follows: John R. Mulvane, J. C. Devlin and Charles S. Gleed, of Topeka; James A. Van Osdol, of Anderson, Ind.; and Henry L. Turner, E. B. Overshiner, A. B. Nettleton, G. A. Wulkup and Arthur Overshiner, of Chicago. Mr. Van Osdol, who is also president of the company, is general attorney for the Indiana Union Traction Company. It is the purpose of the company to build and equip a standard interurban railway between Topeka and Kansas City by way of Lawrence and Olathe. The new road will enter Kansas City over the rails of the Kansas City & Olathe Electric Railway, now nearing completion, and will traverse the counties of Wyandotte, Johnson, Douglass and Shawnee, coming in from Rosedale to the center of the city over the tracks of the Metropolitan Street Railway. Entrance to Topeka has been arranged for over the tracks of the Topeka Railway system.

KENTUCKY.

OWENSBORO.—A 60-kw. unit will probably be installed soon in the Municipal Electric Works here.

PRINCETON.—The Princeton Electric Light and Power Company is expecting to put in a new engine soon to replace the one now in use.

LOUISVILLE.—An ordinance requiring the placing of all wires underground in the business section of the city is being considered by the City Council.

MADISONVILLE.—The Bailey Light and Water Company reports that it is at present supplying the city with fifty lights, a number of lamps having been added recently.

CARLISLE.—The Citizens' Electric Light and Power Company has added 200 lamps to its service and is operating them on an alternating-current system of 1,100 volts.

PRINCETON.—Mr. J. T. Eddins, Mr. Charles Pepper and Mr. E. M. Johnson, all of this city, recently filed articles of incorporation for The Princeton Electric Light and Power Company, with a capital of $20,000.

FRANKFORT.—Decision has been rendered against the city in its suit to compel the Capital Gas and Electric Light Company to pay taxes on its franchise. The court held that they need not do so under the existing contract.

WICKLIFFE.—Bids are wanted by May 2 to furnish one 60-kw. 60-cycle single-phase engine-type alternator to be connected to an engine of sufficient horse-power; also an alternating arc-light system of 25 lamps capacity complete with regulating transformers, 17 arc lamps of 6.6 amperes capacity, etc.

LOUISIANA.

BASTROP.—The Corporation of Bastrop is planning to increase all of the equipment in its electric light and power plant.

ALGIERS.—The Algiers Water Works and Electric Company is arranging for the construction of an electric railway line and contemplates installing alternating-current machines in the power house.

OPELOUSAS.—Owing to the increased demand for electric light and power service, it is expected that the City Electric Light and Water Works will have to double the capacity of the plant before long.

MAINE.

PORTLAND.—It is thought probable that in the near future the electric wires on Congress Street, this city, will be placed underground. The committee on electrical appliances has received instructions to investigate and report upon the matter.

PORTLAND.—Mr. George F. Gould has been elected president of the Solomon River Ditch Company which was recently organized here. The company has a capital stock of $1,000,000, of which nothing has been paid in, and will conduct a general electric power, light and heat business.

MARYLAND.

BALTIMORE.—The City Council has granted a franchise to the Maryland Telephone and Telegraph Company, giving that company the right to extend its business into the electric light and power field.

KENSINGTON.—The proposition to issue bonds to the amount of $50,000 for the purpose of installing a water and lighting plant was op-

Readers are cordially invited to contribute to this department items of news relating to plants in their vicinity.

posed so strongly by the taxpayers that the mayor and council at a recent meeting decided to defer the matter indefinitely.

MASSACHUSETTS.

WESTON.—The Weston Electric Light Company recently increased its boiler plant.

MILFORD.—The office of the Milford Electric Light and Power Company is now at 131 State Street, Boston.

FALL RIVER.—The Fall River Electric Lighting Company recently declared a quarterly dividend of 1½ per cent.

STROUGHTON.—The Stroughton Gas and Electric Company has found it necessary to increase the capacity of its plant considerably.

AMESBURY.—The Amesbury Electric Light, Heat and Power Company, proposes to install an entire new equipment of electrical apparatus.

LYNN.—Mr. J. G. Lurvey has been transferred from the works of the General Electric Company here to the Publication Bureau of the same company at Schenectady.

WESTFIELD.—An appropriation of $10,500 was made at the annual town meeting for the installation and operation of a municipal power plant.

CLINTON.—The city contract of the Clinton Gas Light Company now includes, besides the arc lamps originally provided for, 205 incandescent lamps, to burn all night.

GREENFIELD.—The Greenfield Electric Light & Power Company recently put in a new boiler and a 750-h.p. engine. When the installations contemplated by the company are complete, the plant will have a capacity of 1100 horse-power.

NATICK.—In consideration of $14,000, the title to the plant formerly owned by the Natick Electric Lighting Company was transferred from the Edison Electric Illuminating Company, of Boston, to Messrs. Philip Dooskin and Nathan Finestone, both of Boston, comprising the Boston Bedding Supply Company. The deal included all the machinery, shafting, water supply, etc., formerly the property of the Natick Electric Company, but the deed specifies that the machines and appliances shall not be used by the new owners for the manufacture and distribution of electricity.

MICHIGAN.

ST. CLAIR.—The Municipal Electric Light Plant will add to its boiler plant.

LANSING.—A new arc dynamo may possibly be installed in the City Electric Light and Water Works next fall.

VICKSBURG.—Mr. George Butcher is now superintendent of the municipal electric lighting plant of this city.

ATHENS.—The Athens Electric Power and Lighting Company expects to put in a new completely equipped switchboard.

BAY CITY.—The citizens voted April 4 to issue $50,000 bonds to enlarge the capacity of the city lighting station for commercial lighting.

HART.—The Hart Electric Light and Water Works Company is contemplating installing a complete new equipment at its power plant.

HASTINGS.—This city was recently in darkness for two nights on account of the destruction of the dam of the Thornapple Electric Company by floods.

NORTHVILLE.—The Village of Northville is considering the addition of a generator and engine to the equipment of its electric light and power plant.

GRAND RAPIDS.—Floods recently disabled the electric lighting plant here by putting out the fires in the power house, leaving the city in darkness for a couple of nights.

CHEBOYGAN.—The Cheboygan Electric Light and Power Company has in course of construction an entire new water power plant capable of developing 1500 horse-power.

IONIA.—The Ionia Electric Light Company recently sustained a loss of about $15,000, due to the washing away of its plants and buildings at Wagar's Dam, four miles east of here.

ANN ARBOR.—Recent reports are to the effect that the Michigan Milling Company and Mr. Frank Cornwall are contemplating the construction of an electric light and power plant to cost about $150,000.

THREE RIVERS.—Mr. E. B. Linsley, secretary and treasurer of the Three Rivers Light and Power Company, states that the company's outstanding bonds have been reduced to $4000 as against the former amount of $11,000.

NEGAUNEE.—Extensive improvements are reported to be under consideration by the Negaunee & Ishpeming Street Railway & Electric Company. Plans are now being prepared for the enlargement of the electric light plant, and it is understood that the capacity will be increased from 5,000 to 10,000 incandescent lights. The plant will be completely overhauled and equipped with new machinery as part of the present outfit will be abandoned.

MINNESOTA.

WADENA.—The village electric light plant is to have a new power house.

CHISHOLM.—The Crowley Electric Company, of Duluth, has secured a franchise for a local lighting plant.

MARSHALL.—The city authorities are arranging to install new boilers in the municipal electric light plant.

DELANO.—The Delano Electric Light Plant will probably erect new pole lines some time between now and fall.

VASSAR.—A new 200-h.p. engine will probably be added to the equipment of the Municipal Electric Light Plant.

ATWATER.—The establishment of an electric light and water plant is reported to be under consideration by the council.

UNION CITY.—It is understood that the Union City Electric Light Plant contemplates installing a new engine and boilers.

WEST BRANCH.—The Rifle River Electric Light Company is planning to increase its equipment by putting in a new water-wheel and alternator.

WINONA.—The Winona Railway & Light Company is displacing its small engines and generators with two Curtis steam turbines and 500-kw. generators.

FARIBAULT.—The Faribault Gas & Electric Company is contemplating several improvements at its plant, among which will be the installation of a steam turbine.

WEST BAY CITY.—City Electric Light Plant is said to be contemplating an extension of its circuits which will necessitate the erection of about eight miles of lines.

BRECKENRIDGE.—The city council is considering the question of increasing the capacity of the Municipal Electric Light and Water Works by installing a 1,000,000-gallon steam pump.

MONTEVIDEO.—It is reported that the Montevideo Electric Light and Power Company, which is owned by Mr. E. A. Aspnes, is to be incorporated shortly and will utilize water power from some nearby source.

SHELBY.—It is reported that the present capacity of the municipal electric light plant is entirely too small to meet the demands of its increased business, and the plant will probably be enlarged and improved in the near future.

ST. PAUL.—Mr. G. S. Edmondstone, chief engineer for the Cannon River Electric Company, states that the company is preparing to build a dam and power house and install hydraulic and electric machinery for developing 2000 kilowatts on Cannon River, near St. Paul.

MISSISSIPPI.

MACON.—The Macon Ice, Light and Power Company is planning to enlarge its plant and equipment.

MERIDIAN.—The Meridian Light and Railway Company is engaged in erecting a new power house for its plant.

OSYKA.—A bond issue of $15,000 for water works and an electric light plant was recently voted for by the citizens.

YAZOO CITY.—The city light plant is making arrangements to operate continuously in order to supply current for fan and other motors.

HATTIESBURG.—The order providing for the sale of $60,000 bonds to construct or purchase an electric light plant has been passed by the Board of Aldermen.

DURANT.—A new plant is in course of construction at Lexington, this state, which will be operated by power furnished from the Durant municipal electric light plant.

STARKVILLE.—New equipment, consisting of one 150-h.p. boiler, a 3000-volt G. E. alternator and a 200-h.p. engine, will probably be installed in the municipal electric light plant.

BROOKHAVEN.—It is expected that a new boiler equipment will shortly be installed at the municipal electric light plant, and the alternators will probably be changed to 60 cycles frequency.

MISSOURI.

SHELBINA.—The Shelbina Electric Light Plant is adding to its lines.

CAMERON.—The municipal electric light plant is putting in a 6.5-amp. enclosed arc lamp circuit.

LIBERTY.—The Liberty Electric Light Plant is to put in a new generator during the coming summer.

BOWLING GREEN.—The power plant of Mr. N. H. Ledford is to be enlarged to three times its present capacity.

ST. LOUIS.—The Carondelet Electric Light and Power Company is putting in 150-kw. units in place of those now in use.

PLEASANT HILL.—Mr. J. O. McAllister states that he is now sole owner and manager of the Pleasant Hill Electric Light Plant.

BLOOMFIELD.—The Bloomfield Electric Light, Heat and Power Company is planning to extend its lines to another town seven miles distant.

DEXTER.—Several improvements to the city light plant will probably be installed and considerable new construction work will be done.

VERSAILLES.—Bids were recently closed for furnishing the necessary labor, material and equipment for the installation of an electric light plant.

HIGGINSVILLE.—It is rumored that the City Water and Light Plant is to be rebuilt and its equipment increased by about 200 horse-power in boilers and engines.

BUTLER.—The municipal electric light plant management contemplates installing two generators, one engine and a boiler, which will be duplicates of the machinery in use at present.

SEDALIA.—It was recently reported that the Sedalia Water and Light Company would consolidate shortly with the Gas Company and the Street Railway Company's lighting plant.

MOBERLY.—The citizens recently voted a franchise to the Moberly Light, Power & Fuel Company for the construction of an electric, gas, power and fuel plant; also a contract to light the city for a period of ten years.

ST. LOUIS.—Mr. Charles F. Foster, vice-president of the National Supply Company, of Chicago, has been appointed chief operating engineer of the immense World's Fair plant which has a capacity of 40,000 horse-power.

JOPLIN.—The Southwest Missouri Light Company, whose headquarters are in this city, recently closed a contract with the Conkey Mining Company, near Webb City, to supply the necessary power for operating its plant.

CHARLESTON.—The Southwest Missouri Ice, Light & Power Company has been incorporated with a capital of $100,000 for the purpose of erecting an electric light plant and ice factory. Among the incorporators are J. E. Armstrong and R. B. Boyce, of Charleston.

ST. LOUIS.—The Western Electric Company had a narrow escape from fire a short time ago. The fire started at the base of a post between the second and third floors of the building, but was discovered before any damage had been done beyond scorching the woodwork.

ST. LOUIS.—Suit was recently instituted by Mr. Morgan Jones, of Denver, Colo., in the United States Circuit Court to set aside the consolidation of the Union Electric Light & Power Company, the Citizens' Electric Light & Power

Readers are cordially invited to contribute to this department items of news relating to plants in their vicinity.

Company, and the Missouri Electric Light & Power Company, these companies being now constituents of the North American Company, of New York.

MONTANA.

GLENDIVE.—The Hughes Electric Light Company is arranging for the purchase of a 100-kw, 1040-volt, 133-cycle alternating-current generator some time between now and the fall.

NEBRASKA.

HEBRON.—The Hebron Light, Power and Heat Company is enlarging its plant.

FREMONT.—A new 200-h.p. engine is to be installed in the city electric light plant.

OSCEOLA.—The station equipment of the electric light plant here, owned by Mr. Clarence Miller, has been increased.

LINCOLN.—The citizens recently voted to issue $65,000 bonds for the purpose of constructing an electric light plant.

HOOPER.—The Hooper Electric Light Plant, owned by Mr. William T. Martin, is to be equipped with an additional boiler.

SEWARD.—The Seward Electric Light Plant, which began operation February 2, this year, is already contemplating extension of its service lines.

COLUMBUS.—Mr. A. Heinz, who owns and operates the Columbus Electric Light Plant, expects to put all arc lights on an alternating-current circuit.

BEATRICE.—The Beatrice Electric Company is remodeling its steam plant. Among other improvements contemplated are the erection of a new building and the extension of its service lines.

OMAHA.—The new power house which is being erected by the street railway company is about ready for the installation of the machinery. This work will take some time, however, so that the plant will not be ready for operation very soon. The cost of the new plant is estimated at $500,000.

LINCOLN.—Work on the new plant of the Lincoln Telephone Company was delayed a few days by the strike of the electrical workers employed by the General Engineering Company which has the contract for placing the outside work of the new system. No increase in wages was asked, but the men insisted that the scale should be signed for another year before going ahead with the work.

NEVADA.

TONOPAH.—The Tonopah Light and Power Company expects soon to increase the capacity of its plant.

NEW HAMPSHIRE.

BRADFORD.—The Bradford Electric Light Plant, which is owned by Mr. C. A. Hadley, is contemplating the construction of a three-mile extension.

MEREDITH.—Mr. E. Carleton Mansfield, manager of the Meredith Electric Light Company, was recently in Providence, R. I., for the purpose of consulting with the owner of the plant concerning the wishes of Meredith in regard to the lighting of the streets of the town for the ensuing year.

GARVIN'S FALLS.—The electrical apparatus for the new hydro-electric plant here will consist of General Electric three-phase generators with an aggregate capacity of 6000 horse-power. This power will all be used by the Manchester Traction Light & Power Company, which controls the street railway, lighting and power interests of Manchester, N. H. This company also supplies current for a portion of the Concord & Manchester electric branch of the Boston & Maine Railroad.

NEW JERSEY.

WASHINGTON.—Mr. Charles B. Hindle has petitioned the Council for a franchise for a water, gas and electric light plant.

SAYREVILLE.—The Sayreville Electric Light and Power Company is planning to extend its system in the immediate future.

PARK RIDGE.—A municipal electric light plant will be erected at a cost of $12,000. The plant is to be operated by water power.

MORRISTOWN.—The United Electric Company of New Jersey is contemplating the extension of its underground circuits here.

WASHINGTON.—The Washington Electric Light Company recently added improvements at its station and is reconstructing its service lines.

CAMDEN.—The Baxter Lighting Company was recently incorporated with a capital of $25,000. The incorporators are Lewis S. Baxter, George M. DeGunther and L. Howard Weatherby.

EGG HARBOR.—The Atlantic County Electric Company expects to add 25 enclosed arc lamps to its lighting circuit and the equipment of the power plant will be increased by the installation of a 120-kw. dynamo.

AMPERE.—Upon a vote of three-quarters of the stockholders, the Crocker-Wheeler Electric Company has increased its capital stock by $1,000,000 in order to provide additional capital for its rapidly growing business. One-fourth of this amount was issued to present stockholders, the remainder being kept in the treasury for issue later.

NEW MEXICO.

ALMOGORDO.—The Almogordo Electric Light Plant, which was recently rebuilt, is pushing its motor service.

ROSWELL.—An ordinance has been passed, granting to Maynard Gunsal the right to furnish electricity for power, heat and illuminating purposes in this city.

NEW YORK.

CORTLAND.—The Cortland & Homer Electric Company is preparing to improve and enlarge its plant.

SHERMAN.—The Sherman Electric Light Company is increasing the service capacity of its line wires.

GROTON.—A boiler of 125 or 150 horse-power capacity will be installed in the village electric light plant.

HERKIMER.—The Council is considering the question of a new boiler house for the municipal electric light plant.

ELMIRA.—Elmira Water, Light and Railway Company is said to be arranging for the installation of a 1400-h.p. gas engine.

GOUVERNEUR.—A franchise for the construction of an electric light plant has been granted to J. Henry Abbott.

MEXICO.—The Mexico Electric Light Company expects to add a new water-wheel to its power equipment.

WATKINS.—Plans are under way for the construction of a village lighting system at a cost not to exceed $20,000, it is said.

FRANKLINVILLE.—The Empire Electric Company recently installed a direct-current dynamo for supplying power to stationary motors.

CHATEAUGAY.—The Chasm Power Company is preparing to run a line to Burke, five miles from here, for light and power transmission purposes.

SPENCER.—The Spencer Electric Light Plant, owned and operated by Mr. S. A. Seeley, is to be equipped with a new boiler, a feed-water pump and a heater.

MIDDLEPORT.—The Albion Electric Light and Power Company is said to have secured the contract for lighting the city by electricity at $60 per lamp per year.

ELIZABETHTOWN.—The Elizabethtown Electric Light Company is increasing its water power facilities and recently put in a 360-ft. extension of 18-in. steel tube.

SCHENECTADY.—Recent reports show that the Schenectady Railway Company, which has the contract for lighting the city, has made considerable improvement in the service.

DUNDEE.—The Dundee Electric Light, Heat and Power Company, owned by Mr. E. L. Bailey, is said to be planning an extension of its lines to the town of Lakemount, three miles distant.

GOWANDA.—According to recent reports, the plant of the Consolidated Electric Light and Power Company which has heretofore been run by means of a gas engine, will be operated by water power in the future.

MANLIUS.—Articles of incorporation have been filed by The Manlius Gas & Electric Company, with a capital stock of $10,000. M. Murphy and William Murphy, of Manlius, and G. M. Corwin, of Oswego, are the directors.

BUFFALO.—The Bison Motor Company was recently incorporated with a capital of $25,000. Mr. Frederick Wende and Mr. W. A. Lutz, of Buffalo, and Mr. F. I. Alliger, of Tonawanda, are named as directors of the new company.

BATAVIA.—Mr. Edward C. Atwater, receiver of the Consolidated Gas & Electric Light Company, was recently granted permission by the Supreme Court to discontinue the manufacture of gas as the expenditures exceeded the receipts.

MT. MORRIS.—The Mt. Morris Electric Light and Power Company is planning to enlarge and improve its plant. A direct-current day circuit will be added to the present system, the power being supplied from direct-connected units.

PORT DICKINSON.—Walter Moore & Co., of Binghamton, have petitioned for a franchise to string power wires through this place. They desire to erect poles and string wires from the new power plant on Mill Street to the Binghamton city line.

CASTILE.—The municipal electric light plant finds its necessary to construct more new lines in order to meet the increased demands of the village lighting service, and it is understood that another unit is to be installed at the power house.

NIAGARA FALLS.—Mr. Robert E. Drake and Mr. Paul T. Brady, of Syracuse, are reported to be interested in the Niagara Falls, Lockport & Ontario Power Company, which proposes to supply electric power to as many cities in the State as desire it.

BUFFALO.—Bill of complaint was recently filed against the International Trolley Controller Company, of this city, by the Westinghouse Electric & Manufacturing Company on the grounds of infringement of two electrical patents owned by the latter company.

SCHENECTADY.—The Schenectady Railway Company has been engaged for several months in placing all its cables and wires in conduits. The work is nearing completion and it is expected that in a short time all their power will be distributed through the underground circuit.

WATERLOO.—The village trustees have been petitioned by the Senaca Edison Company for renewal of its franchise. The company, it is said, contemplates replacing the present lights with improved lamps such as are now being used in Geneva and Senaca Falls, as soon as the new franchise is granted.

WATKINS.—It is reported that the property and franchise of the Watkins Consolidated Gas & Electric Company have passed into the hands of the United Power & Traction Company, with headquarters in Philadelphia. It is thought that the recent action of the village in voting for a municipal lighting plant led to the sale.

ROCHESTER.—The Clark Syndicate, which controls the Rochester Railway Company, is reported to be negotiating for the purchase of the Rochester Gas & Electric Company. The railway company now obtains 1000 horse-power from the electric company. Extensive water rights are owned by the latter concern, many of which are undeveloped and which could be utilized for the generation of a large amount of power.

NEW YORK CITY.—About 11,000 of the wires running to the Cortlandt Street exchange were recently damaged by fire which originated in the Broadway subway. About one-quarter of the subscribers in this district were cut off from the exchange and several trunk lines to other exchanges were involved, as well as the long-distance lines to Boston, Providence, New Haven, other New England points, and to Buffalo.

UTICA.—At the annual meeting of the stockholders of the Utica Gas and Electric Company, held recently, the following officers were reelected: President, A. N. Brady; vice-president, William E. Lewis; secretary, W. J. Cahill; treasurer, George H. Stack; general manager of gas department, W. J. Cahill; general manager of the electric department, M. J. Brayton. It was said recently that the company expected to put in additional boilers and a 1500-kw. steam turbine.

BROCKPORT.—For some time the electric light service furnished by the Albion Electric Light & Power Company has been more or less unsatisfac-

Readers are cordially invited to contribute to this department items of news relating to plants in their vicinity.

tory. At times the service failed completely, notwithstanding the frequent assurances of better service. The Village Board had the lights examined by an electrical expert, who reported that the lamps were not being supplied with the proper voltage to give the required candle-power. This report was submitted to Mr. Wallace C. Johnson, vice-president and general manager of the company, and he stated that he would have the lights examined himself and if he found that they were not receiving the proper voltage to fill the contract he would not attempt to hold the village to their part of the contract.

ILION.—According to the report submitted by the Board of Light Commissioners of the transactions of the municipal lighting plant for the eleven months ending March 1, 1904, the receipts including an appropriation of $7000.00 were $13,822.60; the disbursements, including maintenance, accounts prior to April 1, 1903, and bond and interest, amounted to $20,139.04, showing a deficiency of $6,316.14. This large deficiency, the Board explains, is due meters having been purchased, to the item for old accounts paid by the commission amounting to $2,985.25 and to the fact that the light furnished for public services for which no remuneration is received, would at current rates add nearly $400 to the income of the plant. The estimate given for the coming year shows a deficiency of $9,000, which the commissioners ask to have included in the appropriation.

NORTH CAROLINA.

FREMONT.—The council is considering the matter of establishing an electric light plant.

TARBORO.—The municipal electric light plant will probably extend its incandescent lighting circuit.

SOUTH PINES.—The South Pines and Carthage Electric Plant is considering the question of increasing its power plant equipment.

GOLDSBORO.—It is expected that a 300-h.p. electric light plant will soon be installed here, equipped with the necessary engines, dynamos and boilers.

WAYNESVILLE.—Contract has been let for developing 1000 horse-power on Pigeon River for B. G. Sloan, proprietor of the White Sulphur Springs Hotel. The power will be transmitted to Waynesville, where it will be utilized for lighting and other purposes.

JONESBORO.—Mr. A. F. Spencer, of Sanford, N. C., is said to have secured the franchise for light, heat and power for this place, and it is understood that the lights will be put in very soon. He has also secured the contract for lighting the streets with arc and incandescent lights for a term of five years.

NORTH DAKOTA.

VALLEY CITY.—At a recent election the citizens voted not to sell the electric light plant.

MANDAN.—The Mandan Electric Company contemplates erecting new poles and putting in larger wires.

KENMARE.—Mr. A. B. Kerlin, of Devil's Lake, has been granted a franchise to put in an electric light plant here.

LANGDON CITY.—The electric light company here is considering extending its lines, for which purpose it will be necessary to erect a new power house and install additional equipment.

OHIO.

COLLINWOOD.—The municipal plant of this place is to add another boiler to its equipment.

READING.—The municipal electric light plant, according to a recent report, will be enlarged one-half.

LONDON.—The municipal electric light plant has adopted series enclosed arc alternating-current street lamps.

BEREA.—The Berea Water Works and Electric Light Plant is building a wall for the protection of the reservoir.

CHARDON.—It is expected that the Chardon Electric Light Works will shortly install a new heater and steam separator.

GREENFIELD.—The Greenfield Corporation is changing the type of lamp used for street lighting from open to enclosed arc.

NILES.—The City Electric Light and Water Works are to have a new building, it is said. A new boiler, engine, heater and piping system will also be installed.

WAPAKONETA.—Bonds to the amount of $7000 have been sold for the purpose of making improvements to the electric light plant and water works.

BELLEVUE.—It is understood that the Bellevue Light and Power Company is to rebuild its power plant and change the lighting system to enclosed arcs.

CLYDE.—Additions to the equipment of the municipal electric light plant, consisting of two 100-h.p. boilers and one 100-h.p. Corliss engine, are said to be under consideration.

SOUTH BROOKLYN.—The municipal electric light plant is to be equipped with an engine and generator to supply the additional power required for the day circuit which has recently been added to the system.

ASHLAND.—The question of whether it would be better to establish a municipal electric light plant or renew the contract with the present company is being discussed. The city is now using 68 arc lamps at $81.00 per lamp per year.

SHELBY.—It is reported that $20,000 have been spent by the city for improvements, enlargements and extensions to the municipal plant since 1892. The streets are lighted all night with 72 arc lights and the city buildings contain 250 incandescent lights.

WEST ALEXANDRIA.—The addition to the power house of the Dayton & Western Traction Company, which has been in course of construction for some time, is about completed and is being equipped with new machinery of the most improved type.

HILLSBORO.—On April 30 bids were opened for furnishing electric arc lights for lighting the streets and incandescent lights for private consumers. The lights for public purposes are to be furnished for a period of ten years.

YOUNGSTOWN.—The Shenango Valley Electric Light Company is now owned by the Youngstown-Sharon Railway and Light Company. Power is furnished by the Youngstown Consolidated Gas and Electric Company, on a 24-hour basis, at 2000 volts over a two-phase circuit.

ALEXANDRIA.—All the equipment for the addition which is being erected at the power station of The Dayton & Western Traction Company has been purchased. The new machinery to be installed includes two 450 horse-power Hamilton Corliss engines, two 250-kw. generators and two 250 horse-power boilers.

PAINESVILLE.—The municipal electric light plant is said to be supplying 100 arc lights for street lighting at an average cost of $69.00 per lamp per year. The plant is said to have a bonded indebtedness of only $1000, the enlargement and extension of the service having been made from year to year without the issue of bonds.

DAYTON.—The ordinance granting a franchise to the Dayton Electric Light Company has been vetoed by Mayor Snyder, for the reasons, it is said, that the company has failed to keep its contract with the city as to prices for commercial lighting and power and that the ordinance does not provide for the placing of wires underground, besides other reasons.

TOLEDO.—The Toledo Railway & Light Company is erecting an addition to the boiler house at its main power station in Toledo. The building will be 45 x 73 feet, and an additional stack will be erected. The company has placed a contract for four 650-h. p. water-tube boilers, and will also install an overhead storage system, coal conveyors and automatic stokers.

TROY.—According to recent reports, the municipal electric plant of this place is a credit to the city. Since purchasing the plant from the lighting company in 1897, the city has spent $36,000 in improvements, all of which has been paid for from the receipts. The number of street arc lights has been increased and 165 incandescent lamps have been put in public buildings.

FREMONT.—Capitalists of this city, Chicago, Waterloo and Auburn, Ind., recently incorporated the Fremont Power & Light Company with a capital of $350,000. The company will establish a water-power electrical plant in Ballville, one mile south of here, on Sandusky River, and for this purpose it has acquired the river frontage on both sides of the river for two miles. It is reported that the company has also combined three private water powers which will be merged into one large power plant.

ST. MARYS.—The Board of Public Service has asked the city council to make an appropriation for the improvement of the Water Works and Electric Light plant. The improvements they desire to make consist of two new water-tube boilers of 300 horse-power each, automatic stokers for two boilers, one heater and purifier of 600 horse-power capacity, one smoke stack, one dynamo, 100 enclosed arc lamps, one air compressor; the drilling of three new water wells, and the repair and extension of electric lines and water mains.

OKLAHOMA TERRITORY.

EL RENO.—Henry T. Smith, Robert S. Trulock and Ernest E. Blake, all of this city, recently incorporated The Union Light & Power Company, with a capital stock of $250,000.

OREGON.

HILLSBORO.—The City of Hillsboro is reported to be extending its lighting system.

McMINNVILLE.—A new engine is to be installed in the municipal electric light plant.

BAKER CITY.—The Baker City Gas and Electric Company is contemplating the addition of twenty miles of pole line.

PENDLETON.—The Northwestern Gas and Electric Company is said to have asked for a 25-year franchise.

PENDLETON.—It is understood that the Pendleton Electric Light and Power Company has been purchased by the Washington and Oregon Power Company, which is erecting a large power plant on the Walla Walla River, Washington.

MILTON.—It is reported that Mr. G. A. Barrett, of the Oregon and Washington Electric Power Company, has announced that contracts have been let for the apparatus and construction of a new plant to be installed here. It is expected that the plant will cost about $250,000.

SILVERTON.—The plant of the Union Light and Power Company is being rebuilt. It is stated that when the new plant is completed, the company will furnish power for the Citizens' Light and Traction Company, of Salem. The power will be supplied over a three-phase transmission line at 15,000 volts.

PENNSYLVANIA.

BEDFORD.—The Bedford Electric Light and Power Company expects to install new arc lamps shortly.

CONSHOHOCKEN.—The Conshohocken Electric Light and Power Company is extending its power circuit.

HYNDMAN.—The Hyndman Electric Light, Heat & Power Company expects to install a new engine shortly.

MECHANICSBURG.—The United Electric Company is reconstructing its power plant and installing new equipment.

WILMERDING.—The Wilmerding Electric Light Company has purchased a site upon which it proposes to erect a power plant.

BERLIN.—The Borough of Berlin has recently installed new power and electrical apparatus which is a duplicate of the old equipment.

SOUTH BETHLEHEM.—Bids were recently asked for to light the town by electricity for a term of five years from June 20, 1904.

MADVILLE.—It is rumored that the old machinery of the municipal electric light plant is soon to be replaced by an entire new equipment.

EBENSBURG.—The Ebensburg Light, Heat and Power Company expects soon to enlarge its equipment by the addition of another 200-h.p. engine.

CLEARFIELD.—The Central Pennsylvania Light and Power Company is adding a new water-tube boiler to its equipment and extending its circuits.

Readers are cordially invited to contribute to this department items of news relating to plants in their vicinity.

CHRISTIANA.—A. J. Melchen, who owns the electric light plant here, is preparing to extend his service so as to include fifteen miles of farm districts and three adjoining towns.

LANSDALE.—Improvements will be made to the municipal electric light plant at an early date, consisting of a 120-kw. alternating-current machine, 250-h. p. Corliss engine and a boiler.

NEW FREEDOM.—It is proposed to construct an electric light plant and water works here at an estimated cost of $13,600. Mr. H. K. McKay, of Baltimore, Md., is the engineer in charge of the work.

LEWISTOWN.—The Lewistown Electric Light Company has secured the contract for arc instead of incandescent lights, at $65.00 per light. The company contemplates some additions to the power equipment during the coming summer.

OAK GROVE.—The work of stringing the light wires from Jersey Shore to Oak Grove, a distance of eleven miles, is well under way. The Jersey Shore Street Electric Railway Company has the contract for lighting the town and is pushing the work as rapidly as possible.

EASTON.—At the annual meeting of The People's Electric Light & Power Company, the following directors were re-elected: Dr. E. W. Evans, John S. Osterstock, F. G. Ormsby, S. R. Bush and M. H. Jones, of Easton; G. B. Garrison, New York City, and W. H. Walter, Phillipsburg. Dr. Evans was re-elected president, Mr. Osterstock treasurer and Mr. Ormsby secretary of the company.

SHENANDOAH.—At a meeting of the stockholders of the People's Light, Heat & Power Company, of Shenandoah, and the People's Light, Heat & Power Company, of Mahanoy Township, it was agreed to merge the two companies into one and erect a plant with sufficient power to furnish light, heat and power to Shenandoah, Mahanoy City and other nearby towns. The plant will be located about midway between Shenandoah and Mahanoy City.

YORK.—The plant of the York Haven Water and Power Company, which was recently wrecked by the ice, is to be rebuilt as soon as the temporary structures necessary for the shelter of the machinery are completed. The foundations will be constructed of granite, and solid masonry will supersede the brickwork in the old building. The lines to this city have been complete for some time, awaiting the completion of the temporary buildings, and it is now expected that they will be in use by June 1.

RHODE ISLAND.

WESTERLY.—The Westerly Gas and Electric Light Company expect to erect a new plant this year, thereby doubling the present capacity.

SOUTH DAKOTA.

REDFIELD.—The municipal electric light plant is about to add to its steam equipment.

WEBSTER.—The municipal electric light plant, of this place, will increase its equipment by the addition of new engines and generators, and is engaged in the work of line extension.

BELLEFOURCHE.—The citizens are contemplating the construction of an electric light, heat and power plant at a cost of about $8000. A company is being formed for the purpose, and plans are being drawn for the proposed plant.

TENNESSEE.

DAYTON.—The plant of the Dayton Lighting & Power Company is being rebuilt.

LAWRENCEBURG.—The city council is investigating the cost of establishing an electric light plant.

COLUMBIA.—Bids for furnishing Columbia with 60 arc lights for a term of ten years have been advertised for.

RIPLEY.—The Ripley Light and Water Company is contemplating the installation of a 12 x 36 Corliss engine and a number of transformers.

CHATTANOOGA.—The mayor and city council are said to be considering the question of municipal ownership of the electric light plant.

UNION CITY.—The Union City Water and Electric Light Works has enlarged its system by the addition of a day circuit for the purpose of supplying fans and other motor power.

NASHVILLE.—The Nashville Railway & Light Company has just installed at its plant, in conjunction with a 1600-kw. engine-driven three-phase alternator, a 500-kw. rotary converter. This will enable them to supply both direct current for railway power purposes and alternating current for lighting circuits.

CHATTANOOGA.—It is reported that the General Electric Company, which owns a controlling interest in the Chattanooga Electric Company, is about to establish a model station here. Four new Curtis steam turbines of 500 kilowatts each have been installed in the power house of the Chattanooga Electric Company, and it is expected that with this additional power the entire system of the Chattanooga Electric Railway Company will be operated from the power house of the electric company. The company is also preparing to install a new series alternating-current system of enclosed arc lamps, the current for which will be supplied by constant-current transformers located in the plant.

TEXAS.

BRYAN.—It is expected that Bryan will soon have an electric light and power plant, as a franchise was recently granted to H. B. Dorsey for the erection and operation of such a plant.

ROCKDALE. — The Rockdale Improvement Company is considering the question of increasing the service voltage of its lines from 50 to 110 volts and a general over-hauling of the plant.

SOUR LAKE.—The city council is considering two applications for franchises to establish an electric light plant and water works here, one by Messrs. Sloane, Maxwell and McVeigh, of this place, and the other by Mrs. C. W. Allen, of Houston.

SHERMAN.—The Sherman Light and Power Company has been organized with a capital stock of $100,000. The incorporators are J. Lobit, of Galveston; E. P. Bomar, of Gainesville; W. P. Brents, M. B. Pitts and C. N. Roberts, of Sherman.

UTAH.

LOGAN.—The citizens recently voted to issue $12,000 bonds in order to complete the municipal electric light plant.

PAYSON CITY.—A new alternator of 75 or 100 kilowatts capacity, with the necessary transformers, is to be installed in the Payson Electric Light Plant.

HYRUM.—The Union Electric Light and Power Company is considering the construction of a five-mile line, and will probably erect another tower of the same size as the present one.

RENO.—The franchise and property of the Reno Traction Company recently changed hands by purchase, and it is understood that work on the prospective road will soon be under way.

CASTLEDALE.—The Town Boards of Castledale and Orangeville are considering figures submitted by W. E. Raines, of the Salt Lake Electric Supply Company, Salt Lake City, for the construction of an electric light plant to be used for lighting both towns. The cost of the plant is estimated at $10,000.

SALT LAKE CITY.—The Standard Power Company was recently incorporated with a capital stock of $1,000,000. The company purposes establishing a power plant on the Sevier River in the southern part of the state and it is expected that the work will be commenced early during the present season. The plant will have a capacity of about 5000 horse-power and will cost $500,000.

LOGAN.—The Hercules Power Company has announced its intention of cutting its price to 15 cents each per month, or to 5 cents each if necessary. If this should be done, it is feared that the evident determination of the city administration to have politics figure in the operation of the municipal plant can but result in the destruction of a plant which will have cost Logan City, when completed, not less than $100,000.

VERMONT.

BURLINGTON.—Articles of incorporation have been filed by the Northern Electric Company. The new corporation has a capital stock of $20,000 it is said.

HARDWICH.—The necessary changes are being made in the village light and power plant to increase the power capacity of the plant.

VIRGINIA.

WOODSTOCK.—The Woodstock Electric Light & Power Company has been incorporated with a capital stock of $2000 to $10,000.

RICHMOND.—Mr. C. E. Bolling, superintendent of water works, in his annual report estimates the cost of constructing an electric light plant at about $150,000.

FREDERICKSBURG.—Cartright & Davis, of this place, state in regard to the development of water power that only work of a necessary character will be done at once, as the details of improvements will probably not be completed by the engineer, Mr. Charles Ruffin, for several months.

LYNCHBURG.—The Lynchburg Traction and Light Company states that it has in the course of construction a water power station of 4000 horse-power capacity. Three 750-kw. G. E. generators will furnish current at 13,200 volts. It is expected that the plant will be in operation by August next.

RICHMOND.—According to a recent report the street railway company here has announced that hereafter it will enforce the law which permits conductors to separate white and negro passengers. Any persons failing or refusing to observe the orders of the conductor will be liable to a fine of $25.00 and may also be ejected from the car for such refusal.

NORFOLK.—It was recently decided to dissolve the Norfolk, Portsmouth & Newport News Company, comprising the Berkley Street Railway Company and the National Gas Company, of Berkley; the Old Dominion Railway Company, of Portsmouth, and the Norfolk County Ferry Company. It is understood that the dissolution was entirely amicable. The various companies did not find the arrangement a profitable one, and all concerned agreed that a larger profit could be made by the individual operation of the several industries.

WASHINGTON.

SEATTLE.—The American Improvement Company has petitioned the Council for a franchise.

KALAMA.—The Kalama Electric Light and Power Company will put in a complete telephone system for the town.

MONROE.—The Monroe Water and Light Company, recently organized, will install a complete electric light plant and water system.

FORT WRIGHT, SPOKANE.—A new electric plant is to be installed here for the purpose of supplying light and power to the Post.

BELLINGHAM.—The City Council has granted to the Whatcom County Railway and Lighting Company a franchise for its Elk Street extension.

TACOMA.—The plant of the Kent Electric Light Company is now understood to be the property of the Puget Sound Electric Company, of this city.

ANACONTES.—The Anacontes Water Power Company contemplates enlarging its equipment by the addition of new boilers and will also build a new boiler house.

BELLINGHAM.—The City Council has decided to install a municipal electric light plant, using the power of the Whatcom Creek Falls. The estimated cost is $17,000.

WEST SEATTLE.—An election will soon be held to decide the question of town ownership of an electric street railway system. If carried, a system will soon be installed.

OLYMPIA.—The Olympia Light and Power Company is asking the City Council for a franchise to extend its Fourth Street line to the city limits, the extension to be complete in one year.

DAVENPORT.—Mr. John A. Hanson, of this city, is reported to have under consideration the construction of an electric line from Reardon to Edwall, and is understood to have also secured a franchise to enter Spokane.

Readers are cordially invited to contribute to this department items of news relating to plants in their vicinity.

SPOKANE.—The Washington Water Power Company proposes to extend its street railway line to the city limits in order to make better connection with suburban lines and has made application for a franchise permitting it do so.

PORT ANGELES.—The articles of incorporation of The Port Angeles Water and Power Company place the capital at $150,000 in shares having a par value of $20 each. H. A. Lingenbrink, George B. Reid and W. F. Delabarre, all of this city, are named as trustees.

BELLINGHAM.—The Bellingham Bay Improvement Company, which has just secured the contract for lighting the city, is erecting a plant capable of developing 1000 horse-power at the falls of Nooksack River, and is preparing to erect fifty miles of transmission line.

BALLARD.—The Ballard Electric Company has under construction a new station of 1000 horse-power capacity. The plant will be housed in a fire-proof building of brick and steel construction, and is to include only modern equipment of the most improved type.

CHEHALIS.—The Council is considering the question of leasing the electric light plant for another fifteen years to Mr. Harry West, the present lessee. The property is owned by the city, but has been leased for several years by Mr. West. It is thought probable that his lease will be renewed.

BALLARD.—A franchise to furnish electric light and power at Ballard has been granted to Mr. H. A. Starkey. The franchise was amended to provide that the electricity should be generated here, the plant to be completed in six months and to cost $40,000. The term of the franchise is fifty years.

SEATTLE.—The Seattle Lighting Company was recently organized by Messrs. Lyman C. Smith and William Nottingham, of Syracuse, N. Y., and Mr. J. W. Clise, of Seattle, with a capital of $4,000,000. It is reported to have taken over the plant of the Seattle Gas & Electric Light, which will be consolidated with the Citizens' Light & Power Company already owned by the new company.

WALLA WALLA.—The engineers for the large power plant of the Washington and Oregon Power Company are at work on the site of the power station which is located on the south fork of the Walla Walla River, near Milton. It is the intention to have the plant in operation by October 1. The company contemplates furnishing light and power to all of the country between here and Pendleton, Ore. A main power line will be run both ways from the plant to the two cities and branches will be run into the towns lying along these main lines. The new company, it is stated, has bought out the Walla Walla Electric Light Company and the Pendleton Electric Light and Power Company.

SEATTLE.—The preliminary test of the power plant of the Columbia Improvement Company at Electron, which is now nearing completion, is said to have shown very satisfactory results. The tests were conducted with power transmitted from the Post Street station of the Seattle Electric Company, Under the direction of Mr. Lukes, lighting and power superintendent, of the Seattle Electric Company, 60,000 volts were turned into the transformers in the new power station; the machines stood the test satisfactorily. It is expected that the full capacity of the plant will have been developed by August 1 next, and it is stated that the entire supply of current will be used by the Seattle Electric Company in conjunction with that already being received from the Snoqualmie Falls Company.

WEST VIRGINIA.

PARSONS.—The Parsons Electric Light & Power Company is contemplating the installation of an auxiliary steam power plant.

WESTON.—The Weston Electric Light, Power & Water Company states that it expects to double the capacity of its plant this summer by the addition of either a turbine or direct-connected gas engine.

WISCONSIN.

MILWAUKEE.—The citizens have voted to issue $500,000 for a municipal lighting plant.

WAUSAU.—The contract for building a new electric light plant to cost about $20,000 has just been let.

GRAND RAPIDS.—The Electric & Water Company of Grand Rapids expects to enlarge its circuits and reconstruct its pole lines.

FENNIMORE.—It has been decided by the City Council to install an electric light plant in connection with the city water works.

FOUNTAIN CITY.—H. & F. Roettiger, owners of the electric light plant of this city, are thinking of adding another dynamo to their equipment.

LADYSMITH.—The power plant of the Ladysmith Electric Company, which was burned recently, is to be rebuilt shortly at a cost of $5,000.

ANTIGO.—The Antigo Electric Light Plant, formerly owned by W. L. Elliott, who died recently, will be sold as soon as Mr. Elliott's estate is settled up.

HARTFORD.—The Hartford Electric Company expects to secure the contract for city street lighting this summer, which would necessitate a considerable change in the plant equipment.

LAKE GENEVA.—The Lake Geneva Water and Light Company has a contract with the city for 25 lights of 1200 nominal candle-power. The lights are run on the moonlight schedule and until midnight.

MANITOWOC.—William Rahr, Sr., and William Rahr, Jr., are the incorporators of The West Side Electric Power & Lighting Company, recently organized with a capital of $25,000 to furnish power and light to manufacturing plants.

MANITOWOC.—The Electrical Construction Company, of Racine, has secured the contract for installing a complete electric plant in the factory of the Manitowoc Malting Company, which is said to have an annual capacity of a million and a half bushels and to be the largest concern of the kind in the world.

CANADA.

BURKS FALLS, ONT.—The McKnight Bros. Co. is planning to enlarge both its plants.

MOOSE JAW.—Bids will be received May 14 for an electric lighting system and engines.

ACTON, ONT.—The municipal electric plant is preparing to put in a day circuit for power purposes.

ORANGEVILLE, ONT.—The Orangeville Electric Light and Power Company recently installed a gas engine as prime mover.

CARLETON PLACE, ONT.—The Carleton Place Electric Light Company proposes to increase the capacity of its plant this season.

PORT HOPE, ONT.—The Port Hope Electric Light & Power Company intends to add another 150-kw. alternator to its plant equipment.

NEWMARKET.—The Corporation of Newmarket is installing a small direct-connected unit at its plant for carrying the load after midnight.

KENTVILLE, N. S.—The Kentville Electric Light & Power Company contemplates installing a small engine and dynamo to run after ten o'clock.

CORNWALL, ONT.—The Stormont Electric Light and Power Company is putting in a new power circuit connected with the Mille Roches power house.

THREE RIVERS, QUE.—The North Shore Power Company is arranging to duplicate the line from its power house to this city, a distance of twenty miles.

OWENS SOUND, ONT.—The Owens Sound Electric Department is considering the advisability of changing from direct to series alternating current for street lighting.

ELLIOTT'S FALLS, ONT.—The electrical equipment for the transmission plant here, which was installed by the Canadian General Electric Company, is now complete.

OTTAWA.—The question of placing the overhead wires in underground conduits is being considered by a sub-committee of the City Council and representatives of the Consumers' Electric Company. Congestion in the busiest thoroughfares will make it necessary sooner or later to remove the poles and wires from these districts.

NANAMIO, B. C.—The City Council has received a communication from Mr. C. Brandies, electrical engineer, representing a Montreal syndicate, asking for a charter for the construction of an electric street railway system. The company also proposes building a suburban line between this city and Brechen at the newly discovered coal fields of the Western Fuel Company. The power will be derived from the Nanaimo River Falls.

WINNIPEG.—The Great Lakes and Northwestern Transportation Company recently filed incorporation papers, with a capital of $10,000,000 fully subscribed. The company was organized for the purpose of supplying electric power to the city of Winnipeg and surrounding towns and municipalities, but the incorporation also permits the construction of canals and other improvements in navigation between Lake Superior and the Red River to a point south of Winnipeg, the construction of transportation lines, and general improvements in the navigation of the lakes and rivers of the Canadian Northwest.

MEXICO.

LAGOS, JALISCO.—The construction of a municipal electric light and power plant is contemplated.

VICTORIA.—Manuel Gonzalezhys has secured a concession from the State Government for the establishment of a water power plant.

SAN ANGEL, FEDERAL DIST.—S. Robert & Cia. are making preparations for the installation of a new water power plant here of 250 kilowatts capacity.

REAL DEL MONTE, HIDALGO.—This place is soon to have an electric light and power plant. The enterprise is being backed financially by the State Government.

AGUASCALIENTES.—The Cia de Luz and Fuerza Electricas is about to make a change in its lighting system. Alternating current series arc lights will be used instead of series incandescent lamps.

TEOCALTICHE, JALISCO.—Application has been made to the state authorities by Longinos Gonzales for permission to establish an electric light and power plant here. The plant will be operated by steam.

PURIFICACION, JALISCO.—The Rosa Amarillo Company, which is being organized to develop timber land in the Cautitlan district, will also construct a large electric power plant to furnish power for an electric railway and to operate small smelters.

ZACATLAN, PUEBLA.—Plans for the erection and operation of an electric light and power plant have been submitted by the City Council to the State Department for formal approval, and it is thought that work on the plant will be begun in a short time.

SAN CHRISTOBAL, CHIPAS.—Mr. F. J. Marley, representing an American syndicate, has applied to the Mexican government for permission to establish an electric power plant for the purpose of supplying light and power for the city of San Cristobal and towns in the vicinity.

ZITACUARO.—It is reported that the Guanajuato Power Company, which is at present furnishing power to mining companies of Guanajuato, contemplates establishing a plant at this place for the purpose of conveying power to the El Oro mining camp. The company is constructing a line to Irapauto.

MONTEREY.—The Monterey Light and Power Company has been incorporated by New York capitalists, under the laws of the State of New Jersey, with a capital stock of $500,000. They have acquired the extensive electric light and power plant here and it is understood that it will be remodeled and enlarged. Mr. P. G. Gossler, head of the operating department of the electrical engineering and contracting firm of J. G. White & Co., New York, is president. About 1100 kilowatts of new machinery will be installed in the plant, which includes a 500-kw. Curtis turbine-generator outfit, two 240-kw. belt-driven alternators, a 125-kw. engine-driven exciter and two small belted exciter generators, together with 150 fan motors. Babcock & Wilcox boilers will be used. The work of remodeling and extending the system will be carried out by J. G. White & Co.

Readers are cordially invited to contribute to this department items of news relating to plants in their vicinity.

American Electrician.

Vol. XVI. New York, June, 1904. No. 6.

A RAPIDLY GROWING WESTERN CENTRAL STATION.

THE GENERATING PLANT OF THE KANSAS CITY ELECTRIC LIGHT COMPANY.

BY E. A. BARTH.

It is not uncommon of late years to hear from central station managers that the contracting department is securing additional load faster than the operating department can take care of it. The plant here described, which supplies the central station lighting of Kansas City, Mo., and Kansas City, Kan., deserves special mention in this respect. The remarkable growth of its business from 1899 to the present is illustrated by the curves in Fig. 2, which show the load on the stations of this company on corresponding Saturdays in December for the past five years. From this it is seen that from a maximum of 900 kilowatts in 1899 the load has grown to a maximum of over 3400 kilowatts in 1903. The greatest increase was recorded between 1900 and 1901. The phenomenal increase is due partly to management and partly to the great growth and prosperity of Kansas City during the past five years.

At the time the present management assumed charge, the property consisted of a number of comparatively small and uneconomical plants containing almost every type of machine arranged in nearly every conceivable way as regards belting and shafting. The manner in which this tremendous increase of load was taken care of while permanent improvements were going on is an interesting story in itself. It was out of the question to install permanent improvements fast enough each year to take care of all the load, and many make-shifts had to be resorted to; each move, however, be-

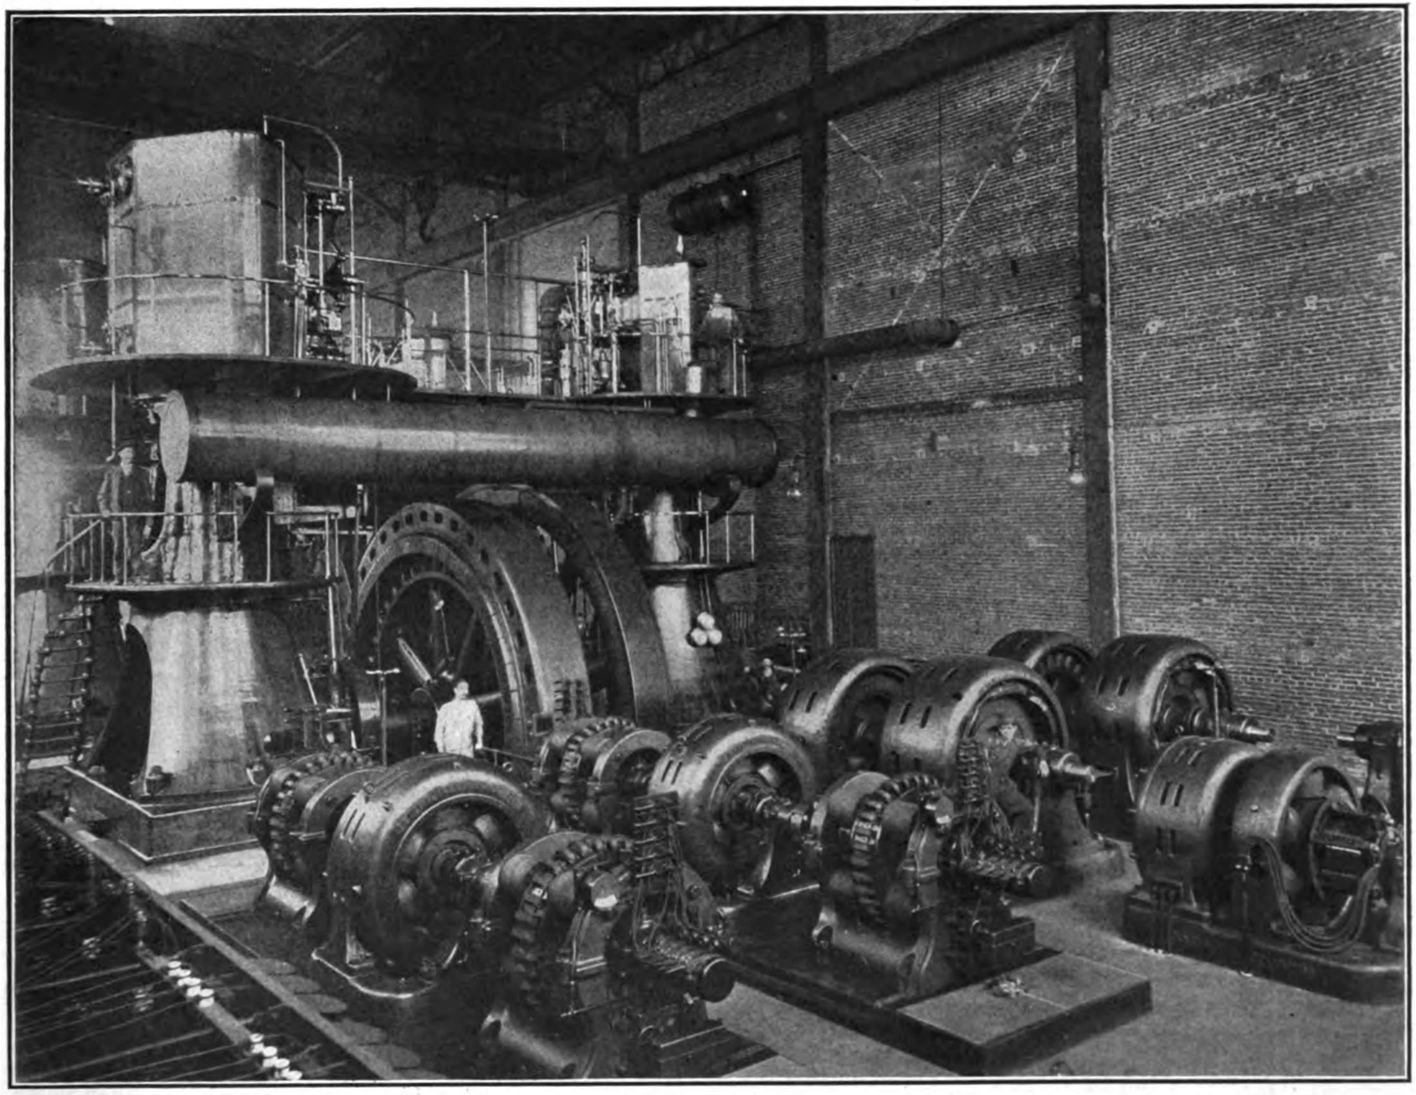

FIG. I.—CENTRAL STATION OF THE KANSAS CITY ELECTRIC LIGHT COMPANY.

ing in the direction of greater economy of operation and the centralizing of generating stations. In order to show what an undertaking the management had before it in June, 1900, a brief summary of the equipment at that time is given.

At the Wall Street station, in the center of the city, was a direct-current Edison plant. Like most of the early Edison stations supplying a low-tension three-wire net work in the central districts of large cities, it was built with a view to economizing ground space. On the lower floor were four B. & W. boilers rated at 200 horsepower each, and on the same floor with these boilers were seven high-speed engines. On the upper floor and belted to the engines were two 45-kw. and eight 60-kw Edison bi-polar generators, and one 500-volt generator for power purposes.

At the South plant, which supplied both series arcs and alternating current incandescent circuits was another two-story station. On the lower floor of this were three B. & W. boilers rated at 250 horse-power each and one of 300 horse-power. There were two cross-compound Allis engines, two Smith Corliss engines, and one Westinghouse compound high speed engine. Driven from various lines of shafting on the second floor were two 75-kw. 1000-volt 133-cycle Westinghouse alternating-current generators, nine 60-light Wood arc dynamos, seven 50-light T-H arc dynamos, one 35-light T-H and six 30-light T-H arc dynamos.

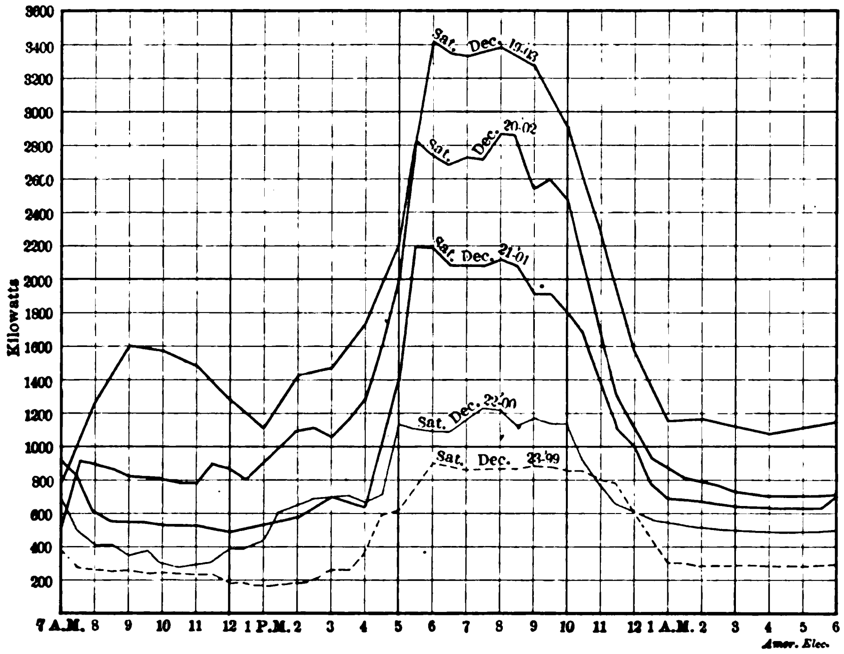

FIG. 2.—CURVE SHOWING CORRESPONDING LOADS FOR FIVE YEARS.

The West plant, which also supplied both arc and constant potential alternating current, was located in Kansas City, Kan. It had three B. & W. boilers rated at 95 horsepower, one St. Louis Corliss engine, two 35-kw. 1000-volt, 133-cycle Westinghouse, alternating-current generators, one 100-light Brush arc dynamo and one 25-light Ball arc dynamo. This made a total of 42 dynamos scattered through the three plants.

To distribute current on the Edison net work in the business district, overhead mains from No. 6 to No. 000, and feeders from No. 000 to No. 0000 and 500,000 circular mils were used. The old style chemical meter was used in this district. The arc lines were in very poor condition, having single petticoat insulators. All kinds of open arc lamps were on the circuits, and three men were kept busy repairing arc lamps. All the copper used in the alternating current distribution was very light and consequently there was a large drop in voltage. Shellenberg meters were used. The lines were separated as far apart as possible, evidently with the idea of increasing the insulation between them, and the majority of the poles were in bad condition.

One of the first temporary changes made was the installation at the South plant, of two 100-kw. Wagner step-up transformers which raised the voltage from 1000 to 2000 volts, thereby decreasing the line loss. This 2000 volts was to be the final standard voltage on this distribution. At the same time the transformers were all changed to G. E. 60-cycle.

On account of shortage of power on the Edison system down town, a Helios-Upton storage battery was installed at the Wall Street plant. This battery was installed rather than more generating machinery because quick delivery could be made. Two 100-kw. bi-polar Edison generators were also put in at this plant. The load on the system increased so rapidly from the start that before the winter was over, the battery and the two 100-kw. generators were overloaded.

In the summer of 1900 it was decided to establish a rotary converter sub-station near Twelfth Street and Grand Avenue, which would ultimately be supplied from a large alternating current central station to be built in the future. Orders were placed for four 200-kw., 125-volt, rotary converters, and not having at the time any available current of 6600-volts, 25-cycles, these were ordered with shafts long enough to carry a pulley so that two of them could be temporarily placed at the company's West Plant and run as belt driven generators, the current being stepped-up and transmitted to the new sub-station where it would be received by the other two rotary converters and fed into the Edison net work. While waiting for these machines summer was rapidly passing and the load increasing. During the fall, the National Street Railway Convention was held at Kansas City and the company purchased the 500-volt 600-kw. rotary converter, which was exhibited at the convention by the General Electric Company and which was therefore available for immediate use. Instead of installing the two 200-kw. 125-volt rotary converters at the West Plant as originally intended, the four rotaries were put in the sub-station at Grand Avenue, and the 500-volt 600-kw. rotary converter was placed in the packing plant of Armour & Co., where it was run as an inverted rotary converter, supplying current to the sub-station by means of step-up and step-down transformers. The four rotary converters at the sub-station were placed in operation in December, and for a time run without regulators or switchboard so badly were they needed to carry the load. How greatly current was needed can be judged from the fact that temporarily the incoming 6600-volt emergency line was controlled with three 220-volt switches. In the alternating current converter circuit, 500-ampere 200-volt switches fastened to 4 x 4 timbers were used for synchronizing. The voltage on the Edison system was regulated simply by manipulating the voltage slightly at the Armour packing plant. By the time three rotary converters were running, the Edison load had increased so that the inverted rotary converter at Armour's was overloaded.

In the mean time, to help out the arc system, four 150-light Brush arc dynamos for enclosed arc circuits were installed at the South plant. The arc circuits had been renewed, and the old lamps partly replaced by Adams-Bagnall series enclosed direct-current arc lamps. Part of the arc system was operated as before. To provide for the increasing load on the alternating-current system, a second-hand 100-kw. 1000-volt Slattery dynamo driven by a high speed engine, was installed at the South plant. Later a 125-kw. 2000-volt G. E. alternating current generator was installed at the West plant. All of the foregoing apparatus aided materially during the winter of 1900 to 1901, but it was soon realized that much greater provisions were necessary for the following winter.

During the winter plans were drawn for a large central station to be located on the Kaw River, but as no help could be expected from this source during the following winter, it was absolutely necessary that more temporary apparatus for the peak load of that winter be installed, and it was decided that the machinery purchased for temporary relief should be such that later on it could be used in connection with the new generating station.

The company owned an abandoned station on Santa Fe Street, where was located the first central station in the United States to use the T-H arc system. The plant had been idle for several years, and four small shell boilers, a small B. & W. boiler and a few high speed engines were still in the plant. These were all taken out, and the building temporarily repaired. Two new 500-h.p. B. & W. boilers which had been ordered for the new station were shipped at once and installed at this place. A 30 x 60 in. Hamilton Corliss and a 26 x 60 in. Brown Corliss were also installed, together with two 500-kw. phase changers. The 60-cycle, 2000-volt generator end of each machine was removed and a pulley placed on the shaft of the 500-kw. motors, which were driven as generators. This temporary plant was laid out in June and was in operation by the middle of December. The generators then supplied 25-cycle current to the four 200-kw., 125-volt rotary converters at the Grand Avenue sub-station, and also two additional rotary converters of the same capacity, which in the meantime had been placed in the Wall Street Edison generating plant. The inverted rotary converter at Armour's establishment was also used to help out with 6600-volt current during the heavy load.

During all these changes an underground system of distribution was being built to take care of the Edison three-wire network in the down-town district. While the service had not all been changed from overhead to underground lines by any means, much of the feeder copper had been installed, and some of these feeders were tapped to the overhead system.

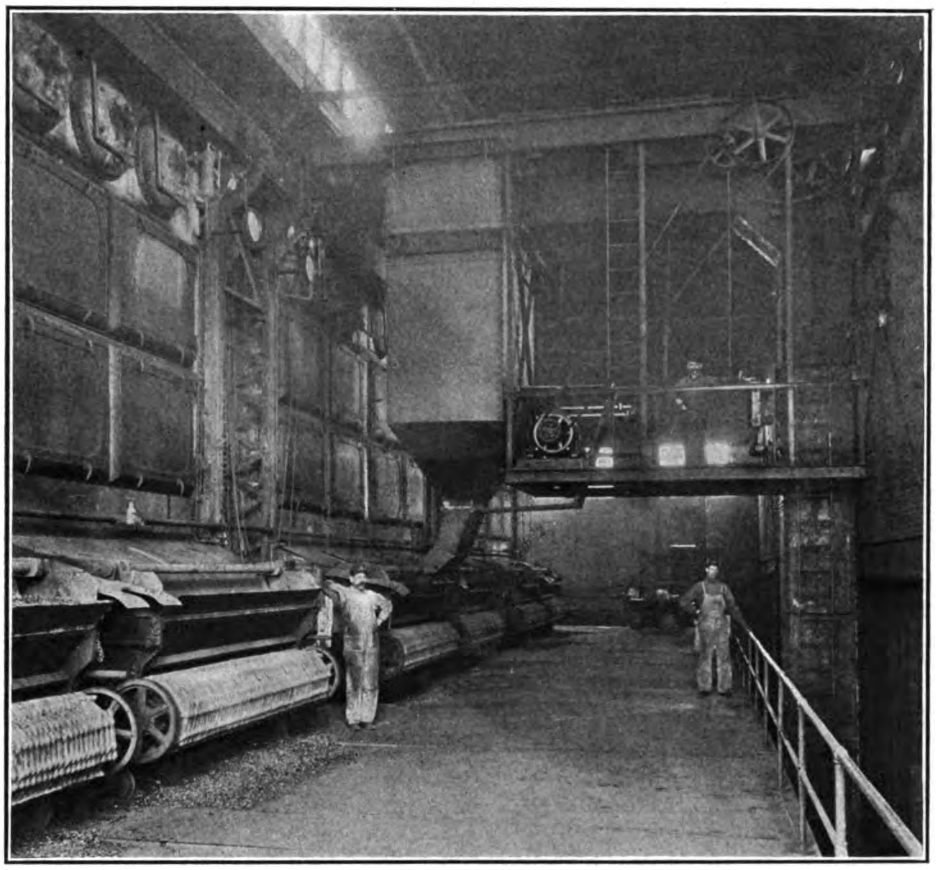

FIG. 3.—BOILER ROOM IN THE CENTRAL STATION.

The foundation for the new central station on the Kaw River was started during the summer of 1901, and finished the following spring, so that the skeleton was erected and the building put up during the following summer. In the meantime the alternating current load had increased so that it was necessary to install a second-hand 300-kw., 2000-volt, 133-cycle alternating current generator at the West plant, and a 100-kw., 1000-volt generator at the South plant. Two more 150-light Brush arc dynamos to operate enclosed arcs were installed at the South plant, and another at the West plant. By this time all of the open arcs had been changed to enclosed arcs.

In view of the fact that the street railway company, which was controlled by the same interests, contemplated erecting a very large central station on the Missouri River, which would ultimately supply considerable power to the electric lighting system, it was decided to simplify the new central station instead of erecting a very elaborate building.

On account of unreliable soil, the plant being located on what was once a river bottom, piles were driven for the building foundation and also for the engine and boiler foundations. The foundations were all built up of concrete and a concrete floor 24 inches thick was placed in the basement. The general dimensions of the building are 117 ft. x 172 ft. A brick fire wall divides it into engine and boiler rooms. The engine room is 60 ft. x 171 ft. The height under the roof trusses is 50 ft. The boiler room is 55 ft. x 171 ft. and its height under the roof trusses 30 ft. The floors of both rooms are of I beam and expanded metal and concrete construction. These floors are at present only finished around apparatus now installed. A 30-ton 3-motor Whiting Foundry and Equipment Company's crane spans the engine room, the rails for it being supported on the steel building columns.

The boiler plant consists of six B. & W. double deck water-tube boilers arranged in three batteries. They are rated at about 514 horse-power and generate steam at 175 pounds pressure. Each furnace is equipped with a Green traveling link grate, the grates being operated from a line shaft below the floor. Two 6-h.p. stoker engines are located in the basement between the ash pits. The ash pits have an approximate capacity of 350 cubic ft. Two steel stacks 9 ft. in diameter and 185 ft. are supported on I beams at the rear of the boilers. The flue gases are conveyed to them by a continuous steel breeching run in the rear of all boilers.

The coal storage bin is located outside the building directly below the street surface, and coal is shoveled from cars into this bin. The bottom slopes toward the basement with chutes every ten feet. A traveling Heil & Patton coal conveyor with a hopper capacity of 10 tons runs on tracks the length of the boiler room. This conveyor is run to any chute, and elevates the coal 48 ft. from the chutes into the hopper. When the hopper is filled, the apparatus is run along in front of the various furnaces, where the coal is discharged as needed. The hopper is suspended on scale beams so that an accurate record of the coal consumed can be kept. The coal conveyor is operated by a 10-h.p., 3-phase, 440-volt G. E. induction motor, which furnishes power both for moving the apparatus and for operating the coal conveyors. All the operations are controlled from a platform on the conveyor. For handling ashes a track on which is operated a steel dump car is installed in front of the ash hoppers. After the car is filled it is pushed to the north end of the building where an elevator raises it to a trestle, outside the building, where the ashes are dumped into empty coal cars and sold. If the demand for ashes is light, they are used to fill in quite an extensive area around the building.

The two engines installed are of the Allis-Chalmers vertical cross-compound condensing type 34 ins. and 70 ins. x 48 in. stroke guaranteed to develop 2250 horse-power with a consumption of 12½ lbs. dry steam per indicated horse-power hour, when running at 75 r.p.m. with 175 steam pressure, and 26 ins. vacuum. A special feature of the governor is a device used for controlling the speed of the engine from the switchboard while synchronizing the generators. It consists of a small motor operating a screw on which a ball weight travels; this weight being run to one side or to the other by the motor as desired when necessary to raise or lower the speed of the engine. A separate governor is also supplied to operate a special valve on the main steam line to shut down the engine in case of an unusual increase of speed. A gravity oiling system supplies the bearings while separate pumps feed oil to the cylinders. A Wheeler surface condenser containing 8000 sq. ft. cooling surface takes care of the exhaust steam. The condenser is guaranteed to take care of 80,000 lbs. of exhaust steam per hour. Circulating water for the condenser is supplied by Worthington centrifugal pumps owing to the dirt and rubbish in the water of Kaw River. Four of these are installed, in pairs, driven by 125-kw., 3-phase, 25-cycle synchronous motors. Each pump has a capacity of 6000 gallons of water per minute with a suction lift of 12 ft. and a head of about 8 ft. Under present conditions it is only necessary to run one pump, but the extra pumps were installed to take care of any future increase in engine capacity. Two Blake air pumps produce the vacuum for the foregoing apparatus. They are vertical twin pumps, each pump having two 12-in. steam cylinders, double-acting, and two 38-in. air cylinders, single acting, with 16-in. stroke. Only one of these pumps is used to take care of the present load. Two Worthington duplicate steam pumps draw water from the hot well to supply the heater, only one being in use at any one time. The pumps are regulated by floats in the heaters so that a constant level of water is maintained. A float in the hot well regulates the supply of city water to the well. Feed water is passed through a Webster heater and purifier having a capacity for heating 80,000 lbs. of water per hour from a temperature of 110 deg. to 190 deg. F. when supplied with 6000 lbs. exhaust steam per hour. The exhaust is supplied by the stoker engines and pumps. Two Worthington Admiralty pumps supply the boilers with feed water. They have a capacity of 450 gallons per minute against 200 lbs. pressure.

All piping is extra heavy, as are also all fittings and valves. A Cochran vacuum oil separater is placed between the header and condenser, the oil being trapped off by two traps which work automatically. A special duplex pump is provided to take water from the river for circulation through the engine guides and bearings and to supply water for washing boilers and other purposes around the station.

Arrangements have also been made so that water direct from the river can be used to supply the boilers. In such a case the water is forced through a Ross filter. A pump pit is located in the basement to take care of all drainage. A Yeoman's motor driven bilge pump, operated by a float in the sump pit, takes care of all the drainage.

The generators are rotating field, 1500-kw., 6600-volt, 25-cycle machines, made by the General Electric Company and direct connected to the engines. The guaranteed efficiency of these machines is 94.5 at full load; 93.5 at ¾ load; and 91.5 at ½ load. The motor-driven exciter is of the same make. The motor is a 215-h.p., 3-phase induction motor operating at 440 volts. The exciter is a 150-kw., 125-volt, 6-pole generator. Three 75-kw., 25-cycle oil transformers reduce the voltage from 6600 to 440 for supplying the motors. An emergency steam-driven exciter set is also provided consisting of old material taken from the Edison station. This set is used very seldom; only in case of a complete shut-down or to give an opportunity to clean the motor-driven exciter.

To supply the 500-volt motor circuit the demands on which were still quite extensive the rotary converter which had been used at the Armour packing plant to supply 6600-volt, 25-cycle, alternating current, was taken out and run as a regular rotary converter at this station. This is an eight-pole, 600-kw., 600-volt compound wound machine with a full load efficiency of 93.5 per cent; ¾ load, 92.5 per cent; and ½ load, 90 per cent. The 6600-volt current to operate this is stepped down through three 250-kw. air blast transformers to 380 volts. The efficiency of the transformers at full load is 97.5 per cent and at half load 96 per cent.

To supply the alternating current incandescent service, two 500-kw. motor generators were installed. Each motor is a 500-kw., 8-pole, 660-volt, 25-cycle machine running at 375 r.p.m. The motors have stationary armatures and are run as three-phase synchronous motors. The generators connected to them are 20-pole, 2300-volt, 62½-cycle, two-phase machines. The motors of these sets were first used as generators in the temporary Santa Fe plant. As the new central station is conveniently located for supplying the arc lights for Kansas City, Kan., two motor-driven arc sets were also installed. Each motor is a 6-pole, 180-kw., 6600-volt, 3-phase synchronous machine equipped with flexible couplings on both ends for direct connection to Brush arc generators. These motors as well as the motors for the phase-changers and the pump motors are supplied with starting compensators. Each Brush arc gen-

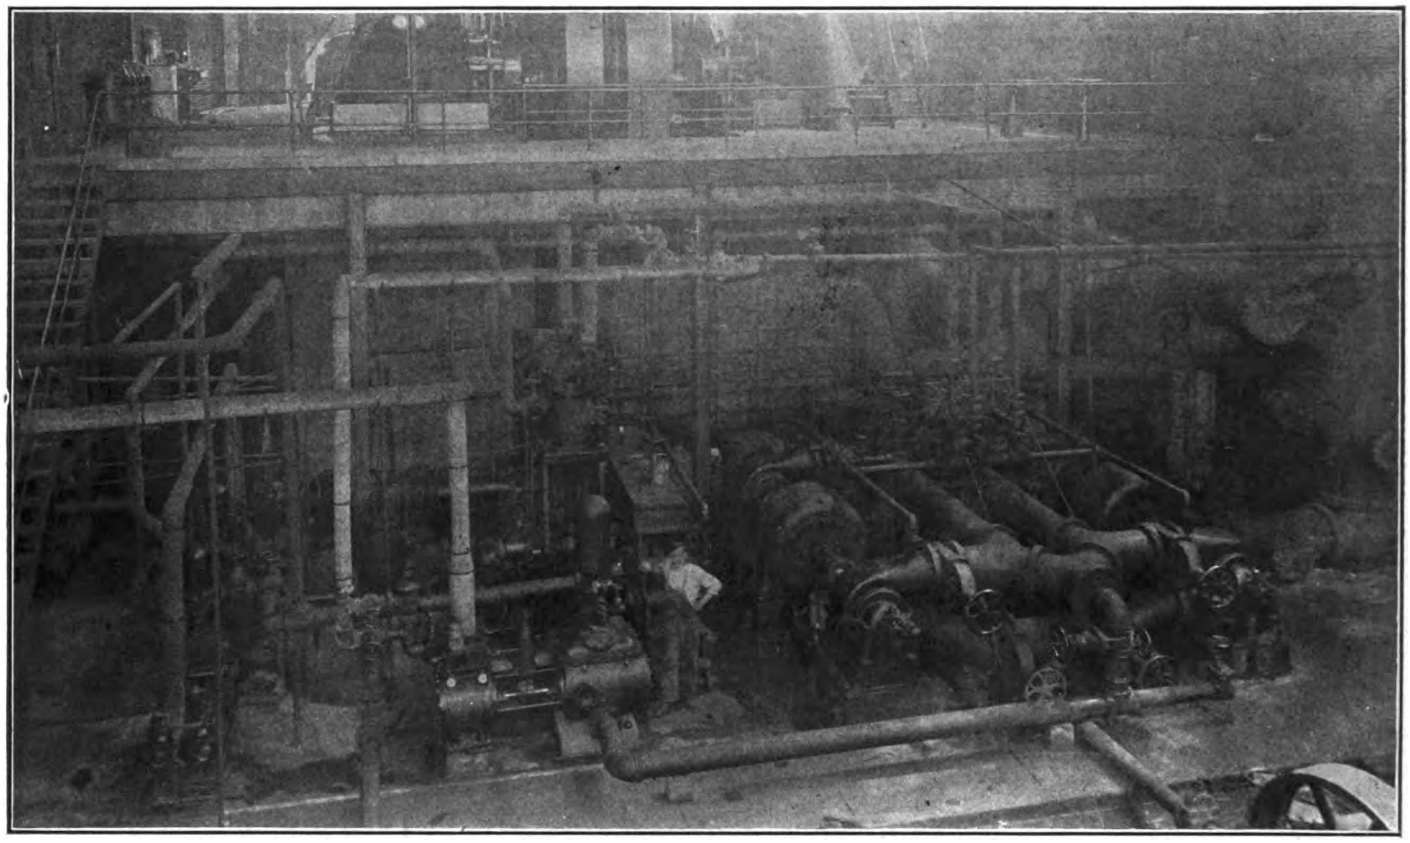

FIG. 4.—CONDENSER AND FEED-WATER EQUIPMENT.

erator is a four-circuit machine and has a capacity of 150 enclosed arc lamps. The current is 6.6 amperes and the machines are equipped with oil regulators. The efficiency of the arc generator at full load is 88 per cent and at half load 79 per cent. The synchronous motors and the arc generators that they drive are mounted on heavy wooden bases. A motor-driven air compressor, such as is used on street cars, was installed in this station for cleaning armatures.

FIG. 5.—DIAGRAM OF HIGH TENSION SWITCHBOARD CONNECTIONS.

The switchboard is of standard blue Vermont marble, mounted on angle-irons. There are three feeder panels, supplying 6600-volt current to rotary converters of the Edison system, on each of which panels are mounted three alternating current ammeters, one time-limit relay for tripping the oil switch, one controlling switch, and two indicating lamps for General Electric, type H oil switches. The totalizing panel for these three feeders is supplied with one balanced, three-phase, indicating wattmeter, and one balanced, three-phase, Thomson recording wattmeter. The panel controlling the induction motor for the exciter has one 150-kw. balanced, three-phase recording wattmeter, one ammeter, one balanced, three-phase indicating wattmeter, one lever for operating the compensator, one controlling switch for operating automatic, type H, oil switch with two indicating lamps, and one time-limit relay. The motor panels for the centrifugal pump motors have a power factor indicator, an ammeter, a field switch, two levers for operating form K. oil switches, and also a panel containing a lever for the starting compensator. Only one compensator is used for both pumps. One panel has on it one time-limit relay, one controlling switch and indicating lamp for a type H oil switch; the other has a balanced three-phase recording wattmeter. There are two exciter panels. The one for the motor-driven exciter has an ammeter, a voltmeter, a 600-volt, 2000-ampere, single-pole toggle-brush, carbon-brake switch, and one five-point, 100-ampere rheostat switch. This latter is not used at present. The panel for the engine driven exciter contains the same instruments as the other, but without the five-point switch. The negative bus is on the switchboard and the positive bus below the floor.

The two generator panels are each supplied with the following: one power-factor indicator, one alternating-current ammeter, one voltmeter, one field switch, one four-point synchronizing receptacle, two type H oil controlling switches, and four indicating lamps. There are also one double-throw switch, to control the engine governor for synchronizing and one pedestal for the rheostat. The panels for the 500-kw., phase-changer motors have a power-factor indicator, an ammeter, a field switch, and two operating handles for form K oil switches. The totalizing panel for these two motor panels contains one balanced three-phase indicating wattmeter, one balanced recording wattmeter, two controlling switches, and four indicating lamps for automatic oil switches. There is also a lever for operating the compensator. For the two motors driving the arc generators, two panels are equipped with the following: one power-factor indicator, an ammeter, a field switch, and two levers for operating type K oil switches. These motors have a totalizing panel which has a balanced three-phase indicating wattmeter, and recording wattmeter, two controlling switches, a time-limit relay, and a compensator lever.

For 2200-volt two-phase distribution the two generator panels of the motor generator each have two indicating wattmeters, two ammeters, two voltmeters, and one operating handle for a four-pole non-automatic oil switch. The two alternating current 60-cycle feeder panels have two single-phase indicating wattmeters, two ammeters, two voltmeters, one two-phase unbalanced recording wattmeter, and two double-pole, single-throw, hand-operated oil switches. For the arc circuits, four panels are installed, each of which accommodates four generator circuits, and four line circuits, together with transfer busses, and voltmeter busses. In addition to the foregoing apparatus, two 6600-volt Lincoln synchronizers for synchronizing the generators have been installed, and also one 220-volt Lincoln synchronizer for motor-generator phase changers. There are also static dischargers, and connecting switches for the feeders in the bus compartments.

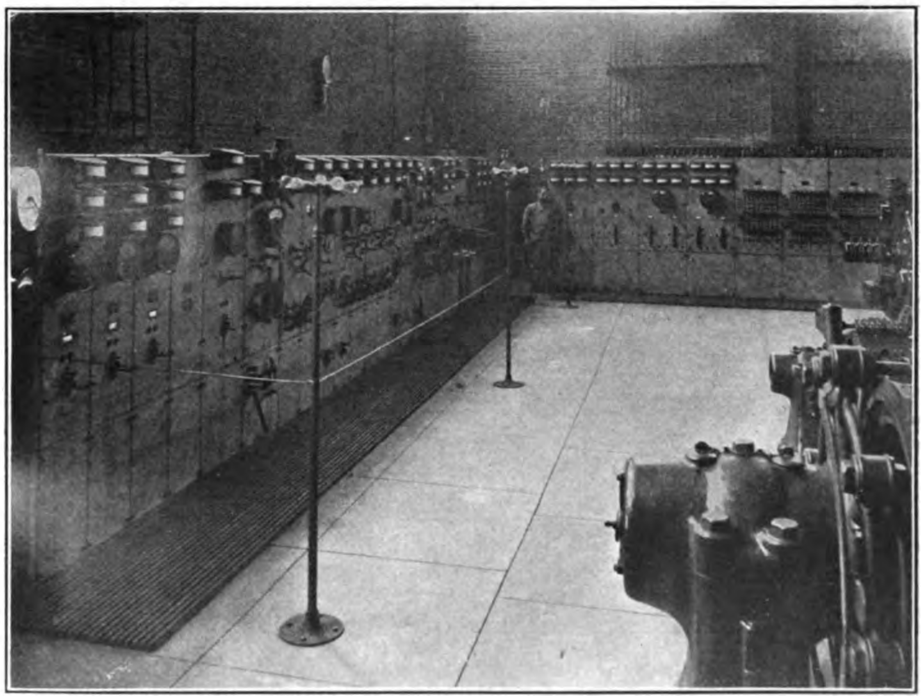

FIG. 6.—MAIN AND ARC SWITCHBOARDS.

The original layout of this plant included provision to supply the street railway company, as it was also short of power. For this purpose special bus-bars for 6600-volt current were provided. All of the high tension bus-bars and leads are confined to the basement, so that the only current that comes to the main switchboards is 125-volt direct current. Of course, the 2200-volt, 60-cycle alternating current, as well as the arc circuits, come to switchboards especially installed for them.

Starting from the two 1500-kw. generators, two cables lead to a sort of an auxiliary double bus-bar compartment, so arranged that either generator may be used to supply either the street railway or the lighting load. One pair of bus-bars is connected to No. 1 generator and one to No. 2 generator. From these bus-bars there are four sets of leads; two sets, one from each generator, connect through switches and "type H" oil switches to the street railway bus-bars, and two by the same means to the lighting bus-bars. The generator bus-bars of the street railway are connected to bus-bars which were laid out to supply four feeders, but only two oil switches were installed for the railway feeders; therefore, the provision for two extra feeders was not used. Later on, two more feeders were brought in, but as they were temporary, they were connected to the leads from the existing oil switches. The short railway generator bus-bars are connected to the railway station bus-bars by means of a cable. These railway station bus-bars were arranged so that later on, when the railway company had its power house in operation, the lighting company could transfer some of its load to the railway power house, and also, when one of the lighting generators was being used to help the railway, a part of the lighting load could be supplied from the same generator. Only the pump motors and arc dynamo motors are run from these bus-bars at such times on account of the variations in railway voltage.

The station lighting bus-bars are so arranged that all auxiliary apparatus can be run from them, while the feeders that supply the rotary converters used on the Edison system down town have their own bus-bars, which are connected through switches to the main station bus-bars.

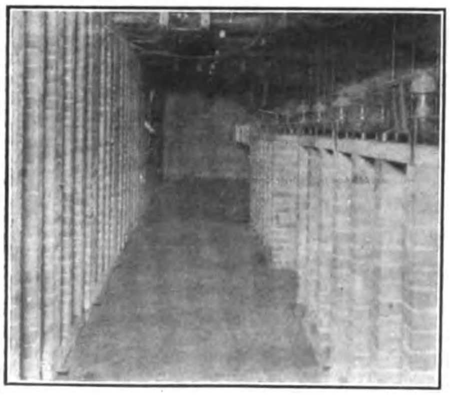

FIG. 7.—OIL SWITCH AND BUS-BAR COMPARTMENTS IN BASEMENT.

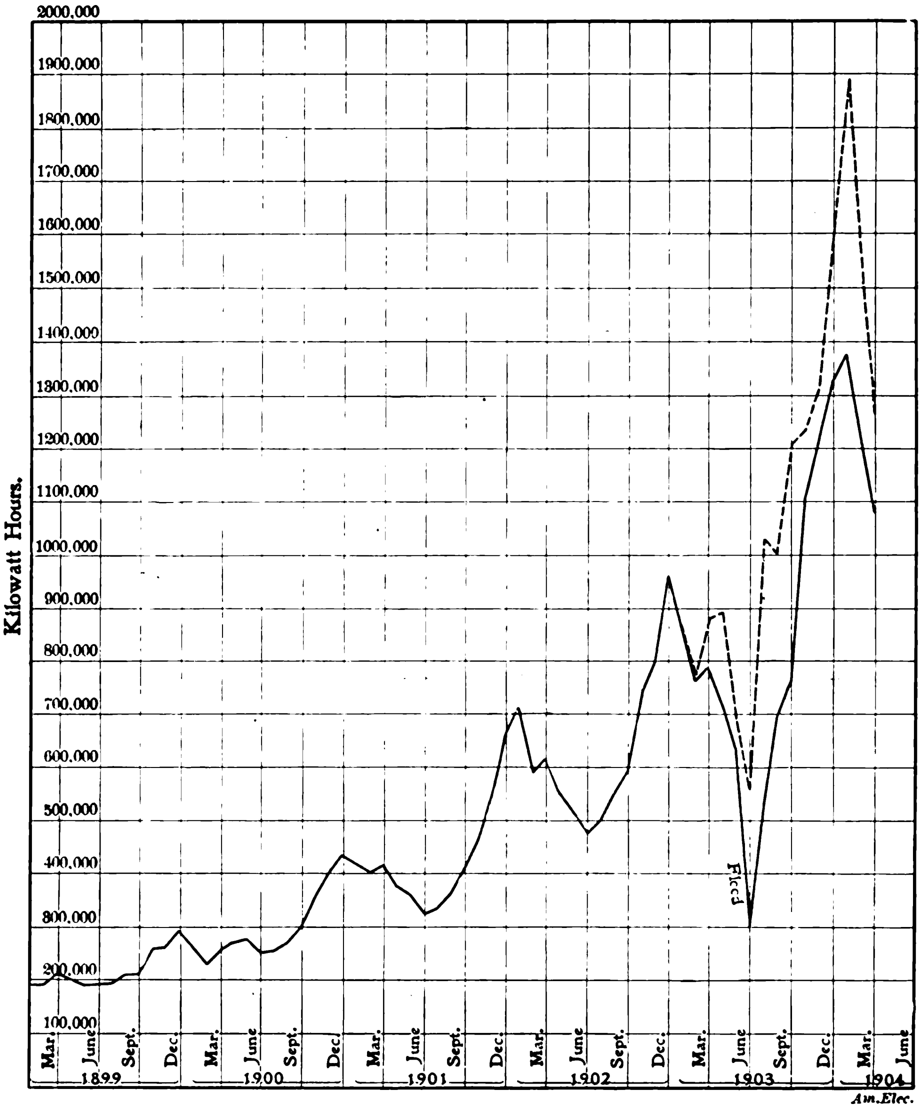
The motors for the 500-kw. phase changers are connected as follows: starting at the main bus-bars two-way switches are arranged so that these motors can be run from either the railway or the lighting bus-bars; a "type H" motor-operated oil switch, controlled by an overload relay, controls both sets of motors, but each motor circuit is controlled after this by a set of "type K" non-automatic switches; one switch cuts in the compensator for starting and when the motor is up to speed the second switch cuts in the motor direct. Only one compensator is used for both motors.



Am.Elec.

FIG. 8.—CURVE SHOWING INCREASE IN OUTPUT FOR DIFFERENT YEARS.

The 600-kw., 600-volt rotary converter for the power circuit also has a "type H" motor-operated oil switch, with an overload relay, but has no starting compensator, as this machine can be started from the 550-volt railway circuit on the direct-current side and when in synchronism, the oil switch is closed. A Lincoln synchronizer is used for synchronizing.

The two 125-kw. synchronous motors for the circulating pumps and the two 180-kw. synchronous motors for the arc-light dynamos are connected up like the 500-kw. phase-changer motors, only one compensator being used for each pair.

All potential and current transformers for indicating and recording instruments are placed in the basement as close to their respective leads as possible, to avoid as much as can be the running of high tension wires promiscuously. The three oil transformers for the exciter motor, as well as the three air blast transformers for the 500-volt rotary converter are also located in the basement. Current for the three-phase, 25-cycle, 440-volt coal conveyor motor is taken from the exciter transformers; these same transformers also furnish current for the ash elevator motor.

The central station described furnishes current for all the series arc lighting in the western part of town and in the immediate vicinity. All of the 60-cycle alternating current for incandescent lighting is furnished from this station at present. The 500-volt power circuit is also furnished from here. The 6600-volt, 25-cycle current is carried to up-town sub-stations by means of three No. 0 and one No. 00 cables. An emergency line running overhead of No. 00 wire was also installed, as at the start some trouble was experienced with cables.

At the sub-station, located at Sixth and Wall Streets, at present two rotary transformers of 200-kw. capacity are operated to supply the Edison system, and a few bi-polar Edison machines are run by steam. This steam plant will be discarded in about a month, as at present a 750-kw. 220-volt rotary is being installed, and later on the four 200-kw. rotaries at the Thirteenth Street and Grand Avenue sub-station will also be installed at this station. The present station, located at Thirteenth Street and Grand Avenue, contains four 200-kw. rotaries, to supply the Edison system; also a motor driven arc set, the same as used at the Central station. This sub-station is to be discarded and a permanent sub-station is to be located at Fifteenth Street and Grand Avenue, where the street railway company has a sub-station in the same building. At this sub-station there is being installed at present a 750-kw., 220-volt rotary converter to be used on the Edison system. There will also be a motor driven arc set installed at this sub-station. At Thirty-first and Holmes Streets, where the street railway company has a sub-station, there will also be installed a motor driven arc set. At present there is installed at this station for the lighting company three 6600 to 2200-volt, 25-cycle static transformers. These are used for furnishing three-phase, 25-cycle current for motor power in that neighborhood, especially for elevator service in apartment houses. A sub-station is also to be installed by the street railway company at Twelfth and Cleveland Streets, where the lighting company will later on install two motor driven arc sets and another phase changer to supply the eastern territory. The present South plant is to be discarded. All of the arc generators there at present are to be coupled in pairs to a motor and installed in the above named stations.

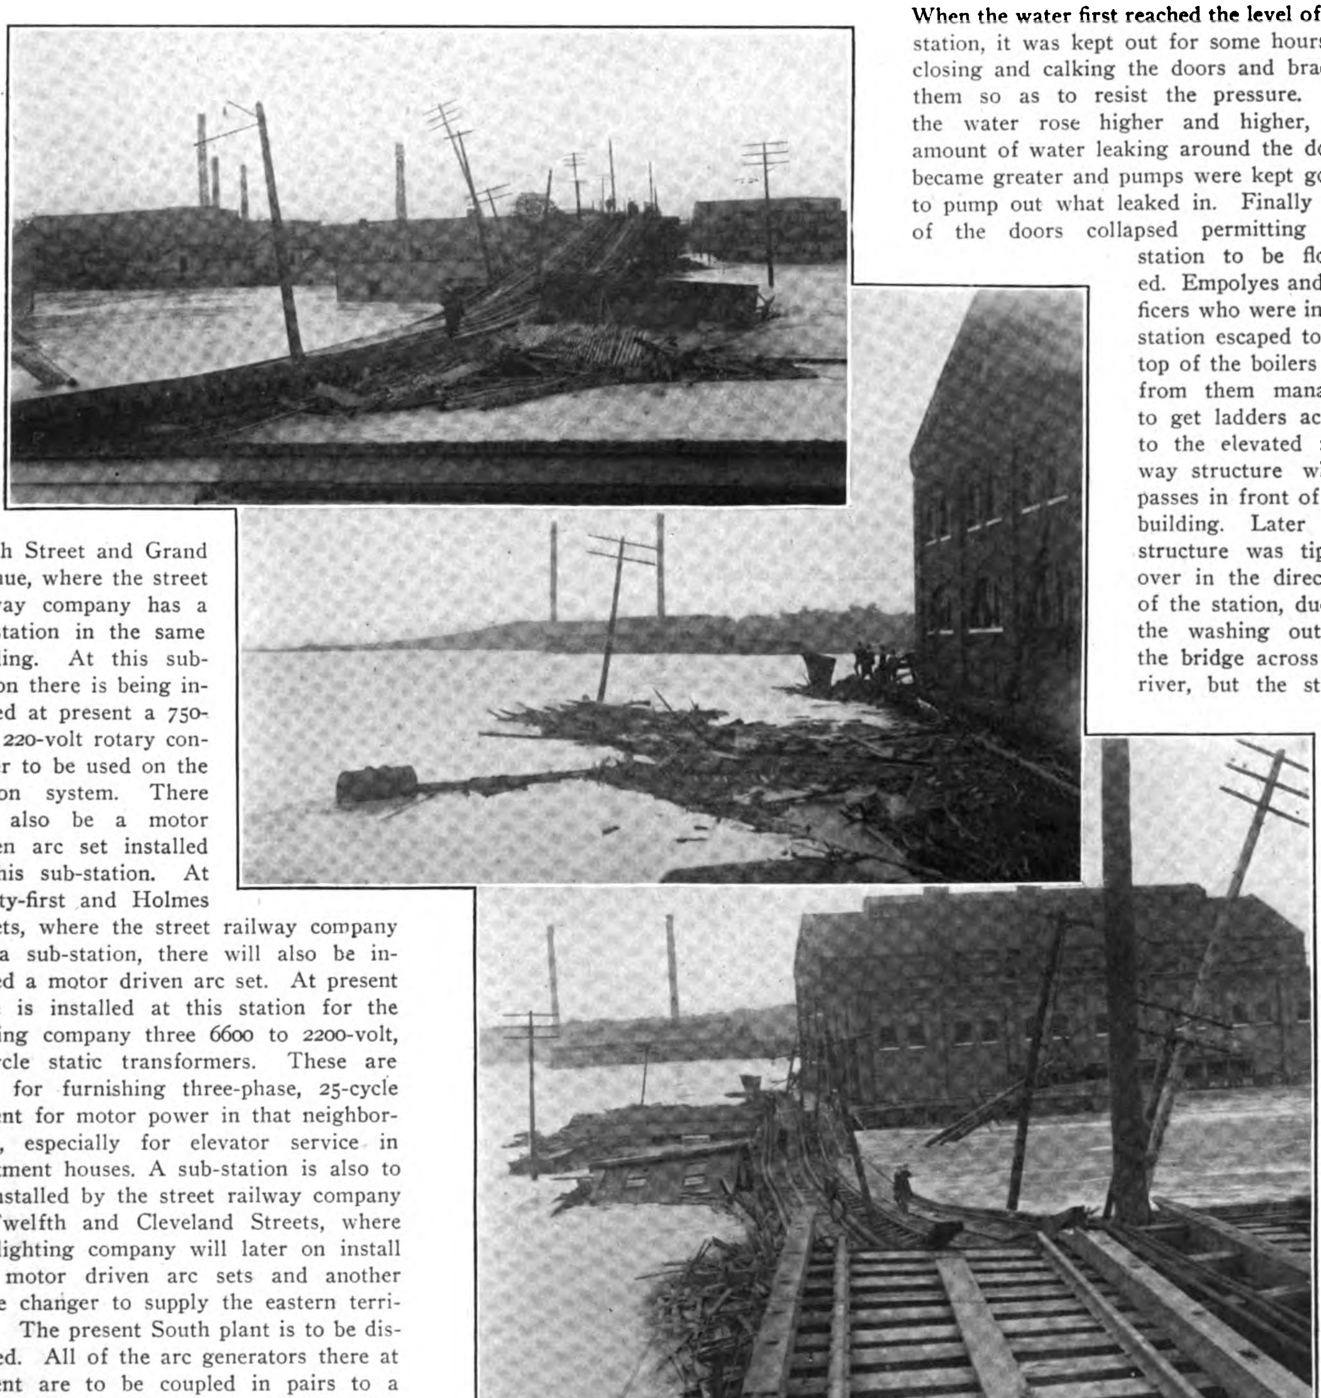


FIG. 9.—VIEWS SHOWING RESULTS OF FLOOD.

As the company has had so many different types of stations under its control, all in the same city and as nearly as possible under similar conditions as to wages, price and quality of coal, and efficiency of management, it has had an unusual opportunity to determine the relative economy of the apparatus in these different stations. The coal burned is Cherokee Kansas slack, containing about 17 per cent of ash and having a calorific value of about 11,000 B. T. U. The new Central station, when running condensing, obtains 225 watts per pound of coal. When running non-condensing, the output is 165 watts per pound of coal. This is a compound condensing station with 1500 kw. units, water-tube boilers, and link grate stokers. The "South plant" gives 127.5 watts per pound of coal. The "Santa Fe" station gives 142.9 watts per pound of coal. The Edison station on Wall Street gives 45.1 watts per pound of coal. The Central station is operated by twenty men, the "South plant" by fourteen men, and the Edison station by eleven men. When open arc lamps were used entirely, fourteen trimmers were required. There are now 3300 enclosed arcs and only six trimmers are employed. All of these figures are interesting because they are the results of actual work and not theoretical assumptions.

THE FLOOD.

On May 30, 1903, the last piece of apparatus had been installed at the Central station and the next morning the river rose very suddenly. The station was flooded for several days, and the water reached just above the main bearings, of the alternators. When the water first reached the level of the station, it was kept out for some hours by closing and calking the doors and bracing them so as to resist the pressure. As the water rose higher and higher, the amount of water leaking around the doors became greater and pumps were kept going to pump out what leaked in. Finally one of the doors collapsed permitting the station to be flooded. Empolyes and officers who were in the station escaped to the top of the boilers and from them managed to get ladders across to the elevated railway structure which passes in front of the building. Later this structure was tipped over in the direction of the station, due to the washing out of the bridge across the river, but the structure was still in such condition that employes could use it as a means of entrance to and exit from the station.

The height of the water above the lowest basement floor was 28 ft., which brought it just above the main bearings of the engines, and just below the top row of instruments on the switchboard, the switchboard being located on the main floor of the station.

When the water subsided, a most discouraging sight was presented to the company's engineers. Not only was every piece of electrical machinery in the station soaked with water, but upon everything there was a thick deposit of mud. The high-tension bus-bar compartments, which are below the main floor, were of course flooded, and filled with this same slimy mud. It was not thick enough to shovel and yet too thick to pump. The only way in which it could be handled was to bale it out. One can imagine the situation. Over half of the big main generators under water and every other piece of electrical apparatus, every exciter, motor generator, potential transformer, high-tension cable, and high-tension bus-bar compartment, full of slime, with a liberal supply of cinders, timber, stockyard refuse, and other choice débris thrown in. As fast as the water receded the company went to work to get its demoralized service into shape again. The mud was scraped and washed off the apparatus as well as it could be, and when the water finally left the station ~~the hose was turned~~ on to the armatures and as much mud as possible dislodged in that way. Then the armatures were turned over and more mud dislodged. After washing out all coils and picking the cinders out of the small cracks, salamanders were started to dry them out. When some of the moisture had been driven off in this way, current was secured from the Wall Street Edison station downtown, and conducted over three miles of trolley line to aid in drying out the generators.

Nine days after the floor receded, the first 1500-kw., 6600-volt generator to be dried out measured 60,000 ohms insulation resistance. Although advised to the contrary, the management decided to start this generator, on account of the urgent need for service, and operated it at an overload within a short time. After operating 36 hours, two coils burned out. The experience with the second generator was similar to that of the first. The two coils lost in both cases were at the high-water mark, and it is thought that they were damaged by chemicals which floated down from chemical works up the river. The balance of the coils were uninjured, and have been in continuous service ever since. The small armatures were treated like the large ones. Steam coils, salamanders, and compressed air, aided by pieces of flat wire to pick out the cinders, were used in the task. The cores and coils of the static transformers were taken out of the cases, washed, and dried in the sun, and the cases also washed out.

The most annoying trouble of all was the leakage of water into the high-tension lead-covered cables at the pot heads. The pot-heads where the conductors leave the cables to connect to the bus-bars were never intended to stand the water pressure they were subjected to, and consequently water entered the cables and worked back distances of 15 and 20 feet, or more. There were over 30 6600-volt pot-heads, and 100 pot-heads altogether in the station.

Current was on the lines eleven days after the flood. The only losses of electrical apparatus which could be traced directly to the flood were some small potential transformers which probably did not receive a proper amount of care in the drying out process, owing to more important things being dried out at the same time. The bearings, which of course were filled with Kaw River mud, were first flushed out with water and then with kerosene oil. No trouble was experienced with hot boxes. The incident shows what a wonderful amount of abuse modern electrical apparatus can withstand and still be brought back into service.

◆

A REVOLUTION IN PRIME MOVERS.

BY DR. LOUIS BELL.

Just at the present moment the whole subject of prime movers for central stations is in a condition of plasticity that leaves its probable future in great uncertainty. One really hesitates in expressing more than a mere tentative opinion, for the present data ~~are entirely insufficient~~. ~~The steam turbine~~ has now been a long time in evolution and has already been brought into a form that is highly satisfactory. It is not necessary or pertinent here to discuss the details of the theory of steam turbines, still less the principle of the internal combustion engine that already looms large in view. The bare facts in the case furnish quite sufficient food for reflection.

At the present time steam turbines of half a dozen different forms are being actively exploited. They represent various modifications of the turbine idea and vary in construction over even a wider range than do water turbines, but in much the same sort of way. They possess in common the characteristic of very high rotative and peripheral speed, rendered necessary by the very great spouting velocity of the tenuous fluid by which they are operated. As is evident on a moment's reflection, this high velocity is the source of their strength and their weakness. It results immediately in a very large output of power from a relatively small machine, and hence in a prime mover of moderate cost and great compactness. The form of construction likewise results in extraordinarily low frictional losses, especially in those turbines which are worked on a vertical shaft, and as a necessary consequence the mechanical efficiency is high at all loads and relatively very high at low loads.

The dynamos connected to turbines are likewise possessed of high speed, which is by far the cheapest way to get electromotive force; so that taken as a whole, a turbo-generator is a cheap, efficient and compact machine, as everybody now realizes.

On the other hand, the very high speed of steam turbines means great extra precautions in both workmanship and material in order to insure safety, and makes the turbine extremely inconvenient for direct coupling to direct-current machinery. There have been a good many direct-current turbo-generators produced abroad, mostly in small sizes, but those who have looked into their operation are seldom enthusiastic about their performance in practical every-day work.

Hence turbines are at least temporarily barred from the very field in which their good qualities would be of the greatest value, that is, the small central station railway plant or isolated lighting plant. In such places the usefulness of the turbine is limited to those which dispense alternating current—at present only a rather small fraction of the whole. If direct current is the product, by the time one has added in the cost of converters and discounted their losses, the combination fails to show high efficiency. The future of the turbine is therefore linked with the future of alternating currents. Recent developments in alternating-current motors, especially for railway use, will tend to remove this disability and there is always a chance for the appearance of a direct-current dynamo suited to extreme rotative speeds.

For the present, however, the large field of steam turbines is in the large lighting and power stations, where they are already in extensive use. For these situations their ~~good light-load efficiency~~ and their low cost are very strong recommendations. Personally, the writer does not attach great importance to the saving in space, except in occasional instances, since turbines need just as much boiler capacity as reciprocating engines of similar output, and the problems involved in the design of the boiler room and piping systems are apt to render it difficult to utilize the full saving of space so readily obtained upon paper.

As to the actual relative efficiencies of turbines and engines in steam required per kilowatt-hour of output, the figures thus far obtained leave the issue in doubt. Worked at the same initial steam pressure, degree of superheat and vacuum, the compound condensing engine seems to hold its own well at full load with the turbine, although the conditions are so seldom the same that comparisons are far from easy. The turbine as at present developed requires more vacuum than the engine, and has rather the worst of the pressure question, since extra pressure aggravates the speed difficulty. At low loads, most tests give a considerable advantage to the turbine, although comparison with engines especially planned for economy at moderate loads show the two machines nearly upon a parity.

The best results with triple expansion engines, however, have not been nearly duplicated by the performance of turbines. The turbine undoubtedly will be considerably improved, but it will also goad the engine builder to the attainment of economy higher than has hitherto been reached. At present the two machines are neck and neck, as it were, in the race for minimum cost of power production, but both have to reckon with a very dangerous competitor in the internal-combustion gas engine. This prime mover, familiar in small sizes, starts with the advantage of a thermo-dynamic efficiency far in excess of anything which there is yet reason to expect from steam engines of any sort. Roughly, it transforms into work twice as great a proportion of the heat supplied as does any other form of heat engine; its efficiency is 20 to 30 per cent instead of 7 to 12 per cent as in steam engines of similar output. What is more, it is relatively in a far earlier stage of development. It loses in its exhaust, probably without sufficient cause, a greater proportion of the heat supplied than the best steam engine transforms into work. The preventable heat losses outside of the exhaust are probably at least as large. The recovery of this lost energy is the task now before the gas engine designer. The engines heretofore built have been heavy and bulky, but the very extensive use of the type in automobiles has already produced great improvements in construction and the resulting competition has reduced prices. Likewise, the need of continuous rotary effort in automobiles has produced engines with carefully balanced multiple cylinders, and worked with high-speed compression, so that the old gas engines with irregular speed and enormous friction losses bear about the same relation to recent machines that the "atmospheric" steam engine of Newcomen's day bears to the engines of a torpedo-boat destroyer.

There is no reason why internal explosion engines of large power should be abnormally heavy or should present unreasonable friction losses. The cylinder pressures involved are not excessive, and the moving parts need not be either very massive or very complicated. One difficulty which is peculiar to the gas engine is the very high initial temperature of the working fluid, a necessary concomitant of very high efficiency. This renders it more difficult to deal with the friction and lubrication problems than in the steam engine, but here again the automobile comes to the rescue. For automobile use the engines must be capable of continuous operation with little attention and at high rotative speeds. Therefore the friction must be kept down within moderate limits. But the bigger the engine, the relatively less is the friction difficulty, and what would be fairly successful avoidance of friction in an automobile would be highly successful in a large engine. And the friction difficulty is greatly exaggerated by the steam contingent anyhow. Even in engines of very moderate size the brake horse-power can be kept up to 80 or 85 per cent of the indicated horse-power, and in large engines the friction is not much in excess of that of a compound steam engine with its accessories counted in.

The outlook at the present seems to the writer to show probable great improvements in the internal-combustion engine within a very few years, greater than can be hoped for in any prime mover driven by steam. Even now the great gas engines used abroad, and just now being introduced into this country, are probably capable, under reasonably favorable conditions, of giving power more cheaply, all things considered, than any existing steam engine. We are not used to the idea in this country and balk at using a gas producer instead of the good old-fashioned boiler, but the lowering of cost is a powerful argument, and whenever the gas engine can show clear gains over the steam engine in total cost of power it must forge to the front. It does not seem likely that so revolutionary a change will come at once in any event, for large gas engines will have to be in use for some years before the cost of upkeep becomes a certain quantity. But the writer is strongly of the opinion that the internal-combustion engine will take a very important place in power station practice in the not distant future. It lends itself very readily, too, to the kind of sub-station work that is now common. Certainly within a moderate radius gas can be distributed to sub-stations with gas engines in large units probably more economically than current can be generated, transmitted and converted. There is also more or less discussion regarding internal-combustion turbines. The outlook in this direction is at present less hopeful than that for the reciprocating form, and whatever it may be, it is with the reciprocating engine that we have now to deal. The St. Louis Exposition is likely to be an eye-opener to those interested in prime movers, and the big gas engine exhibit is one that will be worth very careful study.

It is a curious chance that the steam turbine should have come upon the field just as the internal-combustion engine develops as a serious competitor, but similar things have happened before. As between the turbine and the ordinary steam engine, the battle must be fought out on the present basis. Both must keep an eye out for a very dangerous competitor in the gas engine, which is developing very rapidly. Within a year or two it will force its way into central station practice, not as a freak but as a standard apparatus. From that point out, it is anybody's race in the struggle for supremacy, with certain intrinsic advantages in favor of the newest comer.

◆

FURNACE FITTINGS FOR STEAM BOILERS.

BY R. T. STROHM.

The object of the steam boiler furnace is to furnish a properly arranged chamber in which the combustion of the fuel may take place. In order that it may accomplish this purpose satisfactorily it must provide a support for the fuel during its combustion and it must confine the gaseous products of combustion and direct them against the heating surfaces of the boiler. The furnace fittings then resolve themselves into three classes. First, the materials composing the furnace itself; second, grates for the support of the fuel; third, appliances for aiding the process of combustion.

In order to produce efficient and economical combustion, the furnace must be refractory, since it must not only withstand continued high temperatures, but must maintain them, in order that the ignition of the fuel may be carried on successfully. The combination of carbon and oxygen occurs only at temperatures above 800° F. As a result, it becomes necessary to build the furnace of some material which shall aid, as far as possible, in maintaining a high furnace temperature. Further than this, the material must be fairly durable, not high in first cost, and easily, cheaply and quickly repaired in case of accident or natural deterioration.

The material most largely used for furnace construction is fire brick. The bricks are somewhat larger than the ordinary red brick, but they should be laid more closely. That is, the thickness of the mortar should not be as great as in the case of the ordinary red brick. Again, the mortar used must also possess the refractory qualities of the brick. So it is customary in a large number of cases to use fire clay in laying up furnace walls. The bricks themselves are of fire clay, but there is this marked difference. They have been thoroughly baked and burned, whereas the fire clay is yet raw. The consequence is that when the furnace walls are subjected to a high temperature, the fire clay bakes into the same state as the bricks, shrinking in so doing. For it is a peculiarity of this material that it shrinks under the effects of high temperatures. Unless the wall is very carefully built, this shrinking may so loosen the bricks as to cause them to tumble down under the ordinary conditions of service. The binding value of fire clay is also low, so that it has little effect in cementing the courses together. Where the wall is laid in courses of stretchers with only an occasional course of headers, it will easily disintegrate, and a few light blows from the firing tools, either by accident or in knocking clinker from the walls, may result in the dropping out of bricks until the lining is practically ruined.

To obviate this difficulty, a mortar composed of fire clay, pulverized fire brick and lime has been suggested, which will not shrink to the same extent as the fire clay alone. In addition to this, those portions of the walls immediately enclosing the furnace are laid in courses of headers, giving a much stronger wall and making it better able to resist hard firing and the careless use of fire tools. It is not good practice to allow broken ends of fire bricks to face the furnace. The hard baked surfaces should be in contact with the flames and the hot gases, all cut surfaces being turned into the wall.

The bridge, which directs the gases upward into close contact with the shell, must also be capped with fire brick. In this case, the bricks should be laid on edge, so as to reduce the liability of damage when cleaning or drawing the fire. There are two forms of bridge wall in use. One has a concave top, corresponding to the curvature of the shell, and the other has a level top. The latter is preferable, since it is more easily constructed and less easily injured, and it is the form commonly used. The front of the bridge wall is usually beveled so as to facilitate firing operations.

Grates as used in steam boiler practice may be divided into three general classes, namely, stationary, rocking and traveling grates. The first class includes all grates formed by fixed, rigid bars. The second class includes those grates in which the bars may be given an oscillating or rotary motion, either by hand or by some form of motor. The last class comprises those types in which the entire grate surface moves uniformly in one direction. However, since mechanically operated rocking grates and traveling grates come more directly under the head of mechanical stokers, which may be regarded as a distinct subject in itself, only the stationary grate and the hand-moved rocking grate will be considered in this article.

If it were the sole purpose of the grate to support the fuel, it might be a heavy pier of masonry covered with fire brick. But it must also allow the passage of air through the fuel bed, which necessitates a perforated structure. This is accomplished in various ways. Doubtless one of the simplest and most common forms of grate is that illustrated by Fig. 1. It is nothing more or less than a narrow bar of cast iron, having lugs projecting laterally at the ends and at the middle. The grate is built up by laying a number of these bars side by side. The lugs thus separate the individual bars sufficiently to form the air spaces.

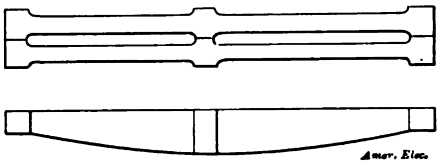

FIG. 1.

It is evident that to obtain the best results the grate should be so proportioned as to give the maximum amount of air space and at the same time prevent the fuel from dropping through. This means that the grate must be selected in accordance with the size and nature of the fuel to be used. The width of the air space is limited only by the size of the coal. The thickness of the metal is limited by the ease of casting on the one hand and the requisite strength of bar on the other hand. The former varies from ¼ inch to 1 inch for the several grades of coal used in steam making, while the latter seldom, if ever, exceeds ½ inch.

FIG. 2.

Grate bars are commonly made of cast iron, the reasons for which are not hard to find. In the first place, the bars are subjected to an intense heat, which demands that they be made of some material which will not easily soften. They must not be affected to any great extent by the impurities in the coal. They should be of a cheap material, and should not be expensive to manufacture. Cast iron meets these requirements better than any other material, and in consequence is the most largely used.

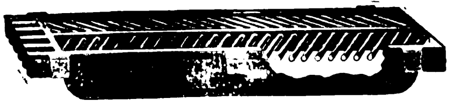

FIG. 3.

Another very common form of grate bar is that shown in Fig. 2, and known as the herringbone pattern. It consists of a large number of short webs between two parallel bars. These shorter webs are made V-shaped so as to provide for their expansion and contraction without damage. The advantage claimed for this type of bar is that it possesses more than 50 per cent. of air space and yet gives a strong, durable grate. It will be noticed that the webs are thinner at the bottom than at the top. The purpose of this construction is to prevent clogging of the grates by ashes or clinker. If a piece of refuse once gets through the space at the surface of the grate, it will not stick anywhere else, since the air space grows gradually wider. A slight variant of this style of grate bar is illustrated in Fig. 3, in which the central web is replaced by a number of short wrought iron bars. The bar shown in Fig. 4 does not differ materially from that shown in Fig. 3, but the pattern for it is easier to construct.

The bars thus far illustrated are held in place in the furnace simply by their own weight. In case the bar is light and narrow, it is necessary to keep it in place by some form of fastening. Fig. 5 illustrates what is known as the interlocking grate bar. The grate is built up of the three kinds of bars shown. Starting at the side wall of the furnace with a No. 1 bar, a No. 2 bar is set next, and so on alternately until the middle of the furnace is reached. Then the grate is built up from the other side in the same manner. This leaves two No. 2 bars next to each other at the middle. A No. 3 bar is placed between them, and the cotters are driven through the lugs on the central bar. These cotters extend across under the bars on either side and effectually lock the whole grate.

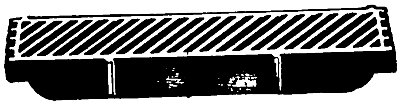

FIG. 4.

It will be noticed that all grate bars are made of considerable depth and that this depth is greater at the middle than at the ends. When a bar is in place in the furnace, it is supported at the ends and loaded uniformly, so that the greatest bending moment occurs at the center, and hence the section should be strongest at that point. An additional reason for using a deep web is that the top of the bar may become red hot, and if the web is deep this heat will be conducted into it, thereby giving a greater convection surface, which preheats the air and also cools the bar.

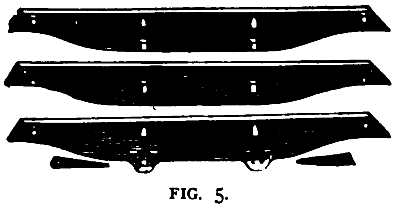

FIG. 5.

Wrought iron is occasionally used in the construction of grates, but as it softens under the effects of heat, grates made of it usually consist of pipes through which a water circulation is maintained in order to cool them. An excellent example of this is the down-draft furnace illustrated by Fig. 6, intended for use with bituminous coal. The upper grate consists of a number of wrought-iron pipes, *A*, connecting two drums, *B* and *C*. These drums extend entirely across the furnace, the larger one being subjected to the heat radiated from the fire as well as that of the gases. Both drums are connected to the boiler below the water level. The smaller drum being placed at a lower level than the larger, and in a position more protected from intense heat, a circulation is set up, the water passing down the pipe *D* into the drum *B*, thence through the grate bars *A* to the drum *C*, and up into the boiler through the pipe *E*. The fresh fuel is fed to the upper grate, where it cokes, the gases being distilled and passing down through the grate to the lower furnace chamber. The wrought-iron bars being widely spaced, the coked fuel falls through to the lower grate, where it burns brightly and heats the air admitted through the ash pit, so that when the combustible gases distilled from the coal enter the lower furnace, the best possible conditions exist to produce complete combustion and smokelessness.

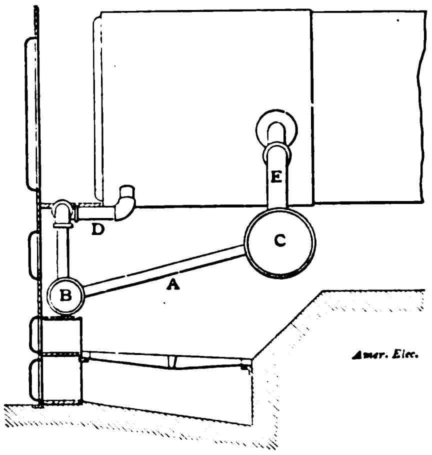

FIG. 6.

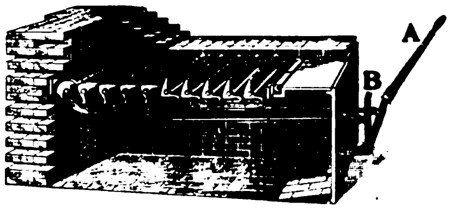

FIG. 7.

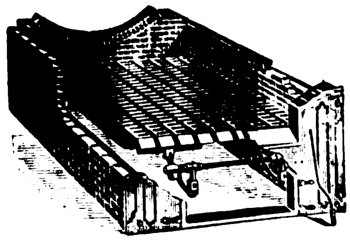

FIG. 8.

The disadvantage of using stationary grates is that the fire is not easily cleaned. Unless the air spaces are kept free of clinker and ashes, the combustion is hindered and the fire rendered sluggish. Nevertheless it is wasteful of fuel to clean the fire repeatedly, or to make frequent use of the slice bar, for the reasons that the finer portions of the fuel are sifted into the ashpit if the fire is broken up, and the volumes of cold air admitted while the fire-door is open chill the fire and lower the furnace temperature. To facilitate cleaning of the fires without opening the fire-doors, to maintain a clean grate and a fairly uniform furnace temperature, and to obviate the loss due to the smaller particles of fuel falling into the ashpit during the cleaning process, rocking and shaking grates have been designed. They are composed of individual grate bars mounted in a suitable framework, and so arranged that the bars may be given a sliding or rocking, or vertical motion, by means of levers operated from the front of the boiler outside the setting.

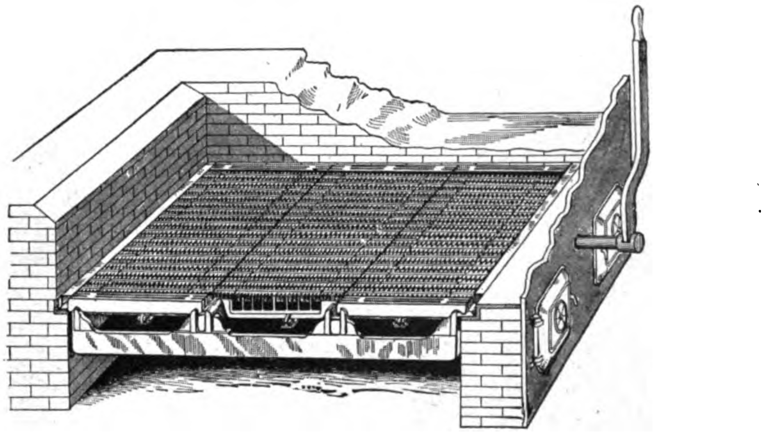

FIG. 9.

A well-known type of rocking grate is illustrated by Fig. 7. It consists of a number of separate bars extending laterally across the furnace and furnished with journals at each end which fit into boxes in the side bearing bars, thus permitting the grate-bar to rock to and fro. The grate is divided into two sections and the bars composing each section are joined together, as shown, by a common connecting bar to which the shaking lever *A* is connected by a rod. This arrangement makes it possible to clean either section of the grate without disturbing the other. Cleaning the fire is a simple matter. The clean fire on the front section is pushed back upon the rear section and the front section is dumped by pulling the lever *A* forward, as shown, after which it is returned to normal position and the live coal pulled forward upon it, while the rear section is cleaned. Then the fuel is evenly spread over the grate surface. The handle is made so that it can engage either or both of the shaking levers, thus allowing the sections to be shaken separately or together. In order to keep the air passages free from ashes, it is only necessary to place the handle on both levers and give it a slight motion to and fro. By repeating this at frequent intervals the fire may be kept in excellent condition. The bars are made so as to give as much air space as is consistent with strength and durability. This grate is particularly well adapted to the burning of the smallest sizes of anthracite, in which case the air spaces are not more than 3-16 of an inch wide.

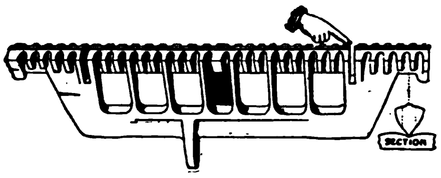

FIG. 10.

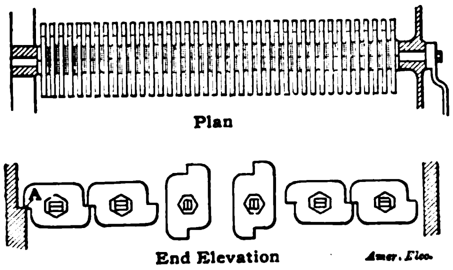

FIG. 11.

In the shaking grate shown in Fig. 8 the bars run lengthwise of the furnace and rest upon swinging bars to which the bracket is attached by a link. The shaking lever is put into the socket and moved up and down, imparting to the grate-bars a vertical and a horizontal motion, which opens the air spaces and thoroughly cleans the under surface of the fire. The bars are made of such section as to resist warping under the effects of the heat of the furnace, and yet present a large and efficient air space.

The temperature of a steam boiler furnace may rise to a point at which cast iron will melt, and trouble is frequently experienced with the burning of grates, especially if the iron is at all soft. This trouble is aggravated when the grate bar is made up of many small, thin fingers or fins. A grate which is designed to overcome this difficulty is illustrated by Fig. 9. In this type, the individual bars are but 1½ inches wide, the webs or fins being very short. A larger view of the bar is given in Fig. 10. The depth of the bar is considerable, but it is made of a skeleton character to reduce its weight. The great depth is necessary to prevent warping, and much of the heat received from the fuel is conducted into the lower portion of the bar, where it is taken up by the air supply. The expansion of the top of the bar is taken up by the two narrow slots shown which give considerable elasticity. These bars are placed lengthwise of the furnace, as shown in Fig. 9, and are rocked from side to side by a lever at the front of the boiler.

A revolving grate, which involves the principle of the shaking and rocking grate, is shown in Fig. 11. In the plan view a single bar is illustrated, extending from the front to the rear of the furnace. A number of these units are placed side by side until the desired width of grate is obtained. Each unit or bar is composed of a number of discs, of the shape shown in the end view, mounted on a revolving shaft which is turned by a lever at the front. The discs of one row rest against those of the next row, and by giving one side row a bearing on the furnace wall, as at *A*, the entire grate may be locked.

The bars of a grate are supported by what are known as bearing bars, shown at *A* and *B*, Fig. 12. These may be made of angle iron or of the cast iron T section shown. The latter is preferable, since it is much stiffer and is not so liable to be affected by the heat as a wrought iron bar. These bars extend across the furnace at the front and at the rear and rest upon the side walls or are supported by iron legs. Many of the shaking grates are constructed so as to be self-supporting, and independent of the boiler setting. This permits their installation or removal without tearing down the setting to any extent. The dead plate *C* is a cast-iron plate reaching from side wall to side wall at the front of the furnace. It forms the bearing in many cases for the front ends of the grate bars and at the same time gives a surface on which fresh coal is piled, where bituminous coal and the coking system of firing are used. It is provided with strengthening ribs underneath, to prevent warping.

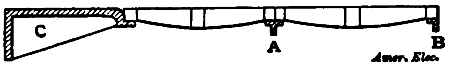

FIG. 12.

The use of blowers as an aid to combustion seems to have gained some favor, especially where smoky coals are used. Generally these blowers consist of a steam jet or a circle of jets so arranged as to entrain a volume of air and force it into the furnace. Figs. 13 and 14 show the forms of blowers referred to. These may be placed in the side walls of the furnace or in the fire doors. When thus located, comparatively cold air is forced over the surface of the fire, and this is opposed by many as being disadvantageous in that it chills the gases and supplies excess air when it is not needed, thereby causing a loss. It is suggested that if blowers must be used, they be so located as to discharge into the ash pit, so that the air supply shall be preheated by passing through the bed of incandescent fuel on the grate.

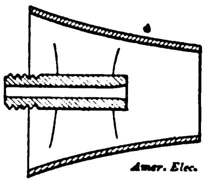

FIG. 13.

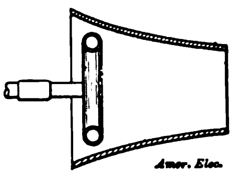

FIG. 14.

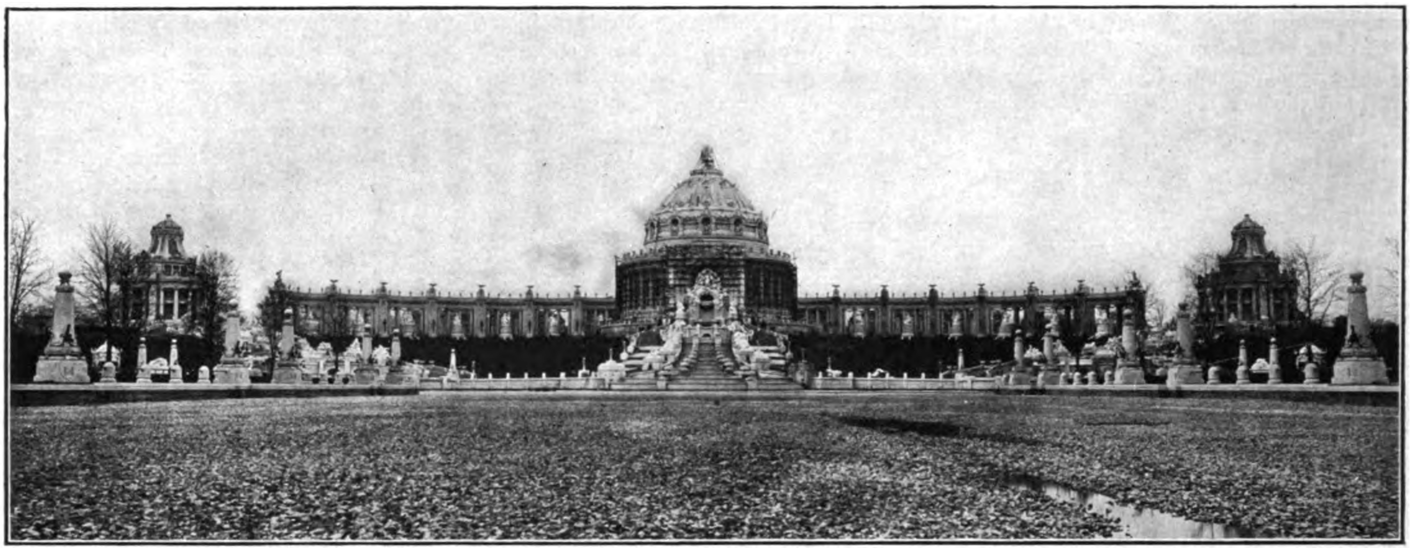


FESTIVAL HALL AND THE CASCADES.

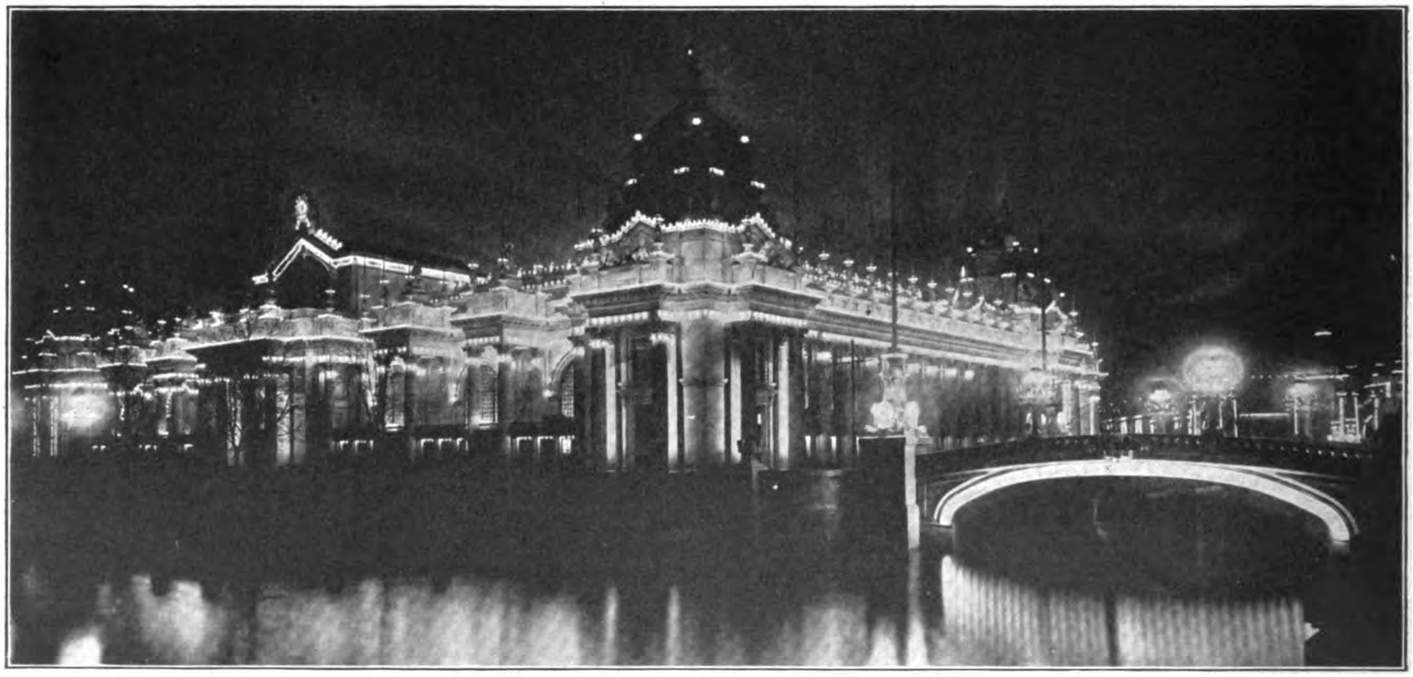
THE LOUISIANA PURCHASE EXPOSITION

After years of elaborate preparation, the great fair at St. Louis was formally opened on April 30; and notwithstanding that the vast array of buildings, the exhibits they contain, and the immense site of the exposition are not fully complete, everything indicates that the Louisiana Purchase Exposition will overshadow both in size and scope all previous expositions of world-wide importance. Life and motion abound throughout. Exhibit buildings become, in many respects, great workshops. The essence of every important art and industry is put in concrete form before the general inquirer, and a world of material is brought together for the information of the technician.

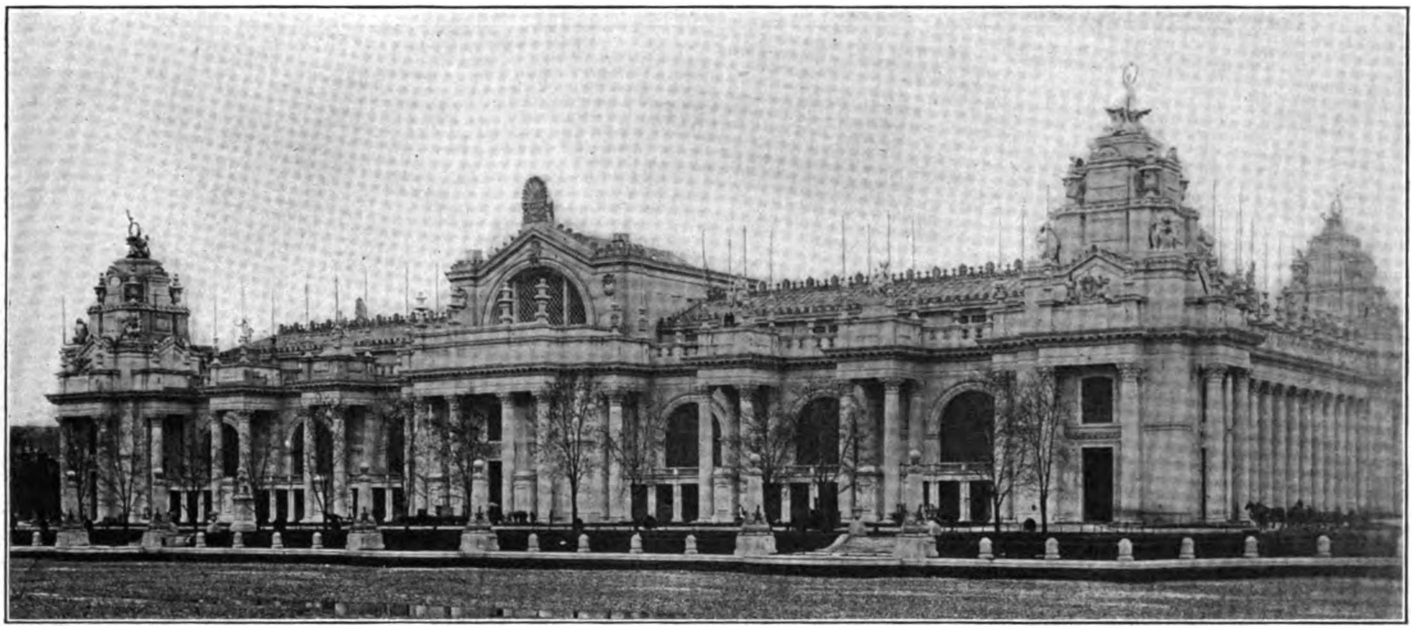
The exposition grounds cover a tract approximately two miles long and one mile wide on the western border of the city limits, the area being 1240 acres. This is for the most part level ground; but there is enough variation to give good opportunity for attractive landscape work. To the northeast lie the main group of exhibit buildings consisting of twelve great structures in symmetrical arrangement, somewhat in the form of a lady's fan, the avenues or courts corresponding to the ribs. The three Palaces of Art stand on a plateau 60 feet above the general level of the other buildings of the main group. Northeast from them is a natural amphitheatre sloping down to a great basin. Down the slopes of this amphitheatre fall three series of cascades with elaborate decorative arrangement. At the brow of the hill above the cascades is a long curved architectural screen. In the center 200 feet high stands the majestic Festival Hall. Below on the three courts, or avenues, radiating from it stand the structures dedicated to Liberal Arts, Mining, Metallurgy, Manufactures, Education, Varied Industries, Electricity, Machinery and Transportation.

From the north side of the Festival Hall at the brow of the hill, a flood of water gushes forth spreading out into a 50-foot stream. The first fall is 25 feet, then a series of cascades for a distance of 290 feet with a total fall of 90 feet. At the Grand Basin, the stream is 152 feet wide. At the sides are two great fountains with cascades 20 feet wide at the top and 50 feet wide at the point where the stream falls into the great basin. All the streams flow into the cascade basin forming a part of the lagoon system. At night the cascades are illuminated from below by vari-colored lights.

This great artificial water-fall while serving as the central feature of the exposition panorama also serves as a cooling tower for the condensing water used by the ex-



RESPLENDENT NIGHT VIEW ON THE GRAND BASIN.



PALACE OF ELECTRICITY.

position power plant, and in this way becomes useful as well as ornamental. The cascade pumping plant consists of three 2000-h. p. Westinghouse induction motors direct-connected to Worthington centrifugal pumps each with a 36 in. discharge and a 40 in. suction. The water is pumped at the rate of 15,000 gallons per minute.

On the west court are located the Palaces of Electricity, Machinery and Transportation, and in them are contained most of the apparatus of interest to electrical and steam engineers. The Palace of Electricity covers an area 525 feet by 750 feet. In the gallery over Sections 1 and 2 are the offices of the department, jury and committee rooms. With this exception there is no second floor to any part of the building. In Section 1 facing Aisle B are the offices of the AMERICAN ELECTRICIAN. Telegraph exhibits and the main exposition offices of the Postal and Western Union Telegraph companies occupy the same locality. Near the center of Section 4 is located the sub-station which contains transformers, switchboards and rotary converters through which the high-potential alternating current is received from the service power plant and transformed to a lower voltage or converted to direct current for lighting and operating exhibits. This machinery was furnished chiefly by the General Electric and Westinghouse companies. Adjoining the station the latter company is installing one of the largest exhibits in the building, embracing the varied branches of electrical machinery and apparatus. Across Aisle B are the electric railway trucks and locomotives of Burnham, Williams & Co. Along the north side of Section 3 the Standard Underground Cable Company and the McRoy Conduit Company are installing a model conduit system. A very conspicuous object is a Burdette-Rowntree electric dumb waiter running from the floor to the roof above Section 3. Its operation is automatic. Over Sections 3 to 17, along the west side of the building, is the craneway.

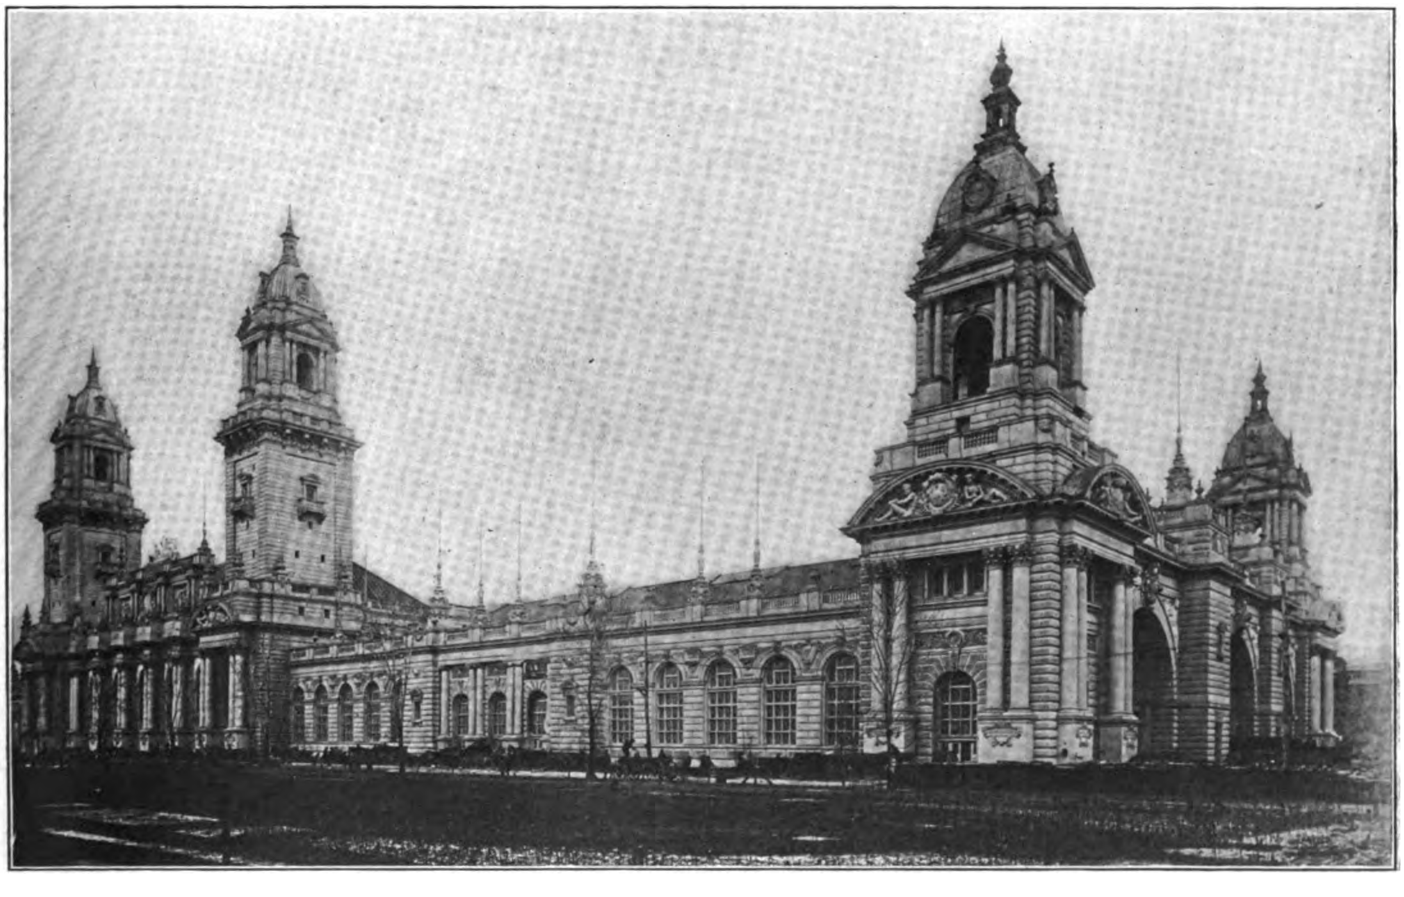
PLAN OF EXPOSITION GROUNDS.



PALACE OF MACHINERY.

Upon this is a four-motor, 30-ton electric traveling crane furnished by Pawling & Harnischfeger. A 20-h.p. 220-volt motor gives a horizontal speed of 250 ft. per minute, and an 8-h.p. motor gives a trolley transverse speed of 150 ft. The main hoist is equipped with a 30-h.p. motor with a speed of 25 ft., and the auxiliary hoist with a 15-h.p motor, and has a travel from 30 to 90 ft. per minute.

FRANKLIN.

In the northwest corner are several displays of electric railway equipment. The electric and air brake apparatus of the National Electric Company is shown as well as a line of alternating and direct-current generators and motors. Block 9 is equally divided between the Fort Wayne Electric Works and the Wagner Electric Manufacturing Company, both putting in working exhibits. The remaining space adjoining the court is occupied by the Bullock Electric Company and will be one of the notable machinery exhibits. A 6600-volt alternating current is received and transformed to 340 volts for a rotary converter which supplies 500-volt direct current for operating street railway apparatus. Other motor-generators and balancing sets furnish current for multi-voltage system as applied to speed control for machine tools. The individual feature of this exhibit is a model testing floor, indicating the best methods of testing electrical machinery before it goes to the customer. Under the traveling crane the Northern Electrical Manufacturing Company will have a complete demonstration of the adaptation of electric motors to every form of tool. In this exhibit the manufacturing of motors is carried out in a way to show the convenience and increased efficiency of motor-driven tools. All of Block 17 under the craneway is taken by the Western Electric Company. Near the center is a large 100-kw. motor-generator set which, with a compensator, furnishes 110 and 220-volt direct current throughout the exhibit. Next Aisle B is a small machine shop in operation, showing the direct application of motors to tools. There are several direct-connected marine sets, transformers and regulating apparatus. On the opposite side is a series of alternating arc light equipment with ornamental lamps and stands.

There are two collective exhibits, embracing nearly all electrical classifications, one by the Wesco Supply Company, of St. Louis, in Block 8, and another by Ewing-Merkle covering a portion of Block 14. In the former a large Warren synchronous motor drives a Triumph generator supplying power for the motors and apparatus in operation. In the second exhibit the Commercial Electric Company has a number of direct-current motors from 1¼ to 35 horse-power, and a 30-kw. three-bearing generator direct-connected to a gas engine, which furnishes power for the other exhibit items. A special feature is a line of variable-speed motors designed for operating on any standard two-wire system, with single voltage, and which will give speed variations of from 4 to 1, with horse-power and efficiency practically constant at all speeds, and little if any variation of speed at all loads with the controller set at a given point.

The western entrance embraces two large spaces, which are occupied by unique exhibits. The Carman Projector & Specialty Company shows stereopticons, lanterns, projectors and automatic electric curtain hoists in operation. Opposite is the electroplating exhibit of the Hall Gold & Silver Plating Works. The different processes of plating and finishing of plated wares are shown in a most attractive manner. The Gould Storage Battery Company and the Gould Coupler Company have a fine combination exhibit in Section 16. In the northern half of Block 16 is placed the artistic exhibit of Japan. This electrical apparatus was designed and made by Japanese. The Italian space, occupying Block 18, is especially worthy of notice on account of the scientific and electrical measuring instruments therein.

HENRY.

The three 75-ft. towers of the De Forest

PALACE OF ELECTRICITY BY NIGHT.

Wireless Telegraph Company support the antenna from which wireless messages are sent and received from other stations in the building and to the large station in the model city. The T. E. Clark Wireless Telegraph-Telephone Company shows a line of wireless apparatus in operation, and the adaptation of such apparatus to fire alarms and safety signalling on railroads. Two wireless telephone stations at opposite ends of the building are used by A. F. Collins to demonstrate the newest application of electricity to the transmission of intelligence. Two telephone operating exchanges are in the south side of the building, both enclosed by handsome booths. Section 17 is occupied by the exchange of the American Telephone & Telegraph Company. This connects with the local and long-distance lines of the Bell Company, so that there is direct communication from the building to all parts of the grounds, city and all points reached by telephone lines. In Section 24 the exchange of the Kellogg Switchboard & Supply Company gives a similar service through its connection with the Kinloch system, of St. Louis. Recent developments of automatic and semi-automatic telephone systems are shown in a thorough manner by the Automatic Electric and the Fuller Automatic Telephone Exchange Companies. An instructive historical collection of telephone apparatus is to be arranged by B. F. Wasson in Block 25. In a fine booth erected by the Hutchinson Acoustic Company are exhibited the "Acousticon" and "Massacon," through whose instrumentality deaf mutes are made to hear and taught to speak. Two beautiful booths in Section 25 are those of the Holophane Glass Company and the Weston Electric Instrument Company, the latter showing a full line of standardizing electrical instruments. The brilliant illumination of the Holophane exhibit is very conspicuous, as 1000 incandescent lamps cover the exterior and interior of their handsome structure. The laboratories of the National Bureau of Standards, covering a space of 23 by 200 ft., contain over $50,000 worth of instruments for testing every kind of electrical machine and apparatus. About twenty government experts are connected with the laboratories to conduct tests and investigations.

PALACE OF TRANSPORTATION.

The largest individual exhibit is that of the General Electric Company, embracing Section 28, and covering a quarter of an acre of floor space. A great variety of electrical apparatus manufactured by this company is installed and will be shown in operation. The Edison exhibits are in Sections 26 and 27, and include the iron-nickel storage battery and a historical collection of great merit. The purification of water by electricity is shown by the Standard Water Purifying Company, in Block 33, and water free from all forms of organic life will be served to visitors. In the northeastern part of the building are the German and French collections of electrical exhibits; the former is especially strong in electrochemistry. France has the most comprehensive display of any foreign country, covering as it does every classification. In the eastern half of Block 7 England is making an excellent showing of its electrical products.

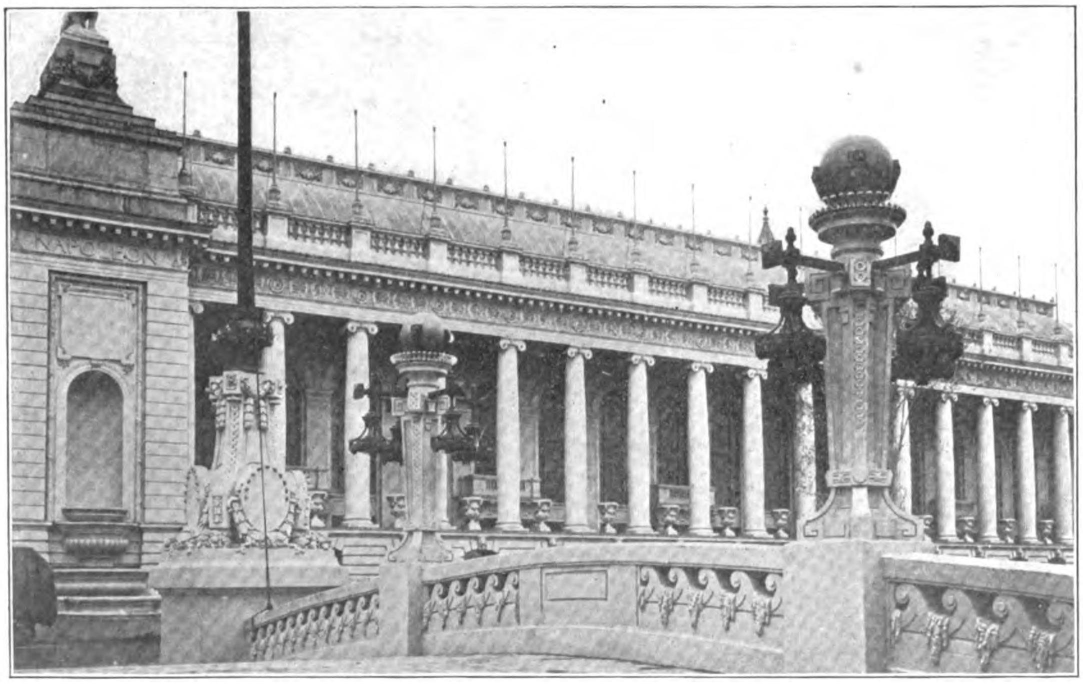
INTERIOR OF MACHINERY PALACE.

This outline of the exhibits placed in Electricity Palace is of necessity incomplete at this time. Many companies preparing displays have not proceeded far enough with their installations in the buildings for any account to be given.

Machinery Palace is a superb structure 1000 feet in length and 525 feet in width In the eastern half is located the great power plant of the exposition. The service plant furnishes 8000 kilowatts of 25-cycle 6600-volt, three-phase current; exhibitors' apparatus supply 8000 kilowatts more of similar current, and the Union Light & Power Company of St. Louis delivers at the switchboard 7500 kilowatts additional. The total amount of 6600-volt, three-phase, 25-cycle current available is therefore 23,500 kilowatts. Besides this 2400 kilowatts of 550-volt direct current and 600 kilowatts of 250-volt direct current is furnished by exhibitors' apparatus.

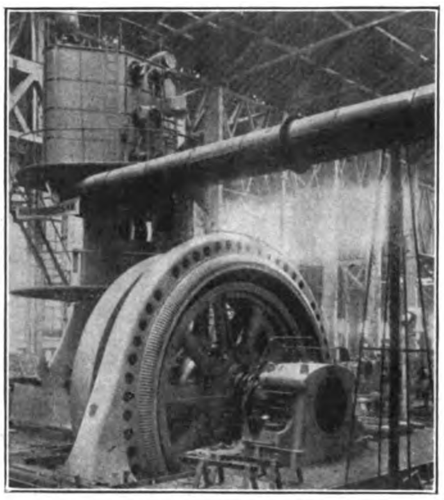
The boilers for the service plant occupy the southern portion of the exposition boiler house. There are eight batteries, each consisting of two 400-h.p. water-tube boilers, having a total capacity of 6400 horse-power. All are equipped with mechanical stokers fed from coal bunkers above, through swinging chutes. The coal bunkers, in turn, are supplied by means of a complete installation of coal conveying apparatus which receives the coal from the hopper located between the rails of a sliding of the Terminal Railway Company. Ash pits under each of the boilers receive the ashes as they fall through the grates. An underground tunnel provided with tracks and ash cars furnishes the means for readily emptying the pits. The plant is so well provided with labor-saving devices that from the dumping of the coal into the hoppers to the removal of the ashes almost no manual labor is employed. The northern portion of the boiler house contains various types of boilers placed as exhibits. These present a very interesting appearance because of the many types represented. They include besides the representative American makes several of European manufacture. Fuel is delivered to all this group by means of an overhead conveying system, and all of the boilers feed into common steam mains, supplying the exhibit engines in the Palace of Machinery. All of the large boilers are provided with systems of induced draft. The boiler house is situated about 100 feet west of the Palace of Machinery.

The four engines of the service plant are all of the same type—Westinghouse, Corliss, vertical, cross-compound. Steam is supplied to them through two 12-in. steam mains. Two of the four generators of this installation are of Westinghouse type, rated at 2200 kilowatts. The remaining two, of 2000 kilowatts' capacity each, are of General Electric Company manufacture. The exhibit installations lying to the east of the service plant consist of several units remarkable for their size and features of design. The most powerful of these is the Curtis steam turbine rated at 8000 horsepower. The space occupied by this machine leads the casual visitor to consider it much less powerful than its neighbor the Allis-Chalmers 5000-horse-power engine coupled to a 3500 kilowatt Bullock generator. This immense engine presents quite a distinctive appearance, its vertical cylinder standing far above the surrounding machinery. Grouped around the larger units are a number of installations ranging in size from 500 to 2000 kilowatts. Lying to the north are those of smaller capacity.



BRIDGE ACROSS A LAGOON, SHOWING DISPOSITION OF LIGHTS.

For the distribution of the current from the main switchboard at the west end of Machinery Palace to the eighteen-sub-stations situated in the various buildings, a complete system of subways has been constructed. These are of a temporary nature, consisting simply of a ditch whose sides as well as top and bottom are boarded over. A few inches of dirt thrown on top hides all evidences of the existence of the subway.



3500-KW. GENERATING UNIT.

Shelves built on both sides of a central passage carry the cables. The largest of these subways measures about seven feet by seven feet. Telephone, telegraph and fire-alarm cables, as well as high-potential power lines, are carried in the same subways. The former are placed on the upper shelves. The power cables, carried on the lower shelves, are lead-sheathed, the three cables of the three-wire system being enclosed in one sheath. Where the distributing system passes under the lagoons and waterways, the wood subways are naturally dispensed with, and at these points a water-tight cement conduit is installed. In most of the buildings the demand for power is limited to alternating current. The sub-stations in these cases consist simply of transformers and the accompanying switchboards.

The machinery exhibits in several of the buildings, however, demand direct current for their operation. In the sub-stations of these buildings—including the Palaces of Electricity, Education and Mines and Metallurgy—rotary converters are installed. In the Palace of Electricity the demands for direct and alternating current at so many voltages and of such frequencies resulted in the installation of the most complete sub-station on the exposition grounds. As the separate items composing the display here are placed as exhibits, the fire-proof construction used in making the enclosures for the sub-stations of the other buildings was omitted, ample precaution being taken by installing the machinery and transformers on a concrete floor and allowing sufficient space for all needs between these and the other exhibits. Four complete sets of three-phase transformers are installed. These range in size from 75 kilowatts to 250 kilowatts, the station having a total transformer capacity of 1575 kilowatts.

The converting apparatus consists of one 200-kw. 550-volt rotary converter, supplemented by two 100-kw. 125-volt motor-generator sets, one for each side of the three-wire 110- and 220-volt systems with which the building is supplied. A switchboard with the necessary panels for distribution and connection is placed in the central portion of the 1400 square feet occupied by the sub-station. The high-tension leads are brought directly to the transformers from conduits under the floor. The transformed and converted current is led to the upper portion of the building by means of a post located on the sub-station space. That part used for lighting the exterior of the building is conducted to distributing boards on the roof. The cables supplying power and light for the exhibits are strung on trusses overhead, from which leads to to the separate exhibits are dropped. The capacity of the transformers in the sub-station of the Palace of Electricity does not by any means represent the total amount of power available in this building. Several of the exhibits include complete transforming and converting sets.

The great number of different combinations of frequency and voltage demanded by the exhibitors in the Palace of Electricity, and the readiness with which these demands were met, show very pointedly the flexibility of the alternating-current systems. In alternating current six different voltages are supplied, ranging from 104 to 6600 volts. These, together with the three frequencies (25, 50, and 60 cycles) and the one-, two-, and three-phase systems, give a possibility of fourteen different combinations from the 6600-volt mains.

Most of the large engines are run condensing. The Westinghouse service plant is equipped with its own cooling towers. The exhibitors' service plant takes condensing water from the lagoons. The condensers in the Machinery Palace discharge hot water into a tunnel, which runs 1100 feet to the suction of the cascade pumps. Much of this tunnel is under the lagoon. From the Machinery Palace to the lagoon a short distance away the water is taken through two 24-in. vitrified tile pipes. Under the lagoon the tunnel is 6 feet by 6 feet, with board walls. The intake for the condensers is of 36-inch vitrified pipe. This pipe is 400 feet long over all. Water runs through it by gravity to four cold wells from which it is drawn by the condensers. Two of these cold wells are 8 feet by 8 feet, and two are 14 feet 8 inches by 14 feet 8 inches.

Adjoining Machinery Palace on the north is the Transportation Palace. This building is devoted mainly to track space for exhibits of rolling stock. In this building electric railway trucks and car bodies are shown, and also some electrical apparatus. Just north of the Transportation Palace are two test tracks, to be used in electric railway testing. One of these test tracks is 1400 feet long, and the other 2000 feet. The shorter one will be used for testing slower speed apparatus on short distance runs, and the longer track for testing high-speed apparatus. This is the first exposition at which the actual testing of electric railway apparatus offered for exhibit has been attempted on a large scale.

The intramural railway, which will furnish local transportation in the exposition grounds, is located so as to form a kind of outer belt line around the principal portion of the exposition. The route of the road has been planned so that a great amount of elevated structure is not necessary. It is approximately 10 miles around the grounds by this line, and there are sixteen stations spaced conveniently along the track. Starting near the main entrance, whence a view of the Grand Basin and Festival Hall may be had, the cars pass between "The Pike" and the Varied Industries and Transportation Palaces. Then they wind about through the buildings at the western end of the grounds, turning the corner of the great Agriculture Palace and coming out upon the wooded sections beyond. After a stop at the Fine Arts Palace, the cars make their way to the extreme northeastern corner of the grounds, skirt the Government Building, Liberal Arts and Manufactures Palaces, and finally return to within a short distance of the starting point. Besides the railway, electric automobiles and push chairs are extensively used.

The power plant for the intramural occupies a space of about 10,000 square feet in the Machinery Palace. The equipment was supplied by the Crocker-Wheeler Company, and consists of seven units, having a combined generating capacity of 3500 kilowatts. Each unit is a standard Crocker-Wheeler railway type generator, direct-connected to the prime mover. There is one unit of 900 kilowatt capacity, driven by a Buckeye cross-compound engine. A 600 kilowatt generator is driven by a Lane & Bodley horizontal cross-compound engine. There are three units of 500 kilowatt capacity each, one driven by a single-cylinder rolling-mill type of Corliss engine, manufactured by the Murray Iron Works, the other two being driven by Brown-Corliss vertical cross-compound engines. The sixth unit is of 400 kilowatt capacity, and uses a Harrisburg horizontal tandem compound engine. The last generating unit in the series is driven by a Doble water-wheel, made by the Abner Doble Company, of San Francisco, the water pressure being furnished by a Jeansville Iron Works pump. The unit is of 100 kilowatt capacity.

The incandescent lamp is used to a very large extent at St. Louis for decorative lighting of the buildings, the cascades, the main feature of the fair, the bridges and lagoons surrounding these buildings. The architectural lines of each building are brought out into bold relief by thousands of 8-c.p. incandescent lamps, 250,000 of these lamps being used for this purpose, not including the energy used for the illumination of the cascades, which amounts to 2100 kilowatts. About 5000 kilowatts is used on the decorative lighting of the exterior of the buildings. Each of the large buildings has a separate feeder supplying the transformers for the decorative lighting of that building. The decorative lighting is run on a 400-volt, four-wire system of distribution. From the four-wire distributing centers two-wire circuits, carrying about 1300 watts each in 8-c.p. lamps, are run. Most of the wiring for decorative lighting is on knob and in tube. Open work has been wired with slow-burning weather-proof insulation on the wires, and concealed work has been wired with rubber-covered wire. The interior lighting of the buildings by the exposition is designed simply to be sufficient for patrol purposes. The lighting is to be done by 50-cycle, alternating-current enclosed arcs, taking 6.5 amperes, which are run on circuits of about 3500 volts maximum. The constant-current transformers for arc lighting are located in Machinery Palace. About 1200 kilowatts is used in such arc lighting. This lighting is run from alternating-current generators in the exhibitors' power plant. A limited amount of 110, 220 and 500-volt direct current is available in each principal building. The three-phase alternating-current circuits for general commercial uses in each building, such as exhibitors' lights and motors, will be supplied by a feeder to each building run independently of the decorative lighting for that building.

The current supplied by the Union Light & Power Company is used on the decorative lighting. This current is taken first to the main switchboard in Machinery Palace over three feeders. Where these feeders enter the grounds there is a terminal house, in which are located water rheostats, employed for putting the decorative lighting load on gradually. The gradual bringing up of all the decorative lighting from dark-

VIEW FROM PALACE OF ELECTRICITY ACROSS CASCADE BASIN, SHOWING PALACE OF EDUCATION.

ness to full brilliancy was one of the most popular and beautiful features of the Pan-American Exposition. This method of bringing on the load was also highly desirable from the power company's standpoint, as it gave the governors time to act and obviated strain on the apparatus. The great switchboard extending entirely across the central bay in the west end of Machinery Palace is designed for the control of all the 6600-volt, three-phase current used on the exposition grounds. It is a brick structure supported upon timber work and occupying a height of two galleries. It consists mainly of feeder panels, as most of the generator panels are located near the machines which they control. The four generators in the service plant have control panels in this switchboard. There are in all 17 feeder panels, four generator panels, three total load panels, three exciter panels, two incoming feeder panels from the Union Light and Power Company's circuits, and one rheostat panel for controlling the water rheostats employed in connection with the decorative lighting.

◆

SMALL CANDLE-POWER ENCLOSED-ARC LAMPS FOR CITY STREET LIGHTING.

BY J. H. HALLBERG.

Many new methods of electric street lighting have been put into practical operation during the past few years, and the public as well as the central station operators have now had opportunities to observe the results obtainable with the various systems. Of all the recent street lighting systems which have proved practically successful the small-candle-power arc lighting systems have probably attracted the most attention.

As there are comparatively few people who have the opportunity to consider the street lighting proposition from the combined standpoints of the public, the operating company and the manufacturer, a few comprehensive facts relating to small-candle-power arc lamps for street lighting may be of interest at this time.

The selection of a street arc lighting system is in most cases left with a body of city officials who have practically no experience in that line and are often influenced by what they see superficially in other cities and hear from other people. This accounts for the fact that systems are sometimes installed in towns or cities to the requirements of which they are not adapted; in some cases the lamps are not even properly spaced and are equipped with globes of unsuitable character. The small-candle-power arc lighting system requires skilful application in order to bring out its highest commercial efficiency; in this respect it differs from the high-candle-power system which is better understood and the success of which does not depend so much upon the details of application and the manner in which the lamps are operated.

The term "small-candle-power" or "low energy" applies to arc lamps consuming about 250 to 300 watts at the arc, and of these there are two general classes, one for direct and the other for alternating current; these classes may be subdivided into two types: one for multiple and the other for series operation. There are now several large installations of each kind in operation and the following may be considered to represent their average comparative values.

The small-candle-power direct-current arc lamps for parallel operation are generally operated in conjunction with an Edison three-wire system of distribution, with the lamps connected directly to the regular commercial mains. With this arrangement, it is necessary to turn on each lamp by means of a hand switch located between the distributing mains and the lamp. In order to overcome this expensive operation it has been suggested, and in some cases practised, to install automatic switches operated by clock mechanism. This scheme is beautiful on paper, but experience has proved that the automatic switches will not keep up to the standard and soon become a source of great expense and annoyance. Furthermore, these switches are very expensive to install. It is, of course, possible to run an additional wire from the power house or sub-station which will constitute one leg of the system and a switch can be inserted in this wire for switching lamps on and off. This, however, leaves the lamps "alive" after they are extinguished.

It has also been proposed to install an electromechanical switch at each lamp, the switches to be operated from the station over a small extra switch-wire which will, of course, have to be installed in addition to the required distributing mains. The cost of the extra switch circuit for a low-tension system is great and in the case of an underground system is often prohibitive. Moreover, the application of electrically operated switches in their present form complicates the system and they are expensive to install.

The usual potential on the mains of the Edison system is about 118 volts. Considering the small-candle-power arc lamp for this service, it should be built for about 3 amperes and adjusted for 85 volts, thus consuming 255 watts at the arc. This would make the commercial efficiency of this lamp at its terminals about 72 per cent. The average loss between the bus-bars in the power house and the arc lamp terminals on the Edison three-wire system of distribution, under most favorable conditions, is not less than 10 per cent. Thus the efficiency of this arc lighting system at the power house bus-bars cannot be over 64.8 per cent, and the arc lamps must be switched on and off by men employed for that purpose, or by means of expensive and complicated switching apparatus.

The small-candle-power alternating-current arc lamps for parallel operation should preferably be operated directly from the regular commercial 118-volt alternating-current mains, as in the case of the direct-current lamp. It is also possible to operate the alternating-current lamps from separate transformers, each having one primary terminal connected to one of the commercial primary wires and the other primary terminal connected to a special wire extending back to the power house or sub-station to a switch which is connected to the opposite side of the commercial primary system, thus providing means for switching the street lamps on and off at the station.

There is a limit to the number of multiple lamps that can be switched on at one time, depending upon the capacity of the generators and primary conductors. It must be remembered that a multiple arc lamp introduces a momentary short-circuit on the line when it is cut in, and the "flush" of current will in most cases exceed the normal current by at least 75 per cent. The normal operating power factor of a small-candle-power alternating-current multiple arc lamp is about 65 per cent, but when the lamp is first switched on, and while establishing its arc, the power factor may be as low as 20 per cent, or even 10 per cent. The effect of switching on a large number of alternating-current multiple arc lamps at one time would thus be to upset the regulation of the entire system, the heavy drop in potential would prevent the lamps from establishing their arcs and the lamp mechanisms would chatter and soon be destroyed.

Small-candle-power multiple arc lamps for alternating-current 118-volt service should be wound for 4 amperes and adjusted for 72 volts at the arc. The apparent watts required by such a lamp would be 472, and with a 65 per cent power factor the actual watts at the terminals would be 306. Assuming the arc to operate at 72 volts with a 93 per cent power factor, the actual watts at the arc will be 267.8. The efficiency at the terminals of this lamp will be about 87.5 per cent on 60 cycles and somewhat higher on higher frequencies.

The average loss in the feeders, mains and transformers for the alternating-current distribution system would run up to about 15 per cent; consequently, the efficiency of the entire alternating-current multiple arc lighting system at the power house bus-bars would be about 74.4 per cent.

Comparing the direct-current and alternating-current multiple enclosed-arc lighting systems, their respective values will be practically as stated in Table I.

TABLE I.

For each multiple arc lamp.	D.C.	A.C. 60 cy.
Voltage at arc	85	72
Voltage at lamp terminals	118	118
Amperes	3	4
Power factor of arc		93%
Power factor at lamp terminals		65%
Actual watts at arc	255	267
Apparent watts at arc	255	288
Actual watts at lamp terminals	354	306
Apparent watts at lamp terminals	354	472
Efficiency at lamp terminals	72%	87.5%
Efficiency at bus-bars in power house	64.8%	74.4%
Required watt capacity for generator and cables	390	542
Required watt capacity for transformers		542

The above table indicates that the efficiency of the alternating-current equipment is about 10 per cent greater than that for the direct-current system, but the alternating-current system requires the installation of about one-third more capacity in generators and distribution equipment, as well as the whole transformer equipment that is devoted to the arc lighting.

As previously stated, small-candle-power arc lamps can also be operated in series. For direct-current series arc lighting, large motor-driven multi-circuit arc dynamos can be obtained which will supply current at about 3.5 amperes to two circuits each containing 50 series enclosed-arc lamps. The full-load efficiency of such generators is about 85 per cent. The efficiency of the distribution system, using about No. 6 B. & S. wire, would not be less than 95 per cent. The small-candle-power arc lamp for this system should be of the differential type and should be wound for 3.5 amperes and adjusted for 75 volts at the arc. Such a lamp would require about 78 volts at the terminals, which at 3.5 amperes represents 273 watts. The shunt coils on the lamp would divert about 1-10 ampere, leaving 3.4 amperes at the arc, which at 75 volts would represent 255 watts. The commercial efficiency of this lamp is thus 93.4 per cent. This system is nothing more than the old constant-current arc lighting system with low amperage, improved generators and modern small-candle-power enclosed-arc lamps substituted for the old-style generators and open-arc lamps. Considering this arc lighting system as described, the efficiency at the bus-bars in the power house would be 75.4 per cent.

The series system of arc lighting permits the gradual starting of the entire circuit of arc lamps, without an excessive flush of current, from the generating station. The series alternating constant-current lighting system with small-candle-power enclosed-arc lamps is the latest development in street lighting and has attracted widespread attention. Such a system can be operated from any ordinary constant-potential alternating source of supply without interfering in the least with the commercial lighting which may be operated from the same source. It is customary to connect the constant-current arc-lighting transformers or regulators directly to the primary bus-bars. To the transformers or the regulators the regular series arc lamp circuit is connected, and series alternating enclosed-arc lamps are cut in the circuit wherever required.

For a small-candle-power series alternating-current arc lighting system, constant-current transformers or regulators can be furnished to deliver 4 amperes and to supply 100 lamps in one or two circuits, depending upon the style of apparatus used. The average commercial efficiency of modern arc-light transformers at full load can be depended upon to be about 96 per cent, and the current regulation is usually within 1-10 ampere from practically no load to full load. The efficiency of the distributing circuit would not be less than 95 per cent.

The series alternating-current arc lamp can be of either the differential or the shunt type. The differential type of lamp has been generally adopted as the standard for series alternating-current work on account of its being better adapted to circuits carrying a large number of lamps operated at high potential. The shunt lamp has been used on circuits including 100 lamps in series, but as the types of shunt lamp used up to the present time require not less than the full-load energy when a circuit is to be started, the sudden "flush" of current is objectionable. The shunt lamp is more efficient and in some respects more flexible, but notwithstanding this, the differential type predominates and will be the only one considered in the present discussion of this system.

The small-candle-power arc lamp for the series alternating-current system is wound for 4 amperes, and with 82 volts at the terminals it requires 328 apparent watts. The power factor of the lamp is about 85 per cent, and the actual power required at the terminals is therefore 278 watts. The arc is adjusted for 75 volts and operates at a power factor of 93 per cent, making the actual watts at the arc 265. The commercial efficiency of this lamp at 60 cycles is 95.3 per cent at the terminals. The efficiency of the complete system, as described, taken at the constant-potential bus-bars in the power house or substation, would be 86.9 per cent.

Table II gives the comparative values for direct-current and alternating-current series arc lighting systems

TABLE II.—Comparison of Direct and Alternating Series Systems.

	D.C.	A.C. 60 cy.
Voltage at each arc	75	75
Voltage at lamp terminals	78	82
Amperes	3.5	4
Power factor of arc		93%
Power factor at lamp terminals .		85%
Actual watts at arc	255	265
Apparent watts at arc	255	285
Actual watts at lamp terminals.	273	278
Apparent watts at lamp terminals	273	328
Efficiency at lamp terminals ...	93.4%	95.3%
Efficiency at bus-bars in power house	75.4%	86.9%
Required watts capacity for generator and lines	340	356
Required watts capacity for transformers		356

This table shows that from an operating standpoint the series alternating system is more efficient than the direct-current series system and that the two systems require about the same capacity in generating and conductor equipment. The series systems, of course, permit the cutting in and out of any circuit of the system, at any time, from the station where the generators or transformers are located. These systems are therefore particularly well adapted to city street lighting where the arc lamps are scattered over a large territory.

Considering the systems as described, Table III indicates that from the central station operator's point of view their respective value is as follows: First, the series alternating-current system; second, the series direct-current system; third, the multiple alternating-current system; fourth, the multiple direct-current system. The cost of maintenance and repair is about the same for all systems, excepting that, as already mentioned, the multiple alternating-current and direct-current systems require special means for cutting lamps in and out which involves a considerable investment or expense for labor. Local conditions may, of course, be such that the multiple direct-current arc lamp could be installed and operated at the same expense as the alternating-current series arc lamp, but as a general proposition this is impossible and where new installations of any magnitude are to be made, either the series alternating or series direct-current system is unquestionably the most suitable, as considered from an operating standpoint.

TABLE III.—Comparison of all Systems.

	D.C. Multiple	A.C. Multiple.	D.C. Series.	A.C. Series.
Actual watts at each arc	255	288	255	285
Power factor at bus-bars		62%		72%
Efficiency at lamp terminals	72%	87.5%	93.4%	95.3%
Efficiency at station bus-bars	64.8%	74.4%	75.4%	86.9%
Watts capacity of generator and line equipment ..	390	542	340	356
Watts capacity of transformers		542		356

As the small-candle-power arc lighting systems described are for city street lighting, their comparative value from the standpoint of the public must also be considered. Taking all details into account, it is safe to state that the direct-current multiple lamp will best meet the demands of the public, because its light is "white" and it is a low-tension lamp, thus making unnecessary high-tension cables, wires and apparatus. The direct-current series system would be the next best on account of its "white" light and the simplicity of wiring and distribution.

The series alternating-current and the multiple alternating-current arc lamps would come next, with practically no choice between them as to their light-giving qualities, but the alternating-current series system would be preferable on account of the simple overhead construction possible with that system.

Considering the small-candle-power arc lighting system for street lighting from all standpoints, the direct-current series system is commercially the most efficient. After this would come the series alternating-current system, which possesses a higher operating efficiency but a somewhat lower commercial efficiency on account of the large proportion of violet rays emitted by the arc; these have a low illuminating value and thus lower the usefulness of this lamp. The direct-current multiple system shows the next best commercial efficiency, but is quite expensive to install if the lamps are scattered over a large territory, as is also the multiple alternating-current system.

For normal street lighting with small-candle-power arc lamps, the distance between direct-current lamps should be about 150 feet in business districts and 200 to 300 feet in residence sections; with alternating-current lamps, these distances should be about 125 feet and 175 to 250 feet respectively. For the business district, lamps should be located on both sides of the street, but in the residence section lamps should preferably be hung near the center of the street. All small-candle-power arc lamps for city lighting should be hung not less than 15 feet nor more than 25 feet above the street and should be equipped with large reflectors if the reflective quality of buildings and surroundings objects is not high.

In conclusion it may be stated that either the direct-current or the alternating-current series arc-lighting system may be successful under conditions outlined above, but in the event of the production of a satisfactory rectifier the direct-current series arc-lighting system would have a great advantage for street lighting

The New Sub-Station at Helena, Montana

In the fall of 1902 the Helena Light and Traction Company, of Helena, Mont., suffered the loss of almost its entire station which supplied the city of Helena with electric power and light. This station was merely a sub-station operated from the Canyon Ferry plant of the Missouri River Power Company. Some remarkably quick work was done in erecting a temporary plant immediately after the burning of the old power house. Plans for a permanent sub-station to replace the one burned were then drawn up, and the results of the work are shown in the accompanying engravings.

Helena enjoys the distinction of being one of the few cities in the United States which depends entirely for its electric railway power and light on a sub-station operated from a water power plant over a long distance transmission line. The majority of the plants so situated have steam power auxiliaries, but in this case, full dependence is placed on transmitted power. The old sub-station was some distance from the center of the city, having been originally a steam plant, and located where it could easily obtain coal. The new station is built in the heart of the city. The building is 50 ft. x 84 ft., one story in height, as shown in both of the interior views herewith. The height from the peak of the roof to the floor is thirty feet, and the height of the traveling crane twenty-four feet. The roof is of iron trusses and purlins and is covered with expanded metal embedded in eight inches of cinder concrete and covered with No. 18 corrugated steel.

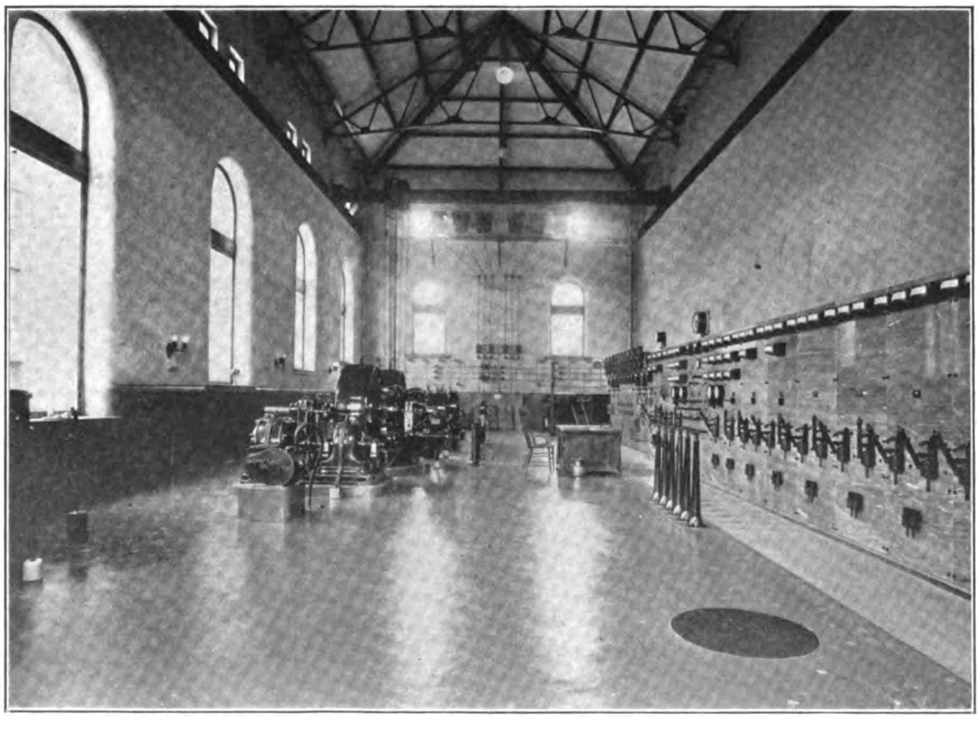


FIG. 1.—INTERIOR OF HELENA SUB-STATION.

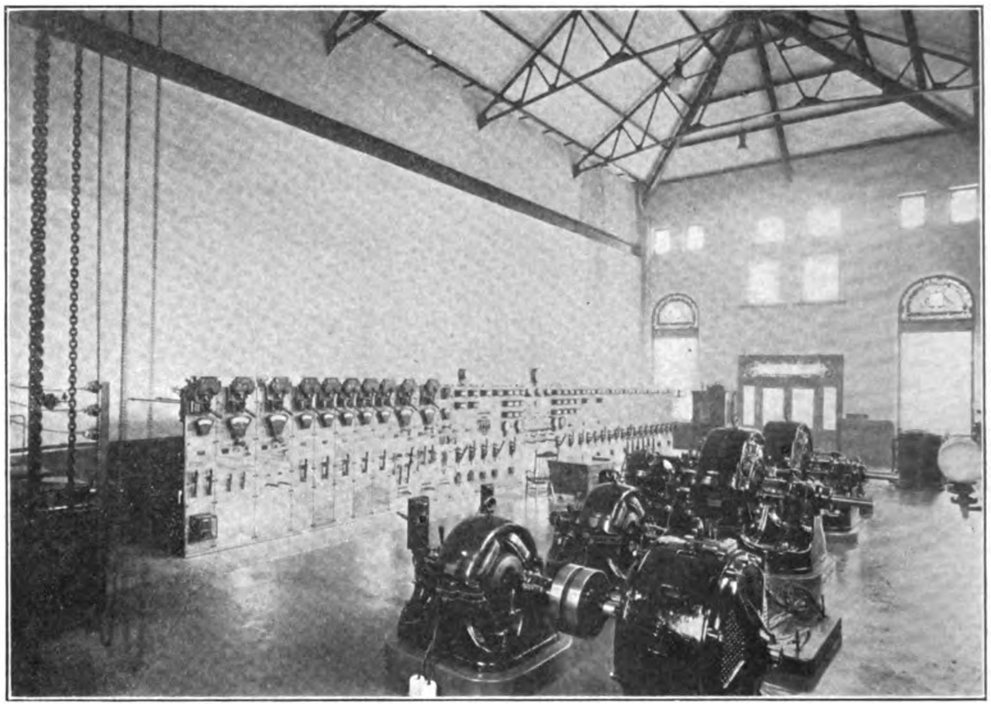

FIG. 2.—INTERIOR OF HELENA SUB-STATION.

There is but one room in the sub-station, which is well lighted, ventilated and floored with concrete. In this concrete floor bituminized fibre conduit is embedded and carries wires from the switchboard and machinery to the subway. This subway extends the length of the building at the rear of the switchboard, and from the center of the switchboard to a point between the rotary transformers.

Externally the building is simple and effective in design. It is faced with porphory (a variety of lava with a light pink tint and extremely hard) and relieved with cut stone trimmings. The main entrance has a well proportioned and finely detailed cut stone porch with columns of pink polished granite. The lower windows are of plate glass; the transoms in front are of art glass, while the windows below the main cornice are of prismatic glass. The building is both substantial and fire-proof. The architectural plans were prepared under the direction of R. A. Willson, superintendent of the company. In the rear of the room are nine Westinghouse step down transformers; three of these, or one bank, are of 450 kilowatt capacity, and are wound with 11,000-volts primary coils and 363-volts secondary coils. These supply current for two 175-kw. Westinghouse rotary converters, two 75-kw. motor generator sets, and three Hartford tub transformers; the latter supplying the series alternating arc circuits. The other six transformers are wound with 11,000-volt primary coils and 2200-volt secondary coils. Three of these transformers are of 175 kilowatt and three are of 450 kilowatt capacity. They supply current for lighting purposes over the city distributing 2200-volt alternating current. The 11,000-volt high-tension current from the Missouri River power plant, eighteen miles distant, enters the building above the transformers on two 3-phase lines. These incoming lines are equipped with choke coils, lightning arresters and G. E. oil switches with automatic trips. They are arranged so as to permit the use of one or both lines either singly or in parallel. Besides the oil switches, each wire is provided with a long fuse switch mounted on high tension insulators.

The lighting transformers are provided with seventeen secondary taps and a potential regulator face plate giving a range of 400-volts regulation on secondaries. The switchboard consists of 29 panels with subbases. Eight three-phase panels with G. E. type M. R. regulators permit of 5 per cent variation in voltage each way. There are two total load panels for incandescent lighting, three Hartford arc panels, one total panel for the 363-volt transformers, four motor generator panels, two for alternating current and two for the direct current; four rotary converter panels, two alternating and two direct; one exciter panel; five 600-volt railway feeder panels, and one panel for a 600-volt non-grounded power circuit. The total panels are equipped with indicating and recording voltmeters, wattmeters and ammeters and also power factor and frequency indicators. The ammeters are connected to the delta or step-down transformers. On each arc panel is an ammeter and an electrostatic voltmeter, reading in hundreds of volts, which can be plugged across any of the circuits or from any wire to the ground. The incandescent three-phase feeder panels are equipped with ammeters, voltmeters and double throw G. E. automatic oil switches. At the end of the board connected to the bus-bars is a static three-phase ground detector. At the rear of the board are two sets of three-phase bus-bars temporarily connected together so that by throwing switches the position of the load can be changed on the phases, making it possible to get two positions for each circuit in balancing. The extra busses are installed for future use.

The switchboard was manufactured by the General Electric Company from a new grade or dark blue Vermont marble, styled Class B1, which is much darker and more mottled than any of the standard marble heretofore used by that company.

The direct-current equipment consists of two Westinghouse, 60-cycle rotary transformers of 175 kilowatts each; two 75-kw. Westinghouse motor-generator sets, one 11½-kw. motor generator exciter, and a Westinghouse air-compressor for cleaning purposes. The rotary-transformers and motors were those formerly used in the old sub-station; but rebuilt by the Helena Light and Traction Company at its repair shop. The exciter set is used in connection with the rotary-transformers during electrical storms, to retain a permanent field on the machinery, when working in parallel.

The direct current bus-bars are so arranged with bus-bar switches that any combination of units can be made between the metallic power circuit and grounded railway circuits. The station is equipped with a Pawling & Harnishfeger traveling crane. All outgoing wires lead from a subway, through tile ducts built in the wall, to a steel tower constructed on top of the building. Provision has been made to put in extra transformers for power and lighting when required; also additional transformers for arc lighting. For these, ducts have been provided in the concrete floor. The company is now operating 25,000 16 candle-power lamps, 250 arc lights, 300 horse-power in stationary motors, and 17 street cars.

CURVE DRAWING OR GRAPHIC RECORDING INSTRUMENTS.

BY H. W. YOUNG.

The importance of using curve drawing, or, graphic recording, instruments, has not, until within a few years, been fully appreciated by many users of electrical apparatus, but, as the art advances, this form of instrument is receiving more and closer attention.

On incandescent lighting systems the curve-drawing voltmeter is particularly valuable, since by its use a continuous record of the line potential may be obtained, and the life and candle-power of an incandescent lamp are vitally dependent upon the pressure maintained at the lamp terminals; a rise in voltage materially shortens the life, while a decrease greatly lowers the candle-power, as is well-known.

Unless a curve-drawing voltmeter is installed, large fluctuations may be known to exist, but no record is made, except, possibly, that obtained from half-hourly readings of the station voltmeter. Of momentary fluctuations, or for the periods between the half-hourly readings, no record whatever is obtained, and between these readings may occur fluctuations of the greatest importance to the system's efficiency.

Voltage fluctuations, like many other evils, may be known to exist, but, unless continuously brought to one's notice, are apt to receive little or no attention. If, on the other hand, the existence of a known evil is continually brought to one's attention, it is very likely to receive serious consideration. A curve-drawing voltmeter may be regarded as a chronic fault-finder with poor voltage regulation, and a faithful recorder of properly maintained pressure. It is also a constant check on the apparatus, operating conditions and employees of a station. If the former is faulty, the conditions too exacting or the employees negligent, the record at the end of the day will indicate it. The manager is thus in a position where he is not obliged to accept anyone's word as to the pressure maintained during the day, and can at once see when and where the system needs his personal attention.

Conditions peculiar to any particular period of day or load are thus brought to light. The exact time is recorded of mishaps to the system, and the hours of starting up and shutting down definitely fixed. Curve-drawing voltmeters can be installed in the office or residence of the manager, and the knowledge of this fact will tend to increase the general watchfulness of the station men and thereby improve the service.

The curve-drawing ammeter is second only in importance to the voltmeter, and is of equal importance where constant current must be maintained, such as on series incandescent or arc lamp systems.

With the rapid introduction of alternating-current power transmission systems, the curve-drawing wattmeter has attained a position of much importance in the electrical instrument field. Such wattmeters are made in both single-phase and polyphase types, and are usually very similar in general appearance to the voltmeters and ammeters. The single-phase instrument, as its name implies, is designed primarily for use on single-phase circuits, although the power of polyphase circuits can be measured, of course, with a single-phase meter by regarding each phase as a separate circuit. The polyphase instrument records the entire energy of the system on a single chart, and, if properly designed, may be used on systems of any power factor and under any degree of unbalancing. The curve-drawing wattmeter furnishes a record of the station's load factor, and by its use the station manager can at once determine the periods of light and heavy loads. With this information he can often adjust the conditions so that more economical operation can be accomplished. These instruments are also extremely useful in determining the load on feeders or other apparatus, and in adjusting the rate of charge per kilowatt-hour.

As station managers begin to realize the importance of having complete station records, the use of the curve-drawing type of instrument will rapidly increase, and result in a general betterment of station operation.

In order that instrument users may have a better understanding of the essential characteristics necessary to the satisfactory operation of the curve-drawing type of measuring instrument, the writer has deemed it advisable to consider at some length the various features which must be taken into consideration. A few years ago the users of this type of instrument were demanding a device which would give a record on a chart, and were not so much concerned about the degree of initial or subsequent accuracy. However, electrical engineering has steadily progressed in every field, and conditions which were allowable a few years ago are not tolerated to-day. The instrument designer has kept pace with these changing conditions, and electrical instruments of all types have been simplified, improved and brought to a degree of excellence comparable with other branches of the art. The curve-drawing instrument has, however, on account of the exacting operating conditions, been one of the most difficult devices to perfect, and a study of the essentials of a satisfactory instrument will be of interest.

In order to insure initial and continued accuracy, the mechanical construction must be simple, robust, and one not easily thrown out of alignment. It is obvious that a complicated or delicate mechanical structure, while possibly satisfactory for laboratory service, would not stand the rough usage to which commercial instruments are subjected during transportation, in course of installation or when in service. The mechanism must be so disposed that all necessary adjustments can be made easily. The facilities for inking the pen, inserting and removing records, winding the driving clock, etc., must be simple and efficient, in order that the instruments can safely be placed in the hands of inexperienced persons.

Measuring instruments, like all other comparatively delicate mechanisms, are more or less fallible, and it is to be expected that ocsional adjustments and repairs will be found necessary. The various parts liable to failure should be interchangeable, as far as possible, so that any necessary repairs can easily be made with the minimum expenditure of time and money.

The Suspension.—One of the most important mechanical details is the proper suspension of the various moving parts. Imperfect or poorly designed bearings introduce serious errors which will increase with service, this latter fact being particularly true if the torque or directive force of the instrument is low. Two principal forms of support or suspension have been generally used, either of which will give good satisfaction under proper conditions. A form of bearing used to a large extent in measuring instruments is the jewel step and pivot bearing. The "step" or jewel consists of a sapphire V-shaped bearing, highly polished, and of extreme hardness. The pivot is made of finely drawn, high grade steel rod, sharpened to a needle point, made glass hard and highly polished. This form of support, when properly made is capable of giving long and continued service, and, if the pivot and jewel are removable, it is easy of repair and renewal. However, great care must be exercised in the selection of the sapphire to make sure that it is free from flaws or soft spots, for, if these conditions exist the pivot will soon roughen the jewel surface, and thus introduce friction which will continually increase.

Knife-edge suspension has been employed to some extent, with very good results, and, in many respects is preferable to the jewel step support. If, however, the knife-edge bearings are suspended by means of the controlling springs, the entire structure is liable to derangement due to buckling or dislocation of the supports. This arrangement is further handicapped by the fact that the controlling spring must necessarily be very weak, in order not to exert too strong a restraining force, and consequently offers a somewhat unstable support for the knife-edges. In places subject to heavy vibration, this unstable condition will cause the armature and recording pointer to vibrate to an appreciable extent, and tend to blur or blot the chart record.

One of the most satisfactory and promising methods in use is to suspend the upper end of the moving element from a steel wire, and center the lower end by means of a highly polished pivot, accurately centered in a sapphire ring-shaped jewel. Owing to the fact that piano wire is of exceedingly close grain and very permanent, it is generally employed in the suspension of curve drawing instrument armatures, and its high tensile strength makes the chance of breakage very small. This form of suspension is strong, simple and of very long life, and it is as nearly frictionless as possible.

Recording Pen.—The recording pen should be of simple construction, and capable of feeding ink freely and uniformly without blotting or sticking. Several forms of recording pens have been devised, all of which are more or less satisfactory. One of the simpler designs consists of a V-shaped trough with one end drawn to a sharp point, arranged so as to press on the moving chart. This form of pen is very efficient, but exposes a considerable amount of ink to the air, thus promoting excessive evaporation. The pen is also subject to a certain amount of chemical action and corrosion by the ink.

A recording pen free from the trouble to which a metal pen is subject, is made from a small section of glass drawn to a capillary tube. By this construction a very small surface of the ink is exposed to the action of the air, and corrosion is, of course, impossible.

In all curve-drawing instruments it is essential that a constant and uniform pressure be maintained between the recording pen and the chart, in order to obtain a clear and accurate record. Many instruments contain a flat spring support for the recording pen, this support being connected to the moving element. Such a construction necessitates a long springy structure, subject to vibration and tending to continuously vary the pressure between the chart and the pen. A preferable method is to mount the pen on a rigid supporting frame, and control the tension by means of an auxiliary spring or weight. This form of mounting allows a considerable range of adjustment for local conditions and is free from the ink effects of vibration incident to the first method.

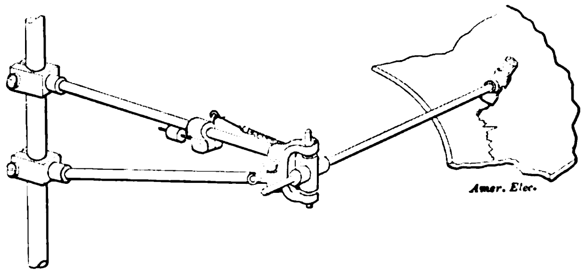

FIG. I.

Fig. 1 illustrates a method of armature suspension and arrangement of recording pen which embodies all of the desirable features outlined in the foregoing paragraphs. The armature is attached to the vertical shaft which in turn is suspended by means of a fine steel wire. The recording pen is made of glass and its support is pivoted in highly polished jewel bearings. This arrangement allows the pen motion to be transmitted in a straight line, a feature of the greatest importance in making records which can be easily read. The pressure of the recording pen on the paper chart is maintained constant by means of a small spiral spring, arranged so that its tension can be easily regulated to suit the local conditions of vibration.

Other Details.—The clock used in curve-drawing instruments for driving the paper chart must be simple, rigid, easily regulated, and an accurate time keeper. Many instruments are provided with a twenty-four-hour clock, which requires attention and winding every day, but whenever possible it is preferable to use an eight-day movement, thus minimizing attention. Hand-wound clocks are invariably employed, as the electrically-wound type has not reached the degree of reliability and simplicity of construction necessary for the satisfactory operation of curve-drawing instruments.

Some mechanical means should be provided for locking the moving parts in position during transportation and installation, for if these parts are unsecured, considerable damage is likely to occur, particularly to the recording pen and suspension bearings.

The electrical, even to a greater extent than the mechanical design, has a vital effect on the curve drawing instruments' accuracy, and this point should receive careful consideration when selecting instruments. Instruments for use on alternating-current circuits must maintain their accuracy under widely varying conditions of frequency, wave form, power factor and external magnetic influences. In order to insure an accurate record under the first three conditions, the various windings and coils must bear correct relations to each other, and not introduce inductive errors.

Effect of External Fields.—Freedom from the influence of stray or external magnetic fields is secured by surrounding the moving coils by a shell or iron casing, thus presenting a path of low reluctance for the stray lines of force. Instruments unprovided with some means of protection are subject to errors of greater or less magnitude due to external fields, and such instruments should be removed as far as possible from cables or bus-bars carrying heavy currents. The shielded type of instrument can, on the contrary, be placed in quite close proximity to such conductors without introducing serious errors, and in this respect are always preferable to the unshielded type.

Torque.—The importance of high torque, as bearing on the life and accuracy of electrical measuring instruments, is not generally appreciated. It is quite possible to produce almost any degree of initial accuracy in such instruments, irrespective of the torque, and this accuracy will continue so long as the initial conditions remain unchanged. However, laboratory and commercial conditions are entirely different, and the fact that a low torque instrument gives excellent laboratory or initial results is no assurance that it will remain accurate when operating under commercial conditions.

The torque of the instrument armature is devoted to two kinds of work, overcoming the coercive force of the controlling or restraining element, and overcoming friction. With a properly designed and constructed restraining element, it may safely be assumed that the coercive factor is of constant value, but friction is always variable, and increases with age and use. An instrument should be so built that the value of the variable factor (friction) should be extremely small in comparison with the constant factor, the restraining force, so that an appreciable increase in the variable work will amount to but a small part of the total work. This condition can only be met in instruments having torque sufficiently high to necessitate a heavy controlling force, as the friction load is then so small in comparison with the torque, that the increase in friction does not materially affect the instruments' accuracy.

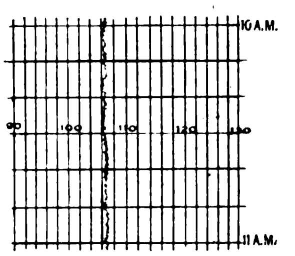
The foregoing holds true to even a greater extent in curve-drawing than indicating instruments, as the friction between pen and chart is added. The effect of low torque on the instruments' accuracy can easily be detected by watching a low torque instrument connected to a slowly varying load. On such a load it will be seen that an appreciable percentage of change in current is required to move the pen from its running position, and when the torque is sufficient to drag the pen away from the point where it has been recording, the momentum carries it beyond the true value, from whence it rebounds, recording a sharp peak which did not actually occur on the circuit. A chart made by such an instrument does not, therefore, represent the changes which actually take place, and may be highly misleading. This sticking of the recording pointer is a common fault in curve-drawing instruments, and can only be remedied by so proportioning the various elements that sufficiently high torque is produced to move the pen to a definite and accurate position instantly upon each change in conditions.

Damping Qualities.—The damping or "dead beat" qualities of all measuring instruments are of much importance, and the proper damping of the armature is of greater importance in a curve-drawing instrument than in almost any other. The damping qualities must be such that the pen will record the actual changes which take place, and not introduce errors by either over-recording or under-recording. If the armature is too heavily damped, its movement will be sluggish, with the result that many of the sudden momentary changes will not be recorded, and the record will appear much more regular than it should. On the other hand, if the damping qualities are not sufficient, the armature will oscillate at each change and the pen will mark sharp peaks in the curve which never occurred on the circuit. It is therefore extremely important that the curve-drawing instrument's movement shall have quick periods, and be perfectly damped, so as to give exactly the right periodicity.

Many methods have been experimented with to produce a suitable damping system, but none have proved so satisfactory as the magnetic form. In the magnetic damping system advantage is taken of the fact that a mass of metal moved across a megnetic field has eddy currents generated within its mass. A sector of sheet aluminum or copper is firmly attached to the armature shaft, and arranged so as to pass between the poles and across the field of either a permanent or an electromagnet. The reaction on the magnetic field by the currents induced in the metal sector causes the movement of the armature to be quickly checked, and brought to rest almost instantly. This method of damping has the advantages of simplicity and reliability, and is free from the objections inherent in liquid or air damping systems.

Liquid damping devices have been used to quite an extent for rendering curve drawing instruments dead-beat, but are far from satisfactory. This form of damper usually consists of a light vane of metal attached to the moving element and playing back and forth in a receptacle filled with oil or glycerine. They are very effective in checking oscillations of the armature and recording pen, but are generally "messy" and objectionable.

Charts.—The charts of curve-drawing instruments must, in order to give satisfaction, be clear, easy of interpolation, and of sufficient size to give at least twenty-four hour runs without renewal. Several forms of chart have been used, each of which has its advantages. A common form is a circular chart which is revolved on its axis in a clockwise or counter-clockwise direction. This chart has the advantage of showing the entire length of record at a time, an arrangement which is often of considerable convenience. However, the circular chart necessitates frequent renewals, as it usually makes a complete revolution in twenty-four hours, and in some instruments in twelve hours. If the chart feed is adjusted so as to run at a higher rate, renewals have to be made at more frequent intervals, in order to prevent the record from overrunning. In order to keep the dimensions of the instrument within reasonable limits, the diameter of the chart is necessarily limited, and this at once limits the scale area and the length of time divisions.



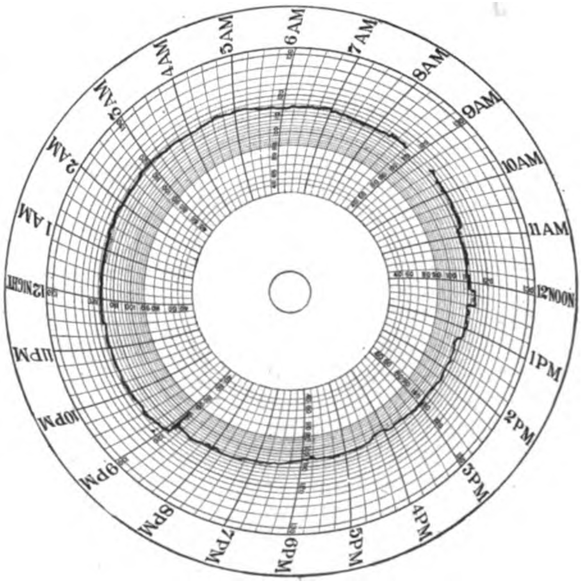


FIG. 2.—BAND AND CIRCULAR FORM OF CHARTS—FIG. 3.

A circular chart also necessitates the use of concentric circles to correspond to the indications of the recording pen, and a set of radial arcs to indicate the time element. The time divisions are, therefore, of unequal area at different parts of the chart scale, diminishing in size as they approach the zero mark on the scale. The use of unequal divisions makes interpolation of the record quite difficult at some points of the scale, and greatly increases the chances of error.

The rate of chart feed must, with the circular chart, be somewhat slow, unless the chart is frequently renewed; the standard rate for the twenty-four hour chart is usually about one inch per hour at the maximum scale reading, five-eights of an inch at the normal and five-sixteenths of an inch at the minimum reading. This slow feed tends to produce a broad blotted record, which shows the maximum and minimum but not the intermediate values, as these have been obliterated by the blotting of the ink.

The circular chart is convenient and useful wherever comparative and broad records are desired, but to obtain the highest accuracy it is preferable to use a fast moving straight-line chart. This form of chart consists of a band of paper approximately 4 ins. wide and from 50 to 75 feet long. In place of the arcs and concentric circles of the circular chart, straight lines are ruled at right angles to each other, the lines running lengthwise of the paper representing volts, amperes or watts, as the case may be, and the horizontal or crosswise lines representing the time element. The time divisions are thus of equal length throughout the entire range of the recording pen, and the diagram on such a chart is perfectly clear and plain. The great length of paper permits the use of a rapid chart feed, a speed of three inches to six inches per hour being practical, and frequently the driving clock is equipped with a set of gears making possible the use of either the minimum or maximum rate of feed. The availability of two chart feeds is often of much convenience, particularly when special tests are to be made. In order to enable the time calibration lines to be drawn at right angles it is necessary that the recording pen be so mounted that its motion is transmitted in a straight line, instead of traveling in an arc. This is accomplished by pivoting the pen and mounting it in jewels at the end of a main arm, attached to the instrument armature, as illustrated in Fig. 1. Figs. 2 and 3 illustrate the relative advantage of the band and circular form charts. The charts are both reproduced to the same scale so that a fair comparison may be made at a glance.

Summing up, it may be said that the curve-drawing instrument must fulfill the following conditions:

(1) The instrument must have high initial accuracy, and must be capable of retaining this accuracy for an indefinite period.

(2) The various parts requiring attention, such as the recording pen and recording chart, must be readily accessible and not liable to derangement.

(3) The dead beat or damping quality must be such that the recording pen will neither overtravel nor undertravel to an appreciable degree.

(4) The record must be clear, easy of interpolation, and of sufficient length per hour to enable the detection of small variations.

(5) The instrument must be easy of installation, compact, and of pleasing appearance.

Abstracts from Foreign Contemporaries

The Regulation of Alternating Current Motors.—The London *Electrician* describes a system for the regulation of asynchronous, alternating or three-phase motors and rotaries brought out by W. Lahmeyer & Company, who propose to regulate the speed of motors by inserting choking coils into the rotor circuit instead of wasteful resistances, as is at present generally the case. It is further suggested to regulate the choking effect by varying the reluctance of the magnetic path of the choking coil. This may be done by more or less saturating this path by a variable number of direct-current ampere-turns. The amount of these may be regulated, either by hand or by automatic means so as to maintain a constant speed of the motor. A purely electrical method of automatically regulating the speed is this: The choking coil, besides being wound with the leads from the rotor, is also wound with two auxiliary coils which oppose each other. One is permanently fed by direct-current from a constant pressure supply while the other receives its current from a small direct-current generator (or from the generator proper in the case of a motor-generator), driven by the motor. If now the motor exceeds its normal speed, the voltage of the auxiliary direct-current generator driven by it will rise, and the magnetizing effect of the bobbin, which is permanently excited, will be opposed to a greater degree than before. The permeability of the magnetic circuit of the choking coil will increase in consequence, and the choking effect will become more pronounced, *i. e.*, the motor speed will decrease, and if the arrangement be properly adjusted the speed will be brought back to its proper value. If the motor speed decreases the reverse actions take place.

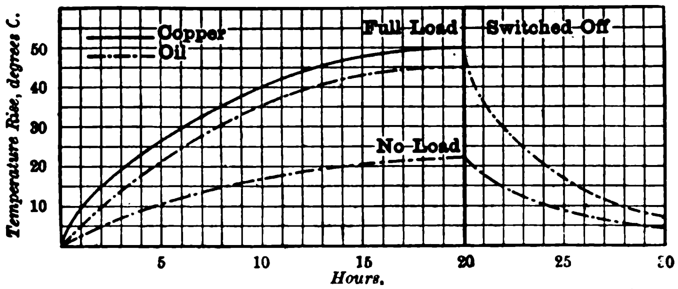

FIG. 2.—TEMPERATURE CURVES OF TRANSFORMER.

Large Oil-Cooled Transformers.—The London *Electrician* describes the oil-cooled transformers built by the Allgemeine Elektricitäts Gesellschaft. These are of the single-phase and three-phase type, and the sizes range from 50 to 500 kilowatts. The core is built up of steel stampings in the manner indicated in Fig. 1, the bolts being insulated to prevent eddy-current losses. Well-ribbed cast iron pieces of the form shown in the illustration are used for firmly clamping together the different parts of the core, the design being such that practically no eddy-currents are set up in them. In the smaller types the low-voltage winding, consisting of a cylindrical bobbin sub-divided into a number of coils, is generally placed next to the core, but in the larger sizes it lies generally on the outside. The radial distance between the high-tension and low-tension windings increases with the voltage. This space is filled in with insulating material. Conductors carrying currents in excess of 100 amperes are sub-divided. Additional cooling-surface is provided for the larger sizes of transformers (from about 150 kilowatts upwards) by flat side tanks, which are connected at the bottom and top to the transformer shell by connections of ample size. The oil in these ribbed side tanks is more rapidly cooled than in the main tank, and, becoming consequently more dense, it sinks and sets up a continuous circulation of oil. Figs. 2 and 3 show the rise of temperature with the time. All connections are brought in through the lid. Strong porcelain insulators are used, and the lower part of them is made to dip into the oil when voltages higher than 10,000 volts are dealt with. Standard voltages are: 10,000, 20,000 and 30,000 volts. The efficiencies at full-load and with unity power-factor are given as ranging from 96.3 per cent for the smallest type designed for a pressure of 30,000 volts up to 98.2 per cent for the 500 kilowatt size built for 10,000 volts. The foregoing figures are based on a frequency of 100 cycles per second and star connection. Both the drop in voltage and the no-load losses of these transformers are small. While the former vary between 1.7 and 0.95 per cent the latter range from 1.8 to 0.9 per cent only.

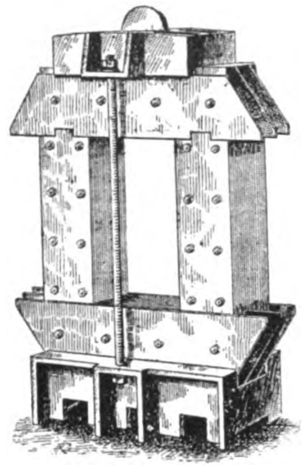

FIG. 1.—TRANSFORMER CORE.

Water Rheostat.—In a paper on the "Equipment of an Engine Testhouse," read before the Birmingham Section of the British Institute of Electrical Engineers, R. K. Morcom says that after considerable trouble and expense in connection with wire resistance, both in wooden and in iron frames, he devised a form of water resistance for taking up the load. The poles are of iron arranged in wooden tanks. Water from a neighboring canal is passed continually through the tanks by a by-pass on the condenser circulating pump, and flows out over a weir. The poles are connected to a load-adjusting switchboard, and can be coupled into the load in many combinations. Three tanks are used for different ranges of voltages, and these ranges are further divided by adjustments of the outflow from the tank. Specially subdivided tanks are used for polyphase work. The first experience when using a water resistance was not very

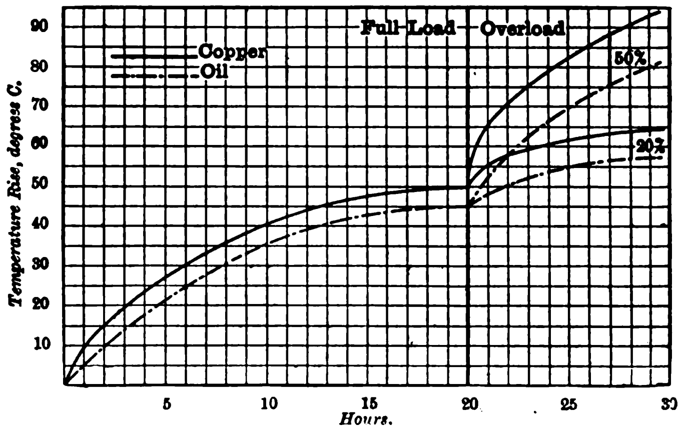

FIG. 3.—FULL LOAD AND OVERLOAD TEMPERATURE CURVES OF TRANSFORMER.

satisfactory. The apparatus consisted of an iron tank about 3 ft. wide and 6 ft. long, with two large iron plates for the electrodes. This tank did not last very long, for the current, as well as passing from plate to plate, found a shorter passage by way of the sides and bottom of the tank. An improvement of this arrangement was a large wooden tank, 4 ft. wide by 10 ft. long, and about 4 feet deep. Into this were fitted four hollow cone-shape castings, large end upwards. Inside each of these cones was a smaller one, suspended from above on a screwed spindle and hand wheel. The outer cone was coupled to one terminal of the dynamo on test, and the inner through a flexible lead to the other terminal. Load could then be varied by raising or lowering the inner cone on the screwed spindle. It was necessary to keep the water level a little higher than the top edge of the outer cone, so that the heated water in the space between the cones might rise naturally and flow away. This arrangement gave very satisfactory results; in fact, some cones are still in use which were fitted about 18 months ago. For higher voltages it was proposed to use a metal rod dipping into the water at the centre of the zone, but the conducting area of water to the outer cone was too large, and the length of water resistance too small for many machines. Accordingly, a wooden trough of small cross section and great length was designed for high-voltage work. The use of wooden troughs did away with the need for conical poles, and it is now found more useful to substitute iron plates fixed at the top to flexible terminals, and movable on insulated rollers along wooden runners. The load can thus be varied by sliding the plates along so that the cross-section between them is varied. By using a considerable number of small plates a very flexible load is obtained, and if care can be taken with the circulating arrangements a very steady load results.

Voltage Drop in Rails With Alternating Current Traction.—Dr. H. Behn-Eschenburg contributes a paper to a recent issue of the *Elektrotechnische Zeitschrift* on voltage drop in rails with alternating current traction, in which he discusses the difficulties which arise from the use of the rails as one conductor in the system, on account of the disturbances set up in telegraph and telephone lines in the neighborhood, using the earth as a return conductor. The Oerlikon Company has made a series of tests on the action of sinusoidal alternating currents of various frequencies on a telegraph relay, a telephone bell and a telephone receiver. The disturbances of telegraph relays and of the electric bell were found to disagree repeatedly with an increase in the frequency from 15 to 50 for a given voltage at the terminals; on the other hand, the vibrations of the telephone membrane will rapidly increase for higher frequencies from 25 to 50 periods. The author concludes that disturbances in telegraph and telephone lines using the earth as return, can only be avoided if the loss of voltage in the railway rails is compensated for. He then describes a system of the Oerlikon Company in which the voltage loss in the earthed rails is avoided by diminishing the current in the rails. For this purpose an auxiliary line is provided which is connected to the rails at regular intervals. Only on that section of the road on which a train is running do the rails carry current. In all other sections the return current does not flow through the rails, but through the auxiliary wire. The advantages of this auxiliary wire, compared with a second insulated return conductor may be questioned, but the enormous simplification of the collection of the current by means of the wheels of the train is of decisive importance. The scheme is shown in Fig. 4, which shows two sections of the road. *L* represents the auxiliary conductor, while *S* represents the rails. Each section contains a transformer, the primary being in the overhead conductor and the secondary in the auxiliary conductor. By properly designing these transformers it is possible to return nearly all of the current through the auxiliary line, while current flows through the rails only in that section on which the car runs. When they applied this method on their experimental lines it was possible to reduce the voltage loss in the rails 25 times. The transformer must be so designed that its self-induction is very large compared with the ohmic resistance of the conductor and the e.m.f. produced must be equal to the voltage drop in the section of the conductor.

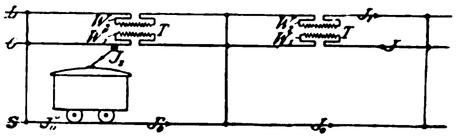

FIG. 4.

Reheater for Steam Turbines.—The accompanying illustration, taken from the *Mechanical Engineer*, shows a method of reheating the working fluid between the stages of expansion in steam turbines, the invention of S. Z. de Ferranti. The arrangement comprises a steam generator 2 having a steam drum 3, the steam being led through the superheater 4 in the uptake. After superheating, the steam divides into two parts, one part going direct to the turbine 5 (indicated by dotted lines as divided into stages) by way of the pipe 6, and the other part passing to the reheaters 7 by way of the pipe 8. In the example illustrated the turbine is provided with five reheaters, the superheated steam from the pipe 8 passing through them in parallel. A pump 9 is provided to return the condensed steam issuing through the pipe 25 from the reheaters to the boiler through the pipe 10, feed-water heater 26, and pipe 27. The steam is conducted from the turbine after the first stage of expansion through the pipe 11 to the bottom of the first reheater, and then upwards in a direction counter to that of the superheated steam, through the coil 12, and back to the turbine. This action is repeated after each stage of expansion in the turbine, the steam finally passing through the exhaust pipe 13 to the regenerator 14. The reheater coils are correctly proportioned to the volume of steam to be dealt with from each stage of the turbine. The steam from the turbine passes through the regenerator to the condenser 19, of the jet condensing type, supplied with cooling water through the pipe 20, and provided with an air pump 21. Another pump, 22, worked off the air pump 21, serves to pass a part of the outflow from the condenser through the regenerator coils 28, whence it passes on and joins the condensed steam from the reheaters. The combined steam may then be pumped through the economizer or feed-water heater 26, placed in the uptake, and returned to the boiler through the pipe 27, thus completing the cycle.

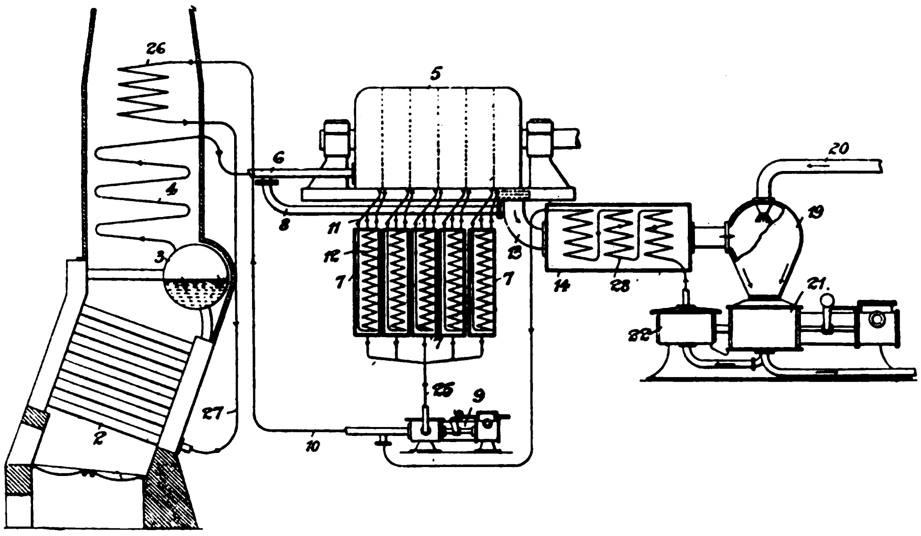

FIG. 5.—REHEATER FOR STEAM TURBINES.

Localizing Faults in Low-tension Network.—If there is one branch of electric light work that is neglected more than any other it is undoubtedly the systematic testing of the lighting mains. For this reason the paper read before the Birmingham Section of the British Institute of Electrical Engineers by W. E. Groves is of timely interest. His remarks refer particularly to a three-wire low-tension network with the neutral earthed at the station through a resistance of 2 ohms. The tests and trials that the author has found convenient are as follows: (*a*) observance of reading of recording ammeter permanently connecting the neutral to earth through a low resistance; (*b*) joint insulation test by Russell method; (*c*) checking polarity of fault by observance of feeder ammeter when "flashed;" (*d*) detection of faulty feeder by "flashing;" (*e*) partial localization by means of "transferring;" (*f*) localization by disconnection of shortest length; (*g*) final localization by induction method. Fig. 6 shows an arrangement of panels for the ready performance of tests (*a*) to (*e*) inclusive. The somewhat elaborate array of neutral switches is necessary to avoid the inadvertent disconnection of a neutral cable when testing.

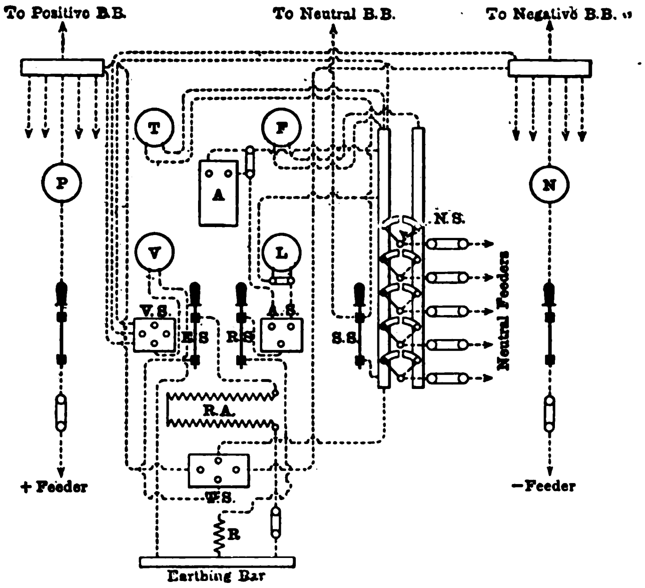

FIG. 6.—DIAGRAM OF CONNECTIONS FOR TESTING.

(*a*) *Recording Ammeter.*—The reading and recording of this instrument shows any alteration in the state of the insulation of the mains, and if this is considerable test (*b*) is necessary. Two qualities render it wholly unreliable as an indicator of the state of the insulation of the mains—its readings are differential and the instrument may be shunted by a neutral fault.

(*b*) *Russell's Test.*—This is most convenient for a rapid and a frequent test. The formula is:

$$F = (V_2 - V'_2) \div c = (V_2 \div c) - R.$$

Referring to Fig. 6, *R* is the resistance in series with the recording ammeter *A*, so that the test resolves itself into the reading of *C* on the ammeter *L* in series with or substituted for *A* at the time of testing, and a momentary opening of the switch *RS* to read V_2 on the voltmeter *V*. For moderately high resistances the value of *R* may be ignored. *V* should be a high-resistance voltmeter. A combined instrument to replace *V* and *L* on the panel is shown in Fig. 12. The object of this instrument is to read *F* directly on an ohm scale when *R S* is momentarily opened.

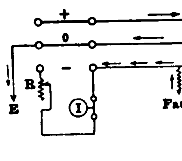

FIG. 7.

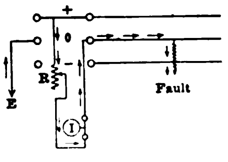

FIG. 8.

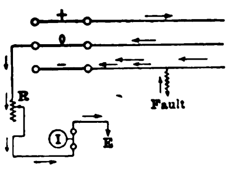

FIG. 9.

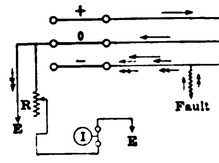

FIG. 10.

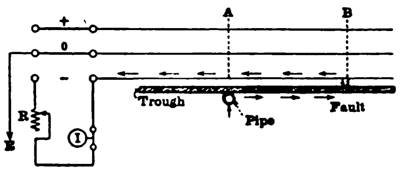

FIG. 11.

It consists of an ammeter and a voltmeter contained in one case. The needles move in two parallel planes and overlap. Between the ampere and volt scales an ohm scale is marked. The scale is plotted for $(V_2 \div c) - R$, the point of intersection of the needles overlying the required readings at *F*. As V_2 and *c* cannot coexist, a special attachment is made to the switch *R S*, which enables the ampere needle to be locked, while the volt needle deflects. An insulating wedge is fixed to the blade of the switch which separates spring contacts when the switch is closed, but when it is slightly pulled forward, and before the "earth circuit" is broken, permits the contacts to come together, thus completing the circuit of a locking magnet, which retains the deflection *c*, after the switch is fully opened and the voltmeter has swung to V_2. The voltmeter and ammeter are entirely independent, and may be used for other tests if required. The voltmeter is provided with a three-way switch, but normally held on the neutral stud by a spring. If the recording ammeter fails to notify any leakage, and the test (*b*) indicates that the insulation is "down," V_2 will be small and *R S* may be left open while the rough tests (*c*) and (*d*) are made. The opening of the switch *R S* avoids heavy local currents *R* and bad sparking at the switches.

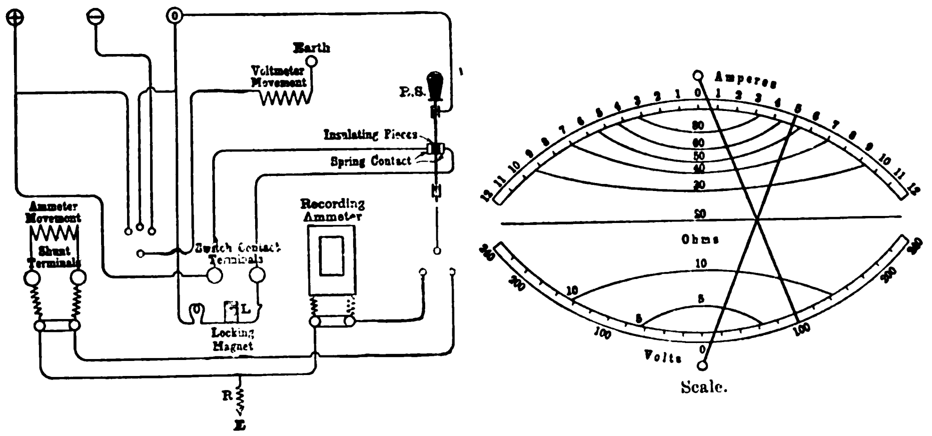

FIG. 12.—DIAGRAM OF CONNECTIONS AND SKETCH DIAGRAM OF SCALE.

(*c*) *Checking Polarity of Fault by "Flashing."*—A central zero ammeter *T* is provided, which can be cut in to take the total neutral current by opening the switch *S S*. Watching this instrument until a fairly steady deflection is shown, either of the outers may be connected to earth through the adjustable resistance *R A* by means of the switches *T S* and *E S*. If the neutral is faulty a "kick" will occur on *T* when *E S* is closed. In the case of a balanced fault the neutral ammeter *T* will be unaffected by this trial, the switch *R S* being open, and the faulty feeder will be indicated by "kicking" of one of the ammeters, *P, N*, on the opposite side of that earthed.

(*d*) *Detection of Faulty Feeder.*—If the last test has proved that the neutral is unsound an ammeter, *F*, may be cut into each feeder separately by means of the switch *N S*, and the last test repeated until the faulty feeder is detected. If considerable fault is shown on *A* the switch *R S* may be momentarily broken while close observation is made of the instruments *P* and *N*. Obviously, a heavy balanced leak is in the nature of a short circuit, and being beyond the control of *R*, makes itself sufficiently apparent on *P* and *N*.

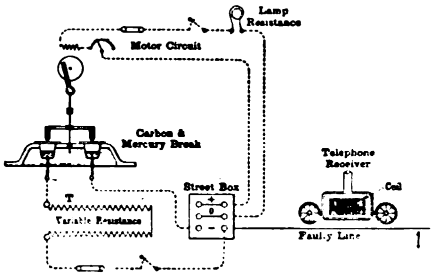

FIG. 13.—INTERRUPTER AND COIL.

(*e*) *Partial Localization by Transference.*—By transferring the distributors from one feeder to another, and momentarily earthing one of the outer wires, if the neutral is faulty, and flashing the switch *R S* if an outer is "down," the fault may be very readily located to the shortest length the arrangement of the network will permit. So far consumers have in no way been interfered with unless operations may have blown the fuse of a faulty internal circuit.

(*f*) *Localization by Disconnection.*—If arrangements can be made for disconnection, tests may be made by means of lamps or instruments. If the fault be on either outer the volts between neutral and earth will be raised. Having connected up the lamp or voltmeter between neutral and earth at the nearest network box, the various lines or services are disconnected until the voltage drops. When the fault is neutral (the earthing switch *R S* at the station being open), an earth connection may be made through a switch and fuse at the junction box where the test is being carried out, the switch being opened after each disconnection until the faulty line is detected by a rise of voltage on an instrument connected between neutral and earth, when the faulty line is cut off. As an alternative to the last trial, a lamp may be connected between either live outer and the faulty neutral, the latter and other outer being disconnected. The faulty line being at or near earth potential, the lamp will glow until the fault is made dead. It is well to make trials at the station before carrying out these rough street tests, in order that the results may be correctly interpreted.

(*g*) *Final Localization by Induction Method.*—The tests described having failed to indicate the exact position of the fault, final localization may be made by means of an interrupter and induction coil. This generally well-known method consists in putting an alternating or interrupted current through the faulty cable, the circuit being completed through earth. A coil, in circuit with which is a telephone receiver, is taken over the route of the faulty cable, starting from the point from which the testing current is supplied. In a successful test, the receiver beats steadily until the point of the fault is reached, when the beat dies away more or less suddenly, owing to the test current going to ground.

The interrupter and coil for fault localization is indicated diagrammatically in Fig. 13. The interrupter consists of a double carbon and mercury break, the carbon-holders being operated directly by the motor spindle by means of an eccentric pin and guide. The motor is run at about 150 r.p.m., and the current (usually about 10 amperes) through the break regulated by the adjustable resistance. The coil is composed of a mile of No. 18 cotton-covered wire wound on a former, through which are placed charcoal iron plates to form a laminated core. The body of the apparatus is supported by two longitudinal beams fitting in grooves in the side of the core, and forming the carriage frame. The wheels have solid rubber tires, and are set wide apart to admit of easy turning. The somewhat cumbersome construction is necessitated by the coil requiring to be as near the road surface as possible. The width of the wheel centres also enables the coil to be run over and along a trench. This is a great convenience if it is necessary to open ground in several places.

Figs. 7 to 11 represent various methods of connecting the interrupter. The small arrows indicate the interrupted earth current, large arrows the supply current, and double-headed arrows the fault current. Fig. 7 represents the simplest case where the faulty line can be disconnected and the interrupter inserted in series with the fault —the fault being on one of the outers. Fig. 8 shows a method of localizing a fault in a neutral. The faulty neutral and one outer are disconnected, and the interrupter connected between the "live" outer and the faulty line. In Fig. 9 the neutral is not "permanently" earthed, or the fault is so bad that the removal of the "permanent" earth connection has no appreciable effect on the pressure between neutral and earth. No interruption of supply is necessary in this case, the pulsating current being superimposed on the supply current. If the coupling is as shown in Fig. 10, no interruption of supply is necessitated, the pulsating current being superimposed on both the supply and the fault current.

When iron ducts are in use or the cables are metal-covered, contact between the ducts or armor and a gas or other metal pipe sometimes leads to false indications, particularly if the soil be dry. The effect is shown in Fig. 11.

SOME RECENT ELECTRICAL PATENTS

Protected Knife Switch.—Figs. 1 and 4 illustrate a protective base for knife-blade switches which has been patented by William McDevitt, of Philadelphia. The base is simply a block of insulating material having deep grooves in its surface and enlarged cavities in the ends; the terminals and switch jaws are located in the larger cavities and the blades and cross-bar lie in the surface grooves when the switch is closed. The object, of course, is to shield the metallic parts of the switch when it is "alive" so that attendants cannot accidentally come into contact with them. Patent No. 757,830.

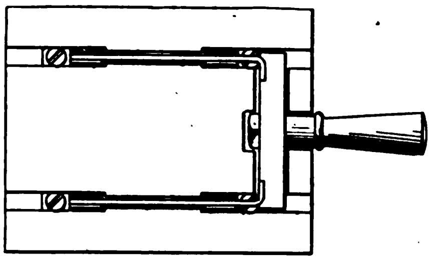

FIG. 1.—PROTECTED KNIFE SWITCH.

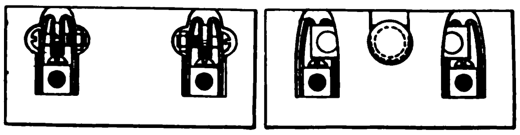

FIG. 2.—PROTECTED KNIFE SWITCH—FIG. 3.

Alternating-Current Motor.—The latest effort to provide a satisfactory alternating-current motor of the commutator type is illustrated by Figs. 5 and 6 herewith, which are taken from a patent issued to Burton McCollum, of Lawrence, Kan. The invention consists in supplying to the field magnet of an ordinary series commutator motor an exciting current lagging behind the main current of the motor by about 90 degrees, and thereby producing a resultant field which lags in time behind the main current. The amount of actual lag is adjustable by adjusting the lag in the superposed exciting current and its strength. The inventor states that he has proved by trial that such motor may be given a power factor of unity, the superposed ampere-turns of the field windings serving to neutralize the self-induction of the armature and main field windings. He does not state what effect his arrangement has upon the torque of the motor; if the field magnetism lags considerably behind the armature current, the torque evidently must suffer considerably. In Fig. 5 the auxiliary field winding is supplied through a transformer and in series with an adjustable reactance, 7; the inventor states that this arangement gave the best results in his tests. Fig. 6 shows the extra winding supplied directly from the mains through the adjustable reactance; the latter is for the purpose of adjusting the lag and strength of the auxiliary field current, of course. Patent No. 759,004.

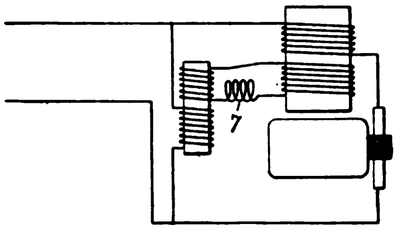

FIG. 5.—ALTERNATING CURRENT MOTOR.

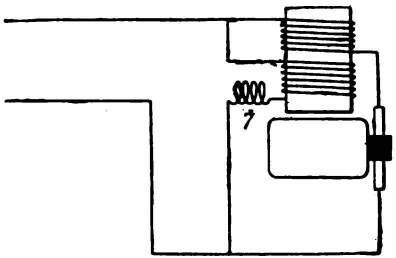

FIG. 6.—ALTERNATING CURRENT MOTOR.

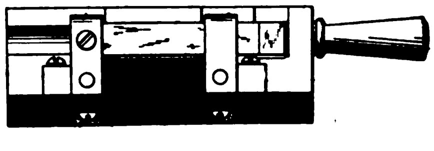

FIG. 4.—PROTECTED KNIFE SWITCH.

Train Lighting System.—It is well understood that in a system of railway train lighting, if the dynamo be driven from a car axle or other source of motion dependent upon the motion of the train itself, means must be provided whereby the dynamo shall deliver current at practically constant potential regardless of the train speed and in the same direction to the storage battery regardless of the train's direction, a battery being invariably provided in systems of the class mentioned for the purpose of furnishing current when the train is stationary or moving at too slow a speed to produce the proper e.m.f. at the dynamo. William A. Turbayne, of Buffalo, N. Y., has devised a system in which the foregoing requirements are met by the use of a small auxiliary dynamo driven by the main dynamo, and a small motor-generator set. Fig. 7 is a diagram of the connections as shown in the patent issued to Mr. Turbayne. The auxiliary dynamo, *C*, is driven by the shaft, *a*, which drives the main dynamo, *A*, and it excites the field magnet of the motor *F;* the dynamo, *D*, driven by this motor, excites the field of the main dynamo, while its field and that of the auxiliary dynamo *C* are excited from the storage battery. The motor, *F*, is worked at low magnetic densities in its iron parts so that its speed is substantially proportional inversely to the e.m.f delivered by the dynamo *C*, and this e.m.f. is directly proportional to the speed of the dynamos, *A* and *C*. When this speed is sufficient to enable the dynamo *A* to deliver normal e.m.f. under maximum field excitation, the solenoid switch *I* is closed by the e.m.f. of the dynamo *C*, and connects the motor *F* to the battery. The motor field being excited at minimum working strength from the dynamo *C*, it starts up and runs at maximum speed, causing the dynamo *D* to furnish its maximum e.m.f. to the field of the main dynamo. As the train speed increases, the e.m.f. of the dynamo *C* increases, strengthening the field of the motor *F* and causing it to reduce its speed in proportion to the increase in car speed; this weakens the field of the dynamo *A*, which is also worked below magnetic saturation, and thereby keeps the e.m.f. of that dynamo normal. No means for connecting and disconnecting the dynamo *A* to and from the battery have been shown in the drawing, but it is obvious that some form of automatic switch would be necessary to disconnect the dynamo leads when its speed falls so low that current begins to flow backward from the battery through the dynamo armature. Reversal of the train direction reverses the direction of rotation at the dynamo shaft, *a*, of course; as the field of the small dynamo *C* is excited always in the same direction from the battery, this reversal of speed reverses its e.m.f.; consequently the motor *F* is reversed, causing its dynamo *D* to excite the field of the main dynamo in the opposite direction, and the e.m.f. delivered by the latter is therefore in the same direction as before its rotation was reversed. Patent No. 757,695.

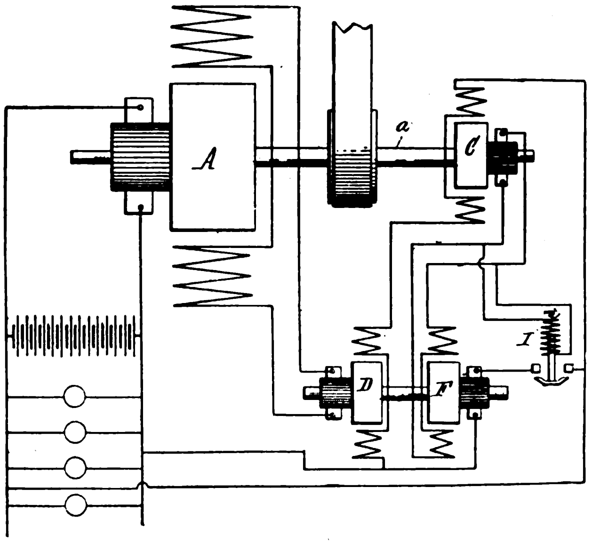

FIG. 7.—TRAIN LIGHTING SYSTEM.

The Steam Turbine vs. the Reciprocating Engine.

To the Editor of the American Electrician:

Sir:—The writer has read with some interest your article on the steam turbine situation by Mr. A. M. Earl. I do not think that he has stated the situation as the merits of the turbine demand.

From the position of the reciprocating engine man, I can readily appreciate his question of "Where are we at?" And while it is true that the development of the steam engine has covered virtually a period of 125 years, as far as its principle is concerned it is very little different from where it started. The limitations of its evolution are all that he has stated in regard to the limiting steam pressure, superheat, vacuum, rotative speed, piston speed, bearing speed, size of low-pressure cylinder, degree of regulation, pressure on bearing surface, cylinder clearance, and he might have gone on with a long list of others, practically insurmountable barriers from a mechanical standpoint to the perfection of the reciprocating engine. All these elements of trouble have been known almost from the inception of the reciprocating engine, and have been simply endured for the reason that there was nothing better to take its place.

That the turbine does not suffer all these elements of trouble should be a well-known fact to every engineer. Mr. Earl says that the troubles of the steam turbine are something like this: Blades wear and strip, governors get out of order, bearings heat and cut, lack of mechanical balance creates disturbances. He gives no further enumeration, and he has stated there about all the elements that there are in the steam turbine that are liable to give any trouble whatever. Now, referring these same troubles to the reciprocating engine, of course the engine has no blades to wear and strip; but the turbine blades do not wear and strip. The writer believes that the Parsons machine when first put out did give some trouble from its blades stripping out, but this trouble has been practically eliminated and there is practically no chance of the buckets of the Curtis-type turbine stripping out. There is a possibility of wear if wet steam is used and the buckets might possibly have to be replaced after a run of several years, which is very easily done provided they are properly constructed.

Mr. Earl speaks of the governor as a source of trouble, as though such a thing were unknown on a reciprocating engine. The writer is perfectly free to admit that he has seen some engines that he thought would operate very much better if the governor were left off, but the governor on a turbine is a much simpler affair, with less wearing parts and less liability to get out of order than anything that has ever been produced for a reciprocating engine giving any satisfactory degree of regulation.

As to bearing heating and cutting: Bearings will heat and cut if they are not properly lined and given plenty of oil, but there is not the element of danger in the bearings on a turbine that there is on an engine, as the number of bearings is reduced to a minimum and there is nothing but a rotative element to cause heating; with proper lubrication a turbine bearing is one of the last places there is any chance for trouble. Perfect mechanical balance is of course necessary and no maker would be foolish enough to put out a turbine without first securing it. There are several things Mr. Earl left out in referring to the reciprocating engine which are necessarily out of consideration in a turbine, such as the danger of fly-wheels bursting and cylinder heads blowing off due to water getting into the cylinder.

As to the economy of steam turbines as compared to reciprocating engines, Mr. Earl makes an off-hand statement about the meagre reports of machines in actual service, indicating limitations which render it very doubtful if the hopes of the designers will be fully realized. I should be pleased to know if he can point out a single case where the Curtis or Parsons turbines have not fulfilled the guarantees of the makers and are not operating satisfactorily where they have been installed. I do not claim that the steam turbine will replace the reciprocating engine for all purposes, but I do claim, and justly, I believe, that for electrical power stations the steam turbine has no equal where steam power is used. While the economy may not be any greater at full load than the best compound Corliss-valve engines working under ideal conditions, the part load efficiency is so far superior that the economy at full load need hardly enter into consideration. I do not think that there is any engine builder today who would under any conditions guarantee that the steam consumption of a Corliss engine at one-fourth load would not exceed by two pounds per brake horse-power the steam consumption required per horse-power at full load, but this is something that is being guaranteed now on steam turbines built in this city—a result there is no difficulty in obtaining.

Summing up, the steam turbine is ideal in its simplicity, it requires when installed a minimum amount of attention, it takes up a very small amount of floor space per horse-power, its economy at full load is equal to the economy of the best Corliss engine, while its economy at part load is far superior to the same class of engine. I believe that the reciprocating engine for use in connection with electric generators will within the next four or five years be considered absolutely obsolete, and there are a great many cases even now where it is only a question of delivery as to whether people shall put in steam turbines or reciprocating engines.

Sandusky, Ohio. E. C. CROCKER.

NOTES.

Ohio Society of Mechanical, Electrical and Steam Engineers held its eighth annual meeting in Columbus, Ohio, May 13 and 14. The convention was a very successful one, both as to the attendance and the character of papers presented.

Electrical Workers in Boston.—Electrical Workers' Union No. 103 has increased its membership to such an extent as to necessitate the employment of a secretary to devote his entire time to the work. Union No. 104 now has a membership of about 400.

High Tension Transmission.—A special meeting of the American Institute will be held at Chicago, June 21 and 22, for the discussion of high-tension electrical transmission lines. The meeting will be conducted by the Transmission Committee of the Institute, and the subjects discussed will include "Steel vs. Wooden Insulator Pins," "Line Construction with Steel Supporting Structures and Long Spans," "Bare vs. Insulated Conductors for Interior High-Tension Wiring," and "Continuous Service over Lines Operated in Parallel."

The Edison Storage Battery.—At a recent meeting of the New York Electrical Society an interesting lecture was delivered by Mr. R. A. Fliess on the new Edison battery, in the course of which the speaker presented some new data regarding the performance of the Type E cell. A test of this cell showed an output of 272½ watt-hours at 30 amperes discharge rate and 240.6 watt-hours at 120 amperes. The weight of the cell was 47¾ lbs. per horse-power at the lower rate of discharge and 54¼ lbs. per horse-power at the higher rate.

General Electric Annual Report.—This report shows that during the year ended January 31, 1904, the General Electric Company received orders for $39,060,038 worth of apparatus as compared with $39,944,454 for the previous year. The orders included generators, steam turbines and rotary converters aggregating about 900,000 horse-power; railway motors aggregating over 300,000 horse-power; transformers aggregating over 650,000 horse-power, and stationary motors aggregating over 200,000 horse-power. The manufacturing floor space aggregates about 3,700,000 as compared with 3,000,000 square feet at the end of the previous year; the space is still being extended.

John F. Wallace Chief Engineer of Panama Canal Work.—Mr. John Findley Wallace, General Manager of the Illinois Central Railroad, has accepted the position of Chief Engineer to the Panama Canal Commission and will take up the work on June 1. Mr. Wallace will have full charge of the construction of the canal, at a salary of $25,000 a year. In accepting the position he made a considerable financial sacrifice, in the estimation of those who are familiar with his prospects with the Illinois Central. Mr. Wallace is not quite fifty-two years old. He is a graduate of Monmouth University, and has had extensive experience in railroad and bridge engineering. He is a past president of the American Society of Civil Engineers, the American Railway Engineering Association and the Western Society of Engineers, and is a member of several other engineering societies.

The Magnetic Club, of Philadelphia, gave its first dinner recently, and the affair was a tremendous success. The officers of the Club are: S. S. Garwood, president; L. Lemon, first vice-president; John C. Sager, second vice-president; F. W. Griffin, third vice-president; J. P. Altberger, fourth vice-president; C. B. Wood, secretary, and H. W. Hetzel, treasurer. Mr. Frank E. Maize is chairman of the Governing Committee. The dinner was given at Boothby's restaurant, and 175 members and guests were present. Just before the opening speeches, President Garwood arose to introduce Mr. F. W. Jones, president of the New York Magnetic Club, when a huge cluster of roses hanging above his head was released electrically by the pressure of a button in another part of the room and Mr. Garwood found himself covered with flowers. Over the head of the banquet table were grouped incandescent lamps forming the figure "73," the telegraphic symbol meaning "best wishes." At the close of the banquet this device was extinguished by the pressure of a button at President Garwood's right hand and the figures "30" in frosted lamps were lighted; this is the telegraphic symbol for "Good-night." Appropriate addresses were made by Mr. Garwood, who presided and acted as toastmaster; Mr. F. W. Jones, Mr. W. C. L. Eglin, and others. The affair was highly enjoyed by those fortunate enough to be present, among whom were: Messrs. Thos. E. Fleming, of New York; W. S. Westbrook, superintendent Delaware & Atlantic Telephone Company; M. J. O'Leary, New York; W. A. Manwaring, superintendent Arc Lamp Department, Philadelphia Electric Company; T. G. Seixas, vice-president, Germantown Electric Light Company, and W. K. Beard, Philadelphia Manager, AMERICAN ELECTRICIAN.

The Exposition Railway Tests.—A full meeting of the Executive Committee appointed to determine the nature and scope of the electric railway tests to be made at St. Louis and elsewhere during the coming summer was held at St. Louis on Friday and Saturday, May 6 and 7. The committee consists of Prof. W. E. Goldsborough, Chief of the Exposition Department of Electricity, chairman; Prof. H. H. Norris, of Cornell University, and Prof. B. V. Swenson, of the University of Wisconsin, and H. T. Plumb, of Purdue University. The committee decided to undertake series of tests (*a*) on the service capacities of electric motors, (*b*) for acceleration, (*c*) of brakes, and (*d*) on train resistance.

In the tests for service capacity of motors, various equipments will be operated on special tracks at different rates and periods of acceleration, coasting and braking, with different lengths of stops, in order to determine the heating of the motors under conditions approaching as nearly as possible those of commercial practice. The motors will also be tested separately for heating and for the determination of their torque curves and accelerating power. This will render possible the comparison of the performance of the same equipment upon the track and upon the test stand. The acceleration tests will be made on single cars and on multiple unit trains to determine the ability of the equipment to bring the cars up to full speed quickly and economically.

Braking tests with single cars and multiple-unit trains will be conducted in order to determine the quickness of action, the shapes of the braking curves, the relation between the braking forces and the applied pressures and the best methods of application of the braking forces.

In the train resistance tests, determinations of the resistances due to the rails, to the journals and gearing and to the air will be made by a systematic and complete series of runs. In addition to this definite series, a number of other tests will be conducted upon various exhibits in the Palace of Electricity in order to determine the efficiency and reliability of the apparatus.

Sections (*a*), (*b*) and (*c*) of the tests will be carried out on the tracks which have been built for the purpose by the Exposition. These are of substantial construction, conveniently located, and of a total length of about 4500 feet. For the tests described under section (*d*) the Indiana Union Traction Company has provided a stretch of eight miles of straight and heavily ballasted track. The resistance tests will be made after the completion of the St. Louis programme.

In all of the work, graphical records of the measurements will be obtained by the use of autographic instruments which will be either built for the purpose or supplied through the cooperation of the manufacturing and operating companies and the technical colleges. The National Bureau of Standards will materially aid in this work by providing facilities for the calibration of all of the instruments.

The actual work of observation and calculation will be carried on under the personal supervision of the superintendents by a corps of young men carefully selected from among the graduates of leading technical schools, the total number of observers being thirty and forty. The Exposition management is cooperating enthusiastically with the Railway Test Commission in providing ample facilities for the tests, and substantial results of permanent value to the profession are confidently expected.

ESTABLISHED 1889.

A Remarkable Central Station Record.

The rapid development of the central station service at Kansas City during the past five years, as described by Mr. Barth in our leading article this month, is typical of the growth of the electric lighting business in every city of appreciable size where there has been progressive management; but the growth at Kansas City has been perhaps more rapid and astonishing than that in most other cities of comparable types. The history of the plant's development is well worth careful reading by anyone interested in central station work. The present general manager of the plant, Mr. R. E. Richardson, upon taking charge of the property was confronted with the problem of taking care of the increasing business with a number of old power stations containing almost obsolete apparatus, and at the same time constructing the new station and feeders. His first move was to institute a complete system of records, which he used as a guide in making the necessary improvements. As these records began when the company was operating the old-style machinery five years ago, and have been continued up to the present time, they furnish information which is invaluable as an object lesson in the advantages of substituting modern for old-style apparatus as well as a fine illustration of the smoothness with which such changes may be made under competent supervision. This information Mr. Barth has presented in the most concise style, without resorting to burdensome statistics.

The account of the company's experience during the great flood of last year is also highly instructive, and is, we believe, the first comprehensive one that has been published, from the electrical engineering standpoint. The incidents of the flood are unprecedented in many respects. Cases are on record of electrical apparatus being dried out and put into operation after having been completely flooded, but we think there has never been elsewhere such a wholesale flooding of large and small apparatus in a station of the magnitude of this one. This fact, as well as the comparative ease with which the 6600-volt apparatus was cleansed and dried after having been subjected to such unwholesome contact with water, mud and rubbish of all sorts, must increase one's respect for electrical machinery immensely. Strange as it may seem, greater difficulty was experienced in restoring to a workable condition 500-volt railway generators flooded in other stations last summer than was encountered in drying out the 6600-volt alternators at the Kansas City station. This was due to the presence of the commutators on the direct-current generators. Well-designed machines of this class have such ample commutator capacity that a current that will heat the armature winding almost to the danger point will not raise the temperature of the commutator enough to dry out the mica strips between the segments. In one case that has been brought to our attention, the commutator had to be dried out by means of blow torches after the armature winding had been thoroughly dried out with current.

That the loss of generator and transformer coils was so insignificant in the Kansas City station was due primarily, of course, to the high grade of construction embodied in the manufacture of the apparatus; but it was also due to the care and attention to details in the drying-out process. And when one considers that the work of drying out was necessarily hurried as much as possible, the results are still more remarkable.

◆◆◆

Small Candle Power Arcs for Street Lighting.

For the problem of street lighting in the smaller cities and larger towns, there seems to be little reason to doubt that the small-candle-power enclosed-arc lamp furnishes by all odds the best solution; and for service even in cities of considerable magnitude there are many valid arguments in its favor. In another part of this number will be found a very comprehensive discussion of the relative merits of the various small-candle-power systems which cannot fail to be of vital interest just at this time; the author of the article mentioned, Mr. Hallberg, has had exceptional opportunities for investigating the operating value of such lamps and systems, and the article is a thoroughly practical presentation of the subject, based on experience.

The author's deductions as to the relative value of the different small-candle-power arc lighting systems from different standpoints will, we believe, not be seriously questioned by any non-partisan expert. As we stated last month, the alternating-current arc lighting system has the great advantage for large stations of reducing the generating units to a single type, but the engineers of some pretty large plants have chosen the disadvantage of separate direct-current arc lighting dynamos in preference to the disadvantages of the alternating-current arc. We heartily agree with Mr. Hallberg that the production of a thoroughly satisfactory rectifier would put the direct-current arc lamp much ahead of the alternating-current lamp for street lighting—and for most other kinds of service, for that matter.

It would seem, from an "outside" standpoint, that the task of devising a rectifier for changing alternating current of constant amperage to pulsating direct current ought not to be a more difficult one than that of providing a transformer to change constant alternating potential to constant alternating current. Yet the latter was accomplished years ago, while some of the brightest modern engineers have failed to develop a rectifier that is wholly satisfactory commercially.

The Embryo Electrical Engineer.

One of the most perplexing of all the requests for advice or information that are received at this office is the letter asking us to advise a young man what course to pursue in order to become an electrical engineer, the means for taking a collegiate course not being available; also to suggest the best branch of electrical work. It is, of course, impossible for us to offer much specific advice in such cases; without knowing intimately a young man's natural characteristics, one cannot intelligently suggest what avenue of work would be apt to suit him best, and there is no "best branch" of the electrical industry from any other standpoint. Naturally, we advise taking up a course of study with some correspondence school, if one cannot have the advantage of personal tutelage, and when this is said it exhausts the possibilities in the way of specific advice under the circumstances.

Generally speaking, technical education is absolutely necessary to even mediocre success in any branch of electrical or other technical work; with a given amount of honesty, intelligence and industry, the better the education, the greater the measure of success. By "education" we do not mean necessarily college advantages, valuable though they are; some of the highest grade men in the electrical field are self-educated, and some of the most hopelessly incompetent boast college degrees. With the facilities that now exist for acquiring technical education, there is no excuse whatever for anyone to remain wholly ignorant of fundamental principles and their application. But the road to complete qualification as an electrical engineer is not an easy one, and while there is always "room at the top," there is no room in the class of the poorly qualified—no demand for the mediocre engineer. If one elects to become an electrical engineer, therefore, the standard should be set very high and the aspirant must determine to sacrifice everything except personal character, if need be, to the drudgery of acquiring the necessary mental training and practical experience. These may possibly be acquired simultaneously, but it is usually necessary to obtain the mental training first. Detailed advice as to just what steps to take in order to secure the requisite knowledge and experience is out of the question; a man's resources, environment and restrictions chiefly determine this, and these are seldom combined in the same way twice. Moreover, a man who possesses the personal qualities essential to thorough success does not require to be steered along from point to point in his upward course.

United States Patents.

The patent situation in this country has long since reached a point where it excites either ribald mirth or mingled disgust and resentment, according to whether one is a spectator or a victim. The actual value of a patent, as is well recognized, is usually nothing until its owner has had it subjected to the expensive judgment of the courts; this is true of at least the large majority of electrical patents, regardless of the intrinsic merits of the inventions or improvements. Moveover, patents are issued which even a layman with fair powers of analysis and access to Patent Office records could easily show to be without justification, and applications are rejected on purely technical grounds when there is no similarity between the subject matter of the invention and that of the invention cited as an anticipation. It would seem to be entirely practical to eliminate the farcical elements just mentioned by the establishment at Washington of a patent tribunal of last resort, which would obviate the necessity for appeal to the regular and usually technically incompetent courts and make it possible to obtain consistent precedents for the guidance of patent examiners; under the present system the courts hand down conflicting rulings without rhyme or reason.
